in comparison, and the power plant below the lowest plane. The vertical rear rudder and the rear horizontal planes almost met the fifth main plane at the top. None of these "freak" machines were attended with any degree of success.

Dirigibles

Roy Knabenshue and Hillery Beachy were in evidence with their well-known dirigibles. A picture of the former in flight is shown in Fig. 7, which also gives a partial view of the field. The dirigibles plainly showed their inefficiency as compared with aeroplanes; one particular advantage they have over the latter, however, is their ability to remain still in the air over a certain spot; the aeroplane is a dynamic machine; to keep aflight it must move.

Performances and Records

At the California meet, $80,000, more than double that offered at Rheims, was distributed (in prizes) for successful aeroplanes and "lighter-than-air" machines. Glenn Curtiss was the first aviator to ever fly in an aeroplane west of the Great Plains; this was in a trial flight on January 9. Mr. Curtiss, the speed champion of the world, carried off the speed honors for the course. On January 12 he circuited the course of 1.61 mile in 2 minutes, 12 seconds, in his 60-horsepower machine. Paulhan's best attempt to lower this record was 2 minutes, 21 seconds, in a Farman. Louis Paulhan, twenty-six years of age (born in the same year that wing-warping was invented), at one time an aeronaut in the French army, and later a mechanic at the Farman aeroplane factory, was the "star" of the meet. Coming to this country, practically unknown, his performances here in eleven days made him world-famous, and earned him the majority of the prizes. His remarkable record for height was made on January 12, when he was officially credited for 4165 feet. The aneroid barometer carried with him registered 4600 feet, but this figure was not considered by the judges, who took their measurements with level and transits. The diagram, Fig. 8, gives the world's records for height, and shows that Paulhan exceeded the former record by 721 feet.

In his endurance trial Paulhan was compelled to descend, because of accident to his fuel tank. His cross-country flight, which stands as a world's record, was to Santa Anita and return, a distance of 45 miles. Former achievements in such flights have been made by Farman (20 miles), by Bleriot in crossing the English Channel (25 miles), and by Cody with the heaviest type of aeroplane, at Aldershot (40 miles). It is noticeable that Paulhan failed to make any of his records with the monoplane; this can probably be attributed to the removing of the wing-warping device as mentioned elsewhere. At the conclusion of the meet, Paulhan was presented with a loving-cup, by the directors, for the best performances.

Willard's feat, of starting and landing in a designated square, was a remarkable one considering that aeroplane brakes for machines in flight have not, as yet, been invented. When these latter are perfected, far greater things may be expected of the machines.

As previously stated, the Gill-Dosh machine met with misfortune at the first part of the meet. Hillery Beachy, who has not had the experience in aeroplane piloting that he has had with dirigibles, wrecked the biplane in making too abrupt a descent after its first flight.

The illustration, Fig. 9, shows a Curtiss biplane, with Mr. Curtiss and Lieut. Beck, U. S. A., who was present throughout the contests in the interest of the government. Lieut. Beck rode as a passenger with many of the aviators, practicing bomb throwing and similar military maneuvers.

So far as distance is concerned, the flying-machine is limited only by the capacity of its fuel tank. Its future, while depending upon minor changes and improvements along established lines, seems to rest primarily with engines and propellers; this is not without solution. When the airship gasoline motor has reached a higher stage of perfection, aerial locomotion will no longer be a novelty and the aeroplane will be the master, not the slave, of the air.

* * *

Models of aeroplanes are said to be in such demand in England that a factory has been started at Sheffield.

CARBURETORS AND VAPORIZERS

By CHARLES A. SCHRANZ*

Charles A. Schranz†

The liquid fuels for operating explosive engines are all petroleum products, with the exception of alcohol, which, although of high efficiency, is, on account of its high price, but little utilized as a power-producing medium in this country. In gas engine practice the liquid fuels require certain devices, which, in accordance with the respective natures of these fuels, atomize or vaporize the same. The vapors combined with air form the explosive mixtures.

The petroleum products mostly used in explosive engines are gasoline (naphtha) and kerosene oil.

Gasoline (Naphtha)

The devices for forming an explosive mixture from gasoline and air are divided into two groups.

1. *Vaporizers.* In these the necessary quantity of gasoline for each charge of the engine is atomized by a valve, and then vaporized by the inrushing air, which process, especially when the air has previously been superheated, is so thorough that the mixture may be used immediately for charging the engine.

2. *Carburetors.* When these are used the engine sucks air directly through a gasoline storage tank, thus saturating it with gasoline vapors. Additional air must be drawn in before the vapors enter the engine cylinder to form an explosive mixture.

Each of these methods has its advantages and disadvantages. The first method renders it difficult to adjust the flow of the gasoline to the varying work done by the engine, but the vaporizers work very reliably, do not require much room, and scarcely any attendance. The main advantage of this method, however, is that any kind of gasoline may be used, while the fact that gasoline is composed of constituents of different volatility is unfavorable to the second method, as with the diminishing gasoline supply the explosive mixtures become variable and finally there remain residues which are too heavy to be taken care of by the air.

While formerly the second method of carbureting the air was much in use, because the forming of the explosive mixture is automatically regulated by the engine, the method of vaporizing the gasoline is now more in favor as it is more economical.

Vaporizers are built in many different designs, and it is difficult to say which construction is the most desirable. The principle, however of all the different designs is the same. Gasoline enters by gravity through a valve into the mixing chamber at the moment that the suction of the engine piston opens this valve. While passing through the chamber the gasoline is atomized, and upon striking the inrushing air vaporizes, and when thoroughly mixed with the air, is drawn off to the engine cylinder. According to the construction of the atomizing valve, the gasoline enters the mixing chamber either as a spray or in fine single streams. The simpler this atomizing device, the more dependable it is. Atomizers, for instance, in which the gasoline is pushed on the wings of a fan, set in motion by the inrushing air, are for this reason less recommendable.

Carburetors are also designed in many different styles, but all consist in the main of a cylindrical vessel, partly filled

* Address: 1163 Kenwood Ave., Camden, N. J.

† Charles A. Schranz was born in Vienna, Austria, 1871. After going through the high school he took a complete course in mechanics at the University of Vienna. Following the completion of his university course, he served one year in the Austrian navy as engineer, and then filled a position with a large Vienna firm as designer of steam engines and boilers which position he held until 1896 when he became superintendent of a branch plant in Pressburg, Hungary. This plant built steam engines, boilers, brick making machinery and, in later years, gas engines and small pumping machinery. In 1905 Mr. Schranz came to America, and has since been employed by the Camden Iron Works, Camden, N. J., as designer of gas machinery, gas holders and structural work.

with gasoline, into which leads the air inlet pipe, reaching almost to the bottom of the vessel, and the gas pipe connecting the carburetor with the engine cylinder. Check or safety valves are placed in the gas pipe line to prevent the flame, at the moment of ignition, from striking back into the carburetor. The lower end of the air inlet pipe is usually designed in such a manner as to finely distribute the air, which is forced in through the suction of the engine piston. In passing through the gasoline these air bubbles become saturated with gasoline vapors.

The carburetor may be placed in the immediate neighborhood of the engine, or at a distance not farther than 50 to 60 feet from it. A practical arrangement is to place the carburetor in a well ventilated room, separate from the engine, so that there will be no danger from handling open lights in the engine room.

In order to increase the efficiency of the apparatus and to make the former independent of the temperature of the atmosphere, it is advisable to heat the air somewhat before it is drawn through the carburetor. This is usually accomplished by leading the air through a jacket placed in the exhaust pipe of the engine. Another method for obtaining the same result is to heat the gasoline instead of the air. In this case either the carburetor is provided with a jacket through which the jacket water of the engine is discharged, or the exhaust of the engine is utilized by placing the carburetor on a hollow pedestal connected with the exhaust pipe. These arrangements are of special value, where the carburetor is placed in the open air or in an unheated room.

Kerosene Oil

While gasoline has a boiling point of from 150 to 180 degrees, and is so volatile that it evaporates at the mean atmospheric temperature, which enables the formation of an explosive mixture by bringing it thoroughly in contact with air, the comparatively heavier kerosene oil needs different devices for the formation of the explosive mixture, as it can only be gasified when sufficiently heated.

When only atomized through a current of air, a mixture of air and minute particles of kerosene oil is formed, which when ignited, is not entirely consumed. If, however, the kerosene oil is previously heated to an extent that it evaporates, these vapors are able to form a mixture with air, which is the most economical explosive power fuel.

With regard to ignition and combustion this mixture has the same properties as mixtures of gas and air. Compression increases the inflammability, and even mixtures which ignite but poorly under atmospheric pressure, ignite readily when compressed, which fact is an important consideration, as quick and high compression in the engine cylinder may cause premature explosion due to compression heat.

The design of vaporizers for kerosene oil is further determined by the fact that it is made up of constituents with greatly variable boiling points (300 to 500 degrees). Therefore, it is not permissible to vaporize a larger quantity of kerosene oil at one time than is required for each single charge of the engine. Furthermore, the vaporizer must be designed to vaporize these small quantities perfectly, as every minute particle of liquid which is carried away by the flow of the gas is entirely lost for the development of power, and settles in the valves, cylinder, etc. The heating surface of the vaporizer must be large enough and sufficiently heated to allow the perfect gasifying of the fuel in the short time determined by the speed of the engine. Considering an engine running at a speed of 200 revolutions per minute, the duration of one stroke is only 0.15 second and as in this time the quantity of kerosene oil for one charge must be perfectly gasified, it is clear that the atomizing of the fuel is best performed by the air itself.

The actual design of vaporizers for kerosene oil conforms with all the above considerations, and consists in the main of the vaporizing chamber through which air and fuel are drawn through the suction of the engine piston. The kerosene enters the chamber through a valve, and is thus atomized and mixed with the inrushing air. This mixture is thrown against the walls of the heated chamber, and the atomized kerosene oil becomes gasified. On the way to the engine cylinder more air is drawn in to form the right proportions of the explosive mixture.

Care should be taken in designing the vaporizers to prevent spheroidal condition of the fuel, and, therefore, horizontal walls should be avoided. Cast iron is a very suitable material for kerosene oil vaporizers because the porous, rough surface forms a large heating area. To gasify the fuel perfectly, the temperature of the vaporizer must be at least 500 degrees F., which coincides with the boiling point of the least volatile constituent of the oil. This temperature may be produced by heating the vaporizer with a flame, or after the engine is started, through the exhaust gases. Another type of vaporizer (Hornsby-Okraid) is only heated while starting the engine, and after this is kept in a red-hot condition by the explosion heat.

To start a kerosene oil engine, either an oil torch has to be used to heat the vaporizer until a flow of exhaust gas is secured, or, as is more common, the engine is equipped with an auxiliary gasoline carburetor having a small tank for fuel, and when well under way the gasoline is shut off and kerosene oil turned on.

For alcohol motors the same vaporizers are used as on kerosene oil engines, and, in fact, all alcohol engines are built to run on both fuels.

EDUCATIONAL DUTY OF GAS ENGINE EXPERTS

By GEORGE CORMACK, JR.*

Women are usually blamed for talking too much, but the ordinary gas engine expert does not talk enough. In a great many gas engine trouble cases where an expert is called in, he fixes up the engine in a few minutes, and is "on his way." The expert who thinks that he has done his entire duty when he has fixed up the engine and got it running is very much mistaken; he has only done half his duty. The expert's whole duty consists not only in fixing the engine, but also in fixing the man who runs the engine. In ninety per cent of gas engine trouble cases, the difficulty is not really with the engine but with the operator. The writer has come to this conclusion from years of experience, and the fixing of the operator of the engine is really the principal duty of the expert or trouble man. If the expert fixes the engine without fully explaining to the man running the engine why the trouble occurred, and what methods to pursue to prevent its recurrence, the remedy is only temporary, and the operator is liable to get into the same difficulty again. The expert must not only be a good mechanic and have a thorough understanding of gas engines, but he must also be able to explain the working of the engine in a simple manner to the operator. He must cultivate this ability to explain the action of the gas engine, its principles, movements and adjustments to the operator. This is no easy task at times; it requires patience and tact together with a realization of the fact that although the gas engine may seem so simple to himself, and the adjustment of its different elements in their proper harmony seems self-evident, the large majority of gas engine users are ignorant even of what the terms four- and two-cycle mean.

The really good mechanic, is perhaps, naturally deficient in the ability to express himself clearly, and to all such the writer would advise a method which he has found very beneficial in his own case. When having a little spare time, when waiting for a train held up over night in some out of the way town, buy a five-cent writing tablet and write out a description of the principles of action, movements and adjustments of a gas engine. If not accustomed to expressing one's own thoughts in writing, the first attempt when read over after having finished it, may not seem a very polished literary effort. Yet, try it again after a few days when the opportunity again offers. On the second attempt it will be surprising how much better one can express oneself. The mental effort of trying to express one's thoughts has set the mind working along new lines. By keeping up this practice for some time, it will be found that when giving an explanation of the engine to the man who is in trouble, the verbal explanation will take the form of expression used in writing. The cases will be few and far between where an engine operator does not appreciate the efforts in giving him real instructions about gas engines.

DERIHON PORTABLE FORM OF BRINELL HARDNESS TESTING MACHINE*

Readers of MACHINERY are acquainted with the method of testing the hardness of materials devised by Mr. J. A. Brinell, which we have previously described. It consists, briefly, of forcing a hardened steel ball into the material to be tested.

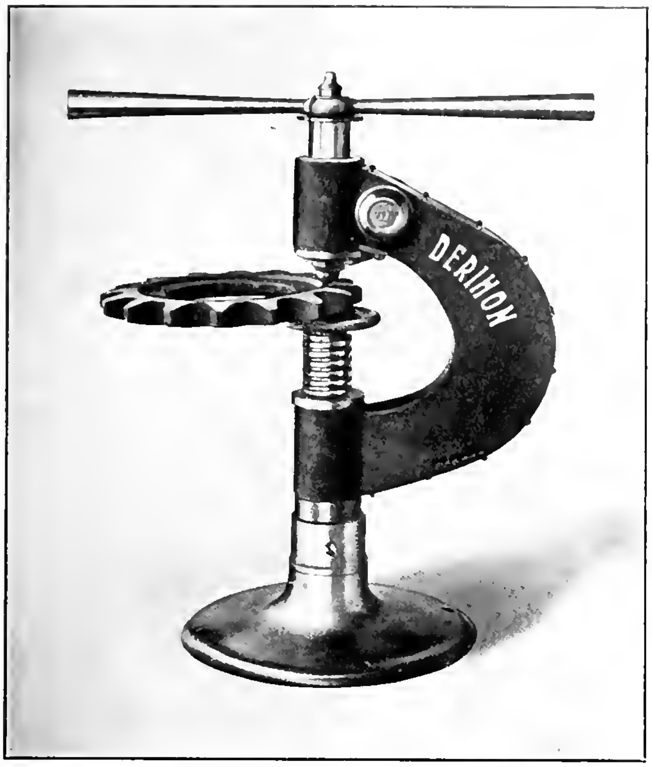

Fig. 1. Portable Press for Testing Hardness by the Brinell Method

For a standard diameter of ball and a standard pressure, the diameter of the impression is taken as a measure of the hardness; and it may be used in comparing the hardness of other materials tested with the same diameter of ball and the same pressure.

The only disadvantage of the Brinell method for practical use, lies in the cumbersome apparatus required and the comparative slowness of the operation. It is usually furnished in the form of a small hydraulic press, operated by hand, and weighing perhaps 300 pounds. It is evident that with such an apparatus the work has to be brought to the machine, so that its regular use for inspection purposes in different parts of a manufacturing plant is impracticable. Various attempts have been made to devise an apparatus in which the pressure is applied in the form of a blow on a falling weight instead of directly, but this scheme has not so far proved effective in the matter of uniformity in results.

The foregoing considerations lend interest to the apparatus shown in Figs. 1 and 2, which was devised by the Usines G. Derihon of Loncin, Belgium. This firm is an important manufacturer of high-grade drop forgings for automobile work, and it originally developed the machine for use in its own plant. As may be seen, the pressure is applied by a hand-operated screw, and the press is small enough to be perfectly portable, weighing about 12 pounds only.

The sectional view in Fig. 2 shows the action of the apparatus most clearly. The work is placed on the platen F, which rests in a spherical seat on top of adjusting screw G. By means of this self-adjusting seat, the work gets an even bearing and a direct pressure, even though its under surface may be quite out of true. The purpose of the adjusting screw G is, of course, to give a rapid adjustment for the thickness of the work. It will take in about 3 inches as shown. The thread of G, while of coarse pitch, still lies within the angle of repose, so that it is not disturbed when the pressure is applied by levers M.

A differential screw mechanism is used for applying the pressure. This mechanism consists of the double handle M, keyed to the sleeve D, which is threaded into the stationary nut E, and onto the ram C; this latter is kept from revolving by a stop K, which enters a slot cut in the flange, and is provided with a threaded chuck for holding the ball B. Sleeve D is, it will be seen, the only revolving member of this differential screw. The thread on the inside has a lead of 8 millimeters, while that on the outside has a lead of 7.25 millimeters. This gives an advance of $8 - 7.25 = 0.75$ millimeters, or about 0.03 inch per revolution of the levers M. The advantage of this construction is, of course, that it gives all the effect of a fine thread of lead 0.03 inch, with the use of threads coarse enough to withstand the great strain to which they are subjected in tightening down the work.

The most ingenious feature of the mechanism is the provision made for gaging the pressure with which the ball is forced into the work. By the arrangement used, the frame A of the press itself serves as the spring by which the pressure is measured. As the ball is forced into the work with greater and greater pressure, the frame A is deflected and B and F spring apart. Arm H is screwed to A at its lower end as shown, but is free at its upper end. Here it is provided with a bearing point X close to fulcrum Y of pointer P. As the frame A springs under the pressure, H, being free at the upper end, remains undistorted and stationary, while pivot Y rises. As pivot Y rises, lever P swings downward, since it

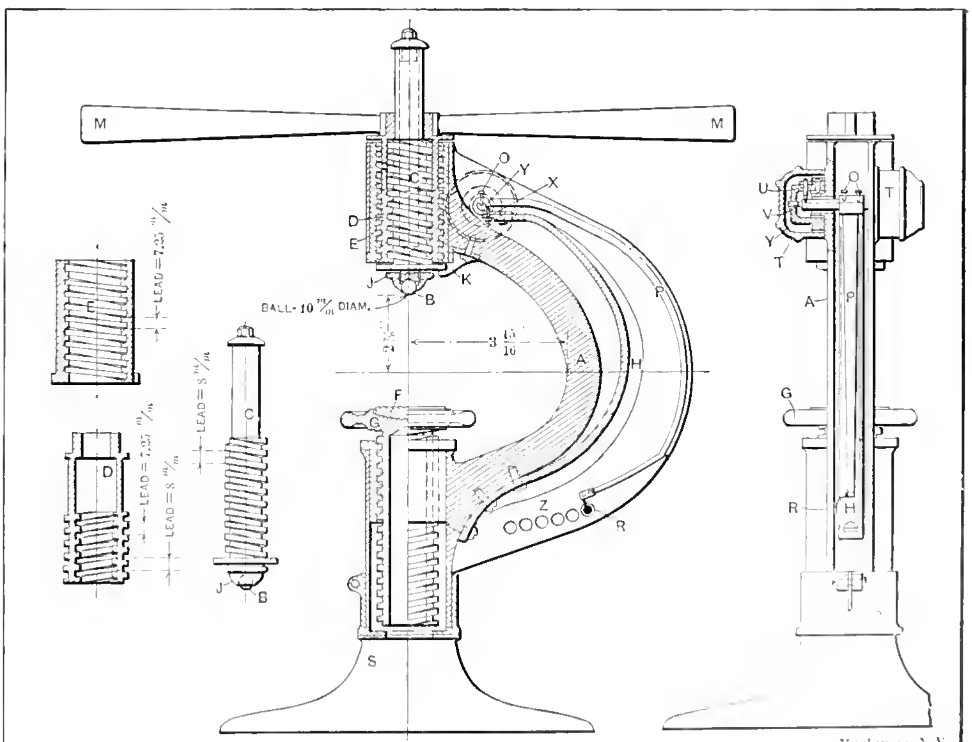

Fig. 2. Details of Design, showing Differential Pressure Screw, Indicating Mechanism

rests only on the point X of stationary arm H. The lower end of lever P is provided with a thin metal disk R, which is thus swung in an arc of a circle about center Y. A series of holes Z, bored in the side of the frame, permit the position of this disk to be seen. These holes are so calibrated that each reads to a definite number of kilograms of pressure.

* For additional information on this subject, see "The Time Element in Hardness Tests by the Brinell System," November, 1909, and "Influence of the Scleroscope in Metallurgy and Manufacturing," August, 1909, with accompanying references.

when disk R is centered with it. Under the extreme tension, when central with the left-hand hole, the reading shows the application of a pressure of 3,000 kilograms or 6,614 pounds.

The construction of the pivot joint at Y is interesting, and is best shown at the right of the engraving in Fig. 2. The hub of pointer P is clamped to Y by two set-screws O, which set in a V-slot cut in Y. Two caps T are screwed on at either side to protect the bearings of pivot Y. Set-screws V are adjusted to take up the end motion of Y; they do not, however, restrain it in any direction other than longitudinally. The real bearing is furnished by the points of screws U (one at each end) in the bottoms of the V-grooves. These furnish a knife edge or, rather, point support, which gives the utmost freedom and sensitiveness of movement to the pointer P and the indicating disk R. The various adjustments in connection with this bearing, and the various contact points in the lever system, will be clearly understood from the engraving.

Fig. 1 shows the instrument engaged in testing the hardness of a sprocket-wheel. The simplicity of its use will be immediately appreciated. The sprocket-wheel is placed on the platen, the adjusting screw is run up until the work makes contact with the ball, and then the handles are revolved until the indicating disk is centered with the particular hole in the frame, which shows that the standard pressure has been reached. Handles M are then screwed back again, the work is removed, and the diameter of the impression in millimeters measured. This gives the hardness number directly. The whole operation is evidently one of seconds only.

* * *

IT REALLY HAPPENED BUT—"IT NEVER CAN HAPPEN AGAIN"

Mr. P———, the president of a big manufacturing establishment in the Middle West, had shown his great factory to a company of Englishmen and upon returning to the president's office, one of the party who had greatly admired the remarkable order and system of the plant, said:

"Mr. P———, may I ask what salary you pay your superintendent?"

"Really, I do not know at the moment, but I venture to say that it is not half enough; I will call him and find out."

Pressing a button he summoned a messenger.

"Call Mr. C——— to my office at once."

In a few moments Mr. C——— came, wondering at the peremptory summons, and secretly quaking.

"Mr. C———, what do we pay you for running this plant?"

"Fifteen hundred a month."

"Very well, hereafter it will be three thousand. That is all, sir."

* * *

BRIGGS PIPE THREADS

Briggs standard pipe threads are known to every mechanic, but few persons know anything of the history of the adoption of this standard. It is named after Robert Briggs, who was for several years superintendent of the Pascal Iron Works and later engineering editor of the *Journal of the Franklin Institute*. Mr. Briggs, however, did not originate the thread standard which bears his name. According to the *Valve World*, the taper thread for tube connection was first used by Nason; and P. W. Gates, as far back as in 1847, patented a solid die for cutting a taper thread. Mr. Briggs was active in the gathering of information relating to various standards in use in this country thirty or forty years ago, and prepared a paper for the Institute of Civil Engineers of Great Britain, describing in detail the thread then generally in use in this country, and which is now called the Briggs standard. This paper was read before the society in 1883. Mr. Briggs died in the previous year. Within a few years the standard was officially adopted by almost all pipe manufacturers, and is to-day practically the only type of thread used in the United States for pipe connections and fittings.

* * *

At the meeting of the executive board of the Association of German Machine Tool Manufacturers at Düsseldorf, the machine tool industry was pronounced to be in an unsatisfactory state. Present prices are said to be too low, and American competition keen.

SUGGESTIONS IN THE DESIGN OF AERONAUTIC MOTORS*

By HARRY E. DEY†

Harry E. Dey‡

Motors of any type—gasoline, electric or steam—are compromises from beginning to end; we cannot design any one part to obtain the theoretically best results from it without interference with some other feature. With the gasoline engine there are certain advantages in a short stroke, but in the short stroke motor we also meet with many objections. This same condition applies to the number of cylinders and their mounting (horizontal, vertical or oblique), to the casting *en bloc* or individually, and to the amount of compression. In many cases the best results can only be arrived at by actual "cut and try" experiments, and the author, therefore, does not propose to give in this article any definite figures except for purposes of illustration. The suggestions given are based upon the writer's experience on automobile and marine engines, and also upon a great deal of thought given to the aeronautic motor.

Any steam engine will deliver more than its rated horsepower, owing to the fact that it is built to run economically by cutting off the steam as it enters the cylinder during the early part of the stroke. With a cut-off of one-quarter or one-fifth, the expansive qualities of the steam are utilized, and the engine is rated at its economical output. If, however, more power is required temporarily, the point of cut-off is shifted ahead until the required power is obtained, up to the maximum attainable, when steam enters during the full length of the stroke. With gasoline engines, however, this conservative rating has never been observed. The A. L. A. M. rating, for example, is about the best that an engine is capable of under the best conditions; under unfavorable conditions, such as bad carburetor adjustment, poor compression, weak spark, and innumerable other troubles, the power output may be an indefinite amount less.

Lack of Economy in Present Automobile Engines

It has always been the aim of the automobile engine designer to obtain all the power possible from a given bore engine, regardless of gasoline economy or other considerations. He has said, "Hang the expense, it's power we're after. What does the average autoist care for the additional cost of gasoline?" To design an engine and obtain less than the A. L. A. M. rating for it would be a disgrace. Hence the old-time efficient suction valves have been superseded by mechanically operated valves, offering no resistance to the incoming charge; and then, to squeeze in still more, the valve is left open long after the piston reaches the end of the outward stroke, thus taking advantage of the momentum of the gases in the pipes to crowd more than atmospheric pressure into the cylinder. The result of all this, of course, is increased power, the same as in the case of the steam engine taking steam the full length of the stroke; but who would buy a steam engine working in such an inefficient manner?

An engine working under the above conditions will exhaust at about 60 pounds pressure. This 60 pounds multiplied by 125 per cent of the piston displacement is a complete loss, and amounts to nearly 50 per cent of the original

* For description of a motor of this type, see MACHINERY, July, 1908: "Adams-Farwell Aeronautic Gasoline Motor."

† Address: 303 Arlington Ave., Jersey City, N. J.

‡ Harry E. Dey was born in Minneapolis, Minn., 1862. He has been employed by the General Electric Co., The Autocar Co., Pope Mfg. Co., United States Long Distance Auto Co., Vehicle Equipment Co., De Dion-Bouton Motorette Co. and other concerns with which he has been chief draftsman, designer, inventor, etc. His specialties are gasoline and electric motor design; for the past four years he has been designer and inventor for the Marine Magnetic Control Co. and its successor, Mr. B. T. Cable, the business being the development of electric steering apparatus for ships. Mr. Dey has spent several years experimenting on storage batteries and automobiles for private parties.

power of the charge. Compound engines have been built to utilize this exhaust pressure, but there is no excuse for this complication when the same results may be accomplished by proper design of a single-expansion engine, by simply carrying the expansion down as far as may be found desirable. When expansion is carried beyond certain limits in a steam engine, trouble is encountered from condensation, but as there is little or no moisture in the explosive mixture, we need fear no trouble from that source with the gasoline engine. With a compound engine of the gasoline type, a great deal of the unused power of the gases is lost by cooling when passing through the ports, a large quantity is used to fill the ports, and the extra piston adds a large amount of extra friction, so that the only benefit obtained is practically the muffling action.

In a flying machine the weight of the fuel is just as important as the weight of the engine, as frequent landings for purposes of replenishments are not desirable. Therefore, a little more weight in the engine is not objectionable when a consequent saving of several times the extra engine weight may be made in the weight of the fuel saved. Take, for example, a motor of 100 horsepower of the present type. It will probably consume about 68 pounds of gasoline per hour. If we can save 25 per cent of this it would mean a saving of 17 pounds per hour, or 170 pounds in ten hours. This percentage of saving is well within the range of possibilities.

In designing an aero engine, without aeronautic experience it should be patterned after the marine engine rather than that of the automobile, as the former is subject to the same general conditions. They are both generally loaded to their full capacity and speed, from the start to the finish, while an auto engine is seldom loaded to the limit, and when so loaded it is only for short periods. An air-cooled engine that is a success on an automobile might be a failure in an aeroplane. The writer does not mean to say, however, that an air-cooled engine will not be a success for flying machines if properly designed to suit the changed conditions. This may be accomplished by working with lower compression, greater expansion, and possibly it might be found advantageous to use a six-stroke cycle. There are also some conditions favorable to the air-cooled motor when used on an aeroplane that may, to a large extent, overcome the handicap of the constant full load; these conditions are the high speed through the air without a bonnet or other covering, and the dispensing with the crank-case. In the air we need not worry about the dust, and consequently the crank-case is unnecessary. Fresh air has then free access to the piston and cylinder.

General Outline of Design of Aeroplane Motors

As to the general design, the writer's choice would lie between a six-cylinder vertical and a six-crank horizontal opposed type. The radial arrangement might have certain advantages for air cooling, and also some advantages for reducing the weight to the minimum. The cylinders should not be rotated, however, as is often done with this form, for the same mechanical efficiency is not obtainable under these conditions. Upon first thought one would suppose that it was a case of "six for one and half a dozen for the other," relative to efficiency; but the facts are that the results are somewhat like those obtained from a worm and gear—the efficiency is much higher when the worm is the driver. The air-cooling qualities of the rotating cylinders would lose their force of argument when an aeroplane is driven at a speed of fifty miles per hour or more; there is no reason to complain of circulation then. And as to the other claim of the advantage of the rotating cylinders, that they serve as a flywheel, that feature is practically useless, as the propeller will take place of that element. In the early days of the automobile it was claimed that a steam engine would require a flywheel. The Stanleys demonstrated with their "Locomobile" the utter fallacy of the idea.

The Cooling Arrangement

If an engine is to be water-cooled, the six-cylinder vertical is probably the best form. Its six-throw crank gives us perfect mechanical balance, which can only be obtained with multiples of three; and the cylinders, all being mounted in one straight line, give us a straight unbroken jacket which may be made of light sheet copper. The cylinders are made of steel (or alloy steel) tubing. If the engine is to be air-cooled it may be designed upon the lines of any of the above forms. If, of the vertical type, however, it would probably be found desirable to mount it "broadside forward," after the manner of the old type Franklin automobile. All the cylinders would then receive an abundant supply of cold air. This arrangement has the objection, however, of slightly complicating the transmission to the propeller. For obtaining the full benefit of the draft of air, the radial type has the best distribution of its cylinders, and is probably the lightest form that can be constructed, due to its short length.

There should be no side pockets (for valves) in the cylinder heads, for the inside surface should be trimmed down to the minimum possible. The less internal surface we have exposed to the heat, the smaller the number of heat units there will be absorbed by the metal. Whatever is taken into the metal has to be gotten rid of, either by air or water, which adds to the difficulties of air cooling in the one case, and to the size of the cooling apparatus and the amount of water carried in the other. In both cases there is the loss in efficiency, for every heat unit radiated is one heat unit less power delivered at the shaft.

If we could obtain a material for the cylinders that was an absolute non-conductor of heat, we would not have cause to worry over any system of cooling. If the metal would not conduct heat, it would not absorb any. But suppose we go to the other extreme and obtain a metal that is a perfect heat conductor; then as soon as the first explosion takes place the outside of the cylinder would be just as hot as the inside surface; it would instantly become red hot. How would we keep the latter cylinder cool?

According to the above theory, it appears that it is desirable to have a very poor conductor of heat for the cylinder, for while we cannot obtain the absolute non-conductor, the nearer we reach that point the less heat will be absorbed by the metal at each explosion, and the greater proportionate effect the incoming charge will have toward cooling the internal surface. If the heat of the explosion were constantly applied, the beneficial results could, of course, not be expected.

Material for Cylinders

There is a nickel steel alloy, of between 25 and 30 per cent nickel, that is used very largely for electrical resistance. It appears to the writer as if it would best fill the conditions. As a general rule a poor electrical conductor is a poor heat conductor, following almost direct ratios. This alloy has about eight times the electrical resistance of plain steel, consequently, according to the above rule, it should have about an eighth of the heat conductivity of the latter. There are, however, no data to prove whether its heat reluctance is so great. The writer once made a rough test by coating thin sheets of each kind of steel with paraffine, and holding the ends in the flame of a Bunsen burner. It was found that the wax remained frozen much closer to the flame on the alloy piece than on the other. In fact, it was so close to the flame that it could not be decided whether it was the direct rays or the conducted heat that did the melting. This metal is very strong, finishes to a fine polished surface and stands up well under the effects of heat. It is worth experimenting with, but it will be quite an expensive experiment, as this alloy steel can be obtained only in the form of forging, for small quantities. It can be obtained in the form of drawn tubing or sheets, however, if a large enough order is placed.

Cylinder Design

The head of the cylinder should be as nearly hemispherical in form as possible and polished inside. With our best endeavors, however, it will be a very much flattened hemisphere unless the length of the stroke is carried far beyond the limits of good practice, for the cubic contents of a hemisphere would be too great for the piston displacement.

and hence the compression would be too low. A cylinder of this form, for air cooling, can be made from a heavy sheet stock of the alloy mentioned above, pressed into shape, and then put into a lathe for the turning of grooves 1-16-inch wide and ½-inch deep, leaving ribs 1-32-inch thick between them. This will give an immense radiating surface, far more than could be obtained by any casting method. The main body of the cylinder need not be more than 1-16-inch thick for a five-inch bore. Below the ribbed portion the whole shell may be turned down to a thickness of 1-16-inch, leaving a flange at the bottom for attaching to a plate, common to all the cylinders. The flange can be made of a square form in the original stamping.

Valves, Crank-case and Other Details

With the pocketless head the placing of the valves has always been more or less of a problem. The most popular method at present appears to be the placing of the valves obliquely, and to mount the cam-shaft directly over the center of the line of cylinder tops. Another method is that which the Franklin Automobile Company has adopted of mounting the valves concentrically; that is, the inlet valve is inside of the exhaust valve. But in the aeronautic motor, is it necessary to have two valves? Suppose we exhaust directly into the open air, with absolutely no piping; then take in a charge of pure air through the same opening, mixing it with a little liquid gasoline taken through a pin hole located at some convenient place. Many of the aeronautic motors are now taking their gasoline direct, without a carburetor. Of course the gasoline would require a minute valve to take care of it, but it need not be over a quarter of an inch in maximum diameter. Our main valve would then be right in the center of the head, free from all complications. It would remain wide open between the time of exhaust and intake giving an exceptional opportunity for clearing out the old charge. Another plan is to use two valves in the ordinary manner, but the inlet valve would be designed like the well-known Lukenheimer mixing valve. This valve is used very largely upon boat motors as a separate carburetor, but it and the inlet valve could be made as one. The first-mentioned plan would be the best, however, for it not only has the advantage of simplicity, but also the feature of cooling the valve with the incoming charge.

The crank-case preferably should be made of skeleton construction, and without covering of any kind. It may, of course, be cast, but the "built-up" construction will be stronger for a given weight. The connecting-rods may also be built up to good advantage, with ball bearings at the crank ends.

The crankshaft should be of a very liberal diameter with all cylindrical parts hollow. The material should be the best alloy steel, and the shaft should be mounted in ball-bearings. Cast iron is the only material that should ever be used for the piston or rings. The valves may be made of nickel steel.

Ratio Between Bore and Stroke

As to the problem of the ratio between the bore and the stroke, there is a wide divergence of opinion among designers. The writer is very strongly in favor of the long stroke, and especially so in flying machines where the increased height of the engine is not objectionable. Abroad, the long-stroke engine has become very popular on automobiles, and where racers have been limited by the bore, the long-stroke types have carried off the honors.

The reasons for a long stroke are several: 1. With a given cubic contents of compression space (and upon that the amount of power obtainable depends), the shape is nearer that of a hemisphere, and consequently possesses the least absorbing surface possible for the quantity of mixture. 2. There is less piston diameter for a given charge, which gives less leakage area. 3. There are less reversals of motion of the reciprocating parts, thus reducing the number of hammer blows, giving higher mechanical efficiency and longer life to the engine.

It may be argued that the engine will have to run slower and thus deliver less power. This difference of speed, however, is made up by the additional amount of the charge due to the additional length of the compression space, which, of course, is made proportional to the length. As a higher piston speed is practicable, an increase of power is thus obtained, although not commensurate to the additional weight; but the advantages obtained outweigh in value the objectionable weight.

Increase of Efficiency of Present Engines

The lack of efficiency of present engines has been mentioned. We will now take up the problem of how to increase it. For illustration, suppose that the compression space of motors as at present constructed is 25 per cent of the combined piston sweep and clearance, and let the bore and stroke ratio be 1 to 1. Design an engine with double this stroke, without increasing the bore; let the compression space remain the same, and design the cam so that the incoming charge will be shut off at one-half the stroke. When the piston returns and compresses this charge it will have the same maximum compression as the first-mentioned engine. Now the explosion takes place, and the pressure at one-half the outward stroke falls to the exhausting pressure of the former engine. Both engines have received the same amount of charge and have thus far delivered the same amount of power. The first one exhausts at this point, but the last one has as much additional distance to travel, commencing with a charge of about 60 pounds' pressure multiplied by four times the compression space. Owing to the latter fact the pressure will drop very slowly during the remainder of the stroke in comparison with the early portion, and there is no compression pressure to subtract from it, as the compression did not begin until after passing this point. Consequently the last half of the stroke is all "velvet," and is obtained at a high efficiency, for we have no losses in compression to subtract for this added power nor the loss due to large leakage and heat losses under the high pressure and intense heat at the beginning of the stroke. Taking these facts into consideration we will probably receive, additional, a third of the power of the first half of the stroke, thus obtaining a gain of 25 per cent in efficiency. The output of the motor, however, is only two-thirds of the maximum obtainable under the old system, and the efficiency and power may be still further increased by raising the compression, for the high point of compression is reached so much later in the stroke that the point of self-ignition will be just that much nearer the dead center. Another advantage of this plan is the fact that the average temperature is lower, and it is thus better suited for air cooling. The dimensions given are used only for convenient illustration. They will, however, probably be found, after experiment, to be not very far from the correct ones.

For a company that intends to take up the manufacture of such an engine the best plan will probably be to make up an adjustable engine—one in which the compression space and the length of the stroke can be varied at will, independently of one another. The cam should be designed so as to give a variable cut-off. This latter feature should also be made an element of the standard engine, as it can then be used in place of a throttle valve, and also for providing a larger charge when at high altitudes, so that the same compression may be obtained then as at lower levels. With the present type of engine there is a large loss in power capacity in high altitudes, as has often been demonstrated with automobiles when taken to elevated sections of the country.

To sum up the advantages of the engine outlined we have: An unusually large cooling surface; a minimum of heat-absorbing surface; a lower average heat inside the cylinder; a metal that is a poor absorber of heat; inside of cylinder and piston fully exposed to fresh cold air; exhausting with such low pressure does not unduly heat the exhaust valve, and as the exhaust and inlet are one, the incoming charge cools it; it also avoids the use of an auxiliary valve; passing through the air at a mile a minute will be far more effective than the artificial draft provided upon automobiles.

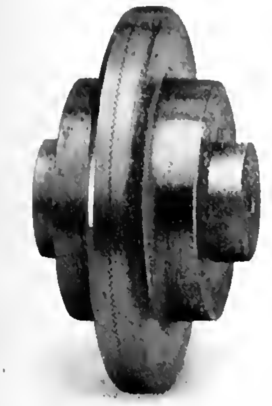
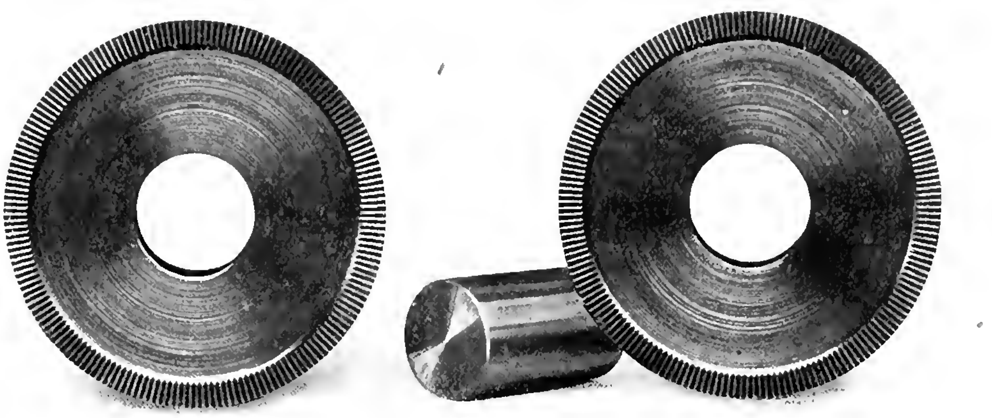
It has been found by Prof. Joly that the lava from Vesuvius is remarkably rich in radium.

UNUSUAL WORK DONE ON THE AUTOMATIC SCREW MACHINE

The new departures from time to time made by progressive manufacturers of automatic screw machines seem to indicate that there is hardly any class of work, circular in shape and within the range of these machines, which cannot be successfully produced on them at a great saving of time. From previous articles in MACHINERY (see the November and December, 1908, issues) our readers have become familiar with some of the interesting work produced on the Cleveland automatic screw machines, manufactured by the Cleveland Automatic Machine Company, Cleveland, Ohio. In the present article a piece of work of an even more unusual kind, finished on the automatic screw machine, is illustrated and described. The pieces of work made, known as adjusting plates, are shown assembled on a stud in Fig. 1, the different parts being shown more clearly in Fig. 2. The outside diameter of the disks is $2\frac{7}{8}$ inches.





Figs. 1 and 2. Adjusting Plates made on the Cleveland Automatic Screw Machine, in Mesh, and Separated to show Rolled Teeth

As will be seen from these illustrations, the work consists of two circular disks, on the inside faces of which teeth are provided, the pitch and uniformity of shape of which are so accurate that the teeth of the one disk will mesh with the teeth of the other in any position. This in itself is quite remarkable, as is apparent when considering that the thread on screws cut on a thread milling machine, for example, is frequently not as accurate as this. If two threaded pieces are milled off down to the center and then laid side by side so that the threads engage with each other, a perfect fit or mesh does not always result in every position. The good fit of the teeth in the disks shown is even more interesting, as these teeth are not cut on the milling machine, as one would naturally suppose, but are produced in the automatic screw machine by means of a rolling process. It is interesting to note that the teeth are as clean and smooth as if they had actually been cut by a milling cutter, and the simplicity of the method used for producing them by rolling, even without gearing up the roller producing the teeth with the piece of work, is startling in its significance of the possibilities of the automatic screw machine.

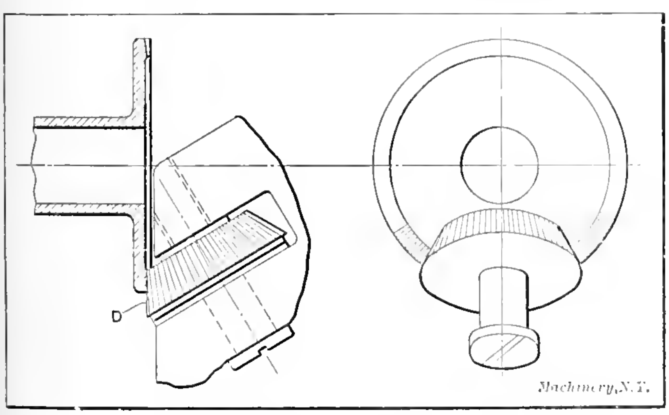


Fig. 3. The Beveled Roller which produces the Teeth

The rolling tool, by means of which the teeth are produced, is shown in Fig. 3. It is beveled as indicated, and the correct pitch and number of teeth is obtained by adjusting the roller radially in relation to the axis of the work on which the teeth are formed. If the face of the roller is sufficiently long in proportion to the width of the face of the teeth on the work, it is possible by this radial adjustment to obtain different numbers of teeth with the same roller on the same piece of work, and the roller can also be used for work of various diameters, rolling then, of course, a proportionately larger number of teeth on the larger diameters. When in action, the roller is held in a fixture or holder, which, in turn, is held in the turret. Owing to the possibility of adjustment, the diameter of the beveled roller is not required to be absolutely accurate, and new rollers can be made without the necessity of extreme precision. This is a great advantage in that the tools used for producing teeth in this way are thus comparatively cheap to make.

In Fig. 4 is shown a general perspective view of the tools in the turret used for making the pieces illustrated in Fig. 2. At *A* is shown the stock stop. At *B* is shown the tool which centers the work for the drill, and at *C* is indicated the tool which finishes the recess on the inside face of the disk between the teeth and the hole. At *D* is shown the beveled roller which produces the teeth, and the method of

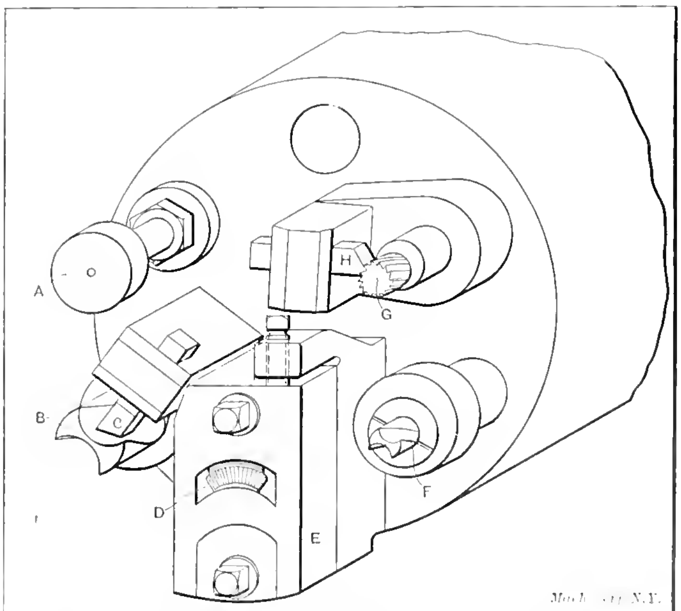

Fig. 4. The Arrangement of the Turret Tools for Making the Disks in Fig. 2

adjustment of this roller is also indicated, *E* being the adjustable slide. At *F* is shown the drill for the hole, and finally at *G* is indicated the reamer which finishes the hole.

One of the most interesting features of this work, outside of the mechanical accomplishment of producing the teeth by a rolling process instead of by a milling process, is the short time in which the work is finished. Each one of the pieces can be made in $13\frac{1}{2}$ minutes. There are 180 teeth in each, and anyone in the least familiar with milling machine work

knows that the milling alone would take a considerably longer time, considering the setting up and the 180 indexing moves that would have to be made. Of course, the actual milling cut can be rapidly taken, but the total time consumed would be out of all proportion to that consumed in the rolling process.

The adaptation of the automatic screw machine to work of this kind indicates to the thoughtful mechanic the possible development of automatic machinery in the future. It shows that radical improvements are possible in methods and processes, which but a few years ago were considered well-nigh perfect. It indicates that we have at the present time but commenced to realize the possibilities of the automatic machine in the mechanical trades, and undoubtedly a few years hence it will be possible to employ the automatic machine on work which to-day nobody dreams of performing on anything but hand-operated machine tools.

LOCATION OF THE IGNITER IN GAS ENGINES

By GEORGE MILLER*

It would seem at first glance that the position of the igniter in the explosion chamber of a gas or gasoline engine is immaterial—that as long as ignition occurs within the explosion chamber the results will be the same, no matter whether the point of ignition is at the top, at either side, or in the center of the chamber. This, however, is not strictly true, as the writer has found by experience. In all internal explosion engines there is some one point in the explosion chamber which gives far better and more satisfactory results.

A large number of manufacturers of gas engines assume, that "any old place" will do for the igniter, and they make its position on the engine conform to the other parts of the mechanism, instead of placing the igniter in its scientifically correct place and making the remainder of the mechanism conform to it. If cheapness of production is the one aim to be attained in the building of gas engines, this practice is all right; but if efficiency and economy are to have any consideration, a different plan must be adopted.

In a certain shop some years ago the writer took part in the building of gas engines, the sizes ranging from two to twenty-five horsepower. The engines with cylinders of six or eight-inch bore gave the greatest power in proportion to gas consumption. All the engines with cylinders of a smaller bore than six inches required a steadily increasing quantity of gas in proportion to the power developed, the increase being in an inverse ratio as the bore of the cylinder decreased in size below six inches. The engines with cylinders of a larger bore than eight inches required a far greater increasing quantity of gas to develop their respective horsepowers. The difference between the fifteen and twenty-five horsepower engines was remarkable, the ratio of increase being almost in a geometrical progression. So great was this difference that several of the larger engines were returned to the factory, as the purchasers refused to accept them; they used by far too much gas. As the design of the engines was the result of years of study by an expert in gas engine design and construction, the writer, with only three or four years in this work to his credit felt, at that time, that it would be sacrilege to question the design of the engine. Yet the occurrence started him on the road of investigation.

Some years later, in another shop, a very similar engine was being built with the exception of the position of the igniter, which was placed directly on top of the cylinder. This engine gave fairly good results. The principal difficulty experienced was in starting it, especially in cold weather, but certain sizes of this engine, although they had this drawback, were both efficient and economical. A new superintendent coming to this shop determined to change the position of the igniter; he had it set lower down on one side of the cylinder as close as possible to the inlet valve—"for the purpose," as he said, "of getting the incoming charge as close to the igniter as possible, and so lessen the possibility of a charge missing fire." But this brought about an entirely different result. The engine missed fire more frequently, and did not give as great power as under previous conditions.

Upon investigation it was found that the charge, coming as it did through the common mushroom-shaped valve, swept past and did not come in contact with the igniter until it had traveled around on the inside of the cylinder. To overcome this slowness in the ignition of the charge, the superintendent designed a shield or deflector to partially cover the inlet valve, and so designed as to force the full incoming charge against the igniter. The igniter on this engine was not in a pocket, as it is often placed, but operated directly in the explosion chamber. The result of this change was almost disastrous. So early and violent was the explosion after this change that no firing lead was possible. Therefore, the time was changed so that ignition took place on the center, with the result of greatly reduced power, and great dissatisfaction on the part of the purchasers. So great was the shock to the engine when any firing lead was given that the flywheel and the bed of the engine vibrated so much that the whole engine would have soon been nothing but a scrap heap. The shock could even be felt through the foundation.

After several consultations with the superintendent, the writer was asked to get out drawings for a new cylinder, with the igniter changed to the position which he advised. This new cylinder was placed on an engine which had been using a charge deflector, and which the purchaser had refused to pay for, as it was using too much gasoline and not delivering the required power. The result was astonishing even to the writer, although he had recommended the change, and expected better results than the engine formerly gave. Not only was the power greatly increased, but the consumption of gasoline was greatly reduced. Before the new cylinder was put on this engine, and while the old cylinder with the deflector was in use, the writer heard over a hundred consecutive explosions without one "cut out," while at the same time the engine was doing inferior work. After the change the engine would cut out after every eight or ten explosions, at the same time giving the required power.

Some of the writer's early experiences with hot tube ignition has had much to do with his present opinion on the question of ignition. In a certain shop, some years ago, a five horsepower engine was supplied with a hot tube. The burner was stationary, so the tube had to be made the proper length to get the best results. After considerable experimenting a certain length of tube was found, which gave the most power for a given consumption of gasoline. Some time later another five horsepower engine was equipped with a hot tube. Naturally the same length of tube as was used on the first engine was employed, but on testing this engine the results were very disappointing. After considerable experimenting it was found that the hot tube for this engine had to be two inches longer than the one on the first engine. After that the hot tubes for each engine were made of such a length as the requirements of each individual engine called for to get the best results with the greatest economy.

On the basis of this data the writer has partially worked out a scheme so that the point of ignition can be somewhat altered as the conditions of each individual engine may require, thus eliminating a considerable amount of "chance" as to what will be the power of a given size engine, and lessening the possibility of there being great variation of power in a number of engines of the same size.

* Address: 108 Symington St., Toronto, Canada.

During 1909, machine tools of the value of (in round figures) $400,000 were imported into Great Britain. The value of the exports of machine tools was $3,800,000. In 1908 the imports amounted to $575,000, and the exports to $2,050,000. These figures indicate that the British machine tool trade is doing a profitable business. The details of the exports for 1909 are not yet prepared, but in 1908 Japan was the best customer of Great Britain for machine tools. Of other foreign countries, France and the Argentine Republic come in the second and third places, respectively. The British colonies take, of course, a great deal of the exports. Thus the British East Indies imported British machine tools to a value of $350,000, and Australia and New Zealand to a value of $215,000.

AUTOMATIC PUNCH-PRESS WORK

BY ETHAN VIALL*

Comparatively few shops have enough punch and die work of any one kind and size to use automatic punch-press feeding devices with any degree of economy, but occasionally a factory building a certain class of articles or machines in immense quantities, finds automatic punch-press work advisable. Such is the case in the factory of the National Cash Register Co., Dayton, Ohio, where numerous parts are made on punch-presses; only a few, however, can be satisfactorily run out automatically, so that only a fraction of the number

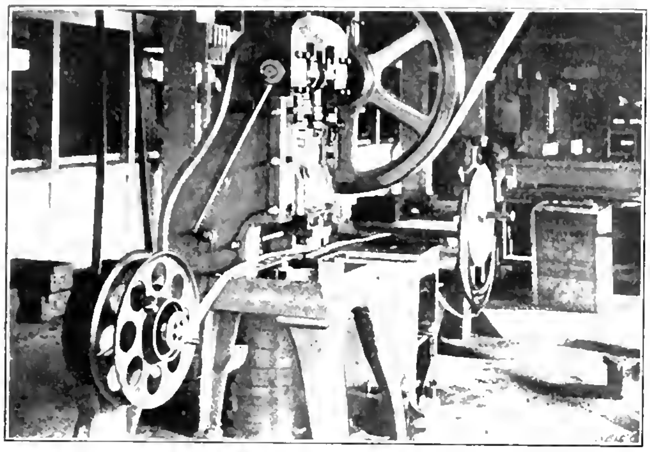

Fig. 1. Punch Press equipped with Automatic Stop and Friction Feed

of presses employed are equipped with automatic feeding devices, though a number of others are practically automatic, except that the stock is fed along by hand.

In equipping a punch press for automatic work, the stop and the method of pulling the stock along are, of course, the

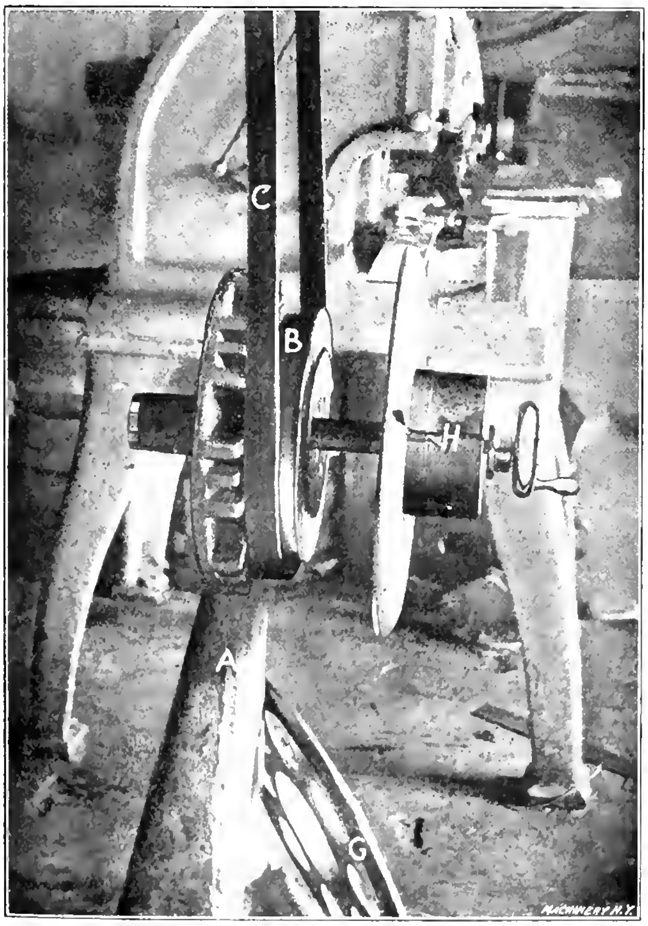

Fig. 2. Detailed View of the Friction Stock-feeding Device

most important points to consider. Mr. Sager, of the company referred to, has the best friction feed device that I have seen, as it is so arranged that any desired amount of tension or speed may be easily obtained. In Fig. 1 is shown a press equipped with one of these friction feeds. The friction feed is shown to the left of the press and a stock spool at the right. All presses whether automatic or not, are equipped with an automatic stop or spacing device, so that it is not

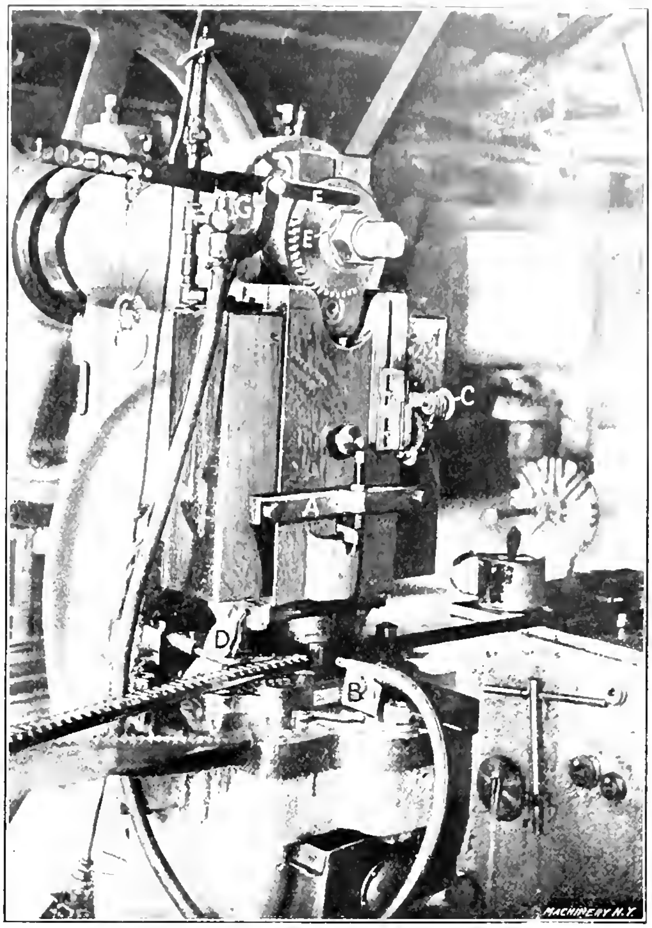

Fig. 3. Hand-fed Press Fitted with Counter, Automatic Stop, Blower and Blank Knock-out

necessary to put stops on the blanking dies themselves. The rod and lever used to operate the stop which will be shown in detail later, may be seen at the side of the press. In starting this press, the stock is, of course, fed through by hand

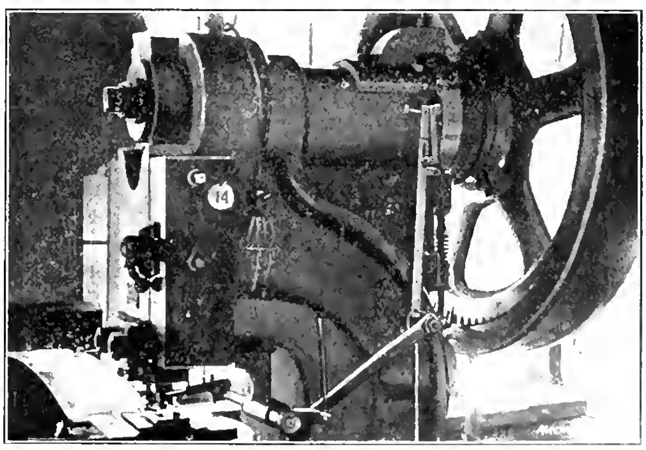

Fig. 4. Side View of the Press showing the Levers which actuate the Automatic Stop

until it can be caught in the slot in the hub of the friction feed, when the feeding becomes altogether automatic.

Fig. 2 shows the friction feed in detail. It consists of a cast iron stand or base A, carrying a pulley B, which is driven by a belt C from an overhead shaft. This pulley has a disk of leather D, fastened to the side next to the spool E, which can be pressed against it to any extent, by means of the small handwheel F. The flange G is slipped onto the hub of the spool and locked with a thumbscrew at the proper place to accommodate the width of the stock being fed. The end of the stock is inserted in the slot H, in the spool hub when starting. It will readily be seen from this engraving, just how the feeding device is made and works.

* Associate Editor of MACHINERY.

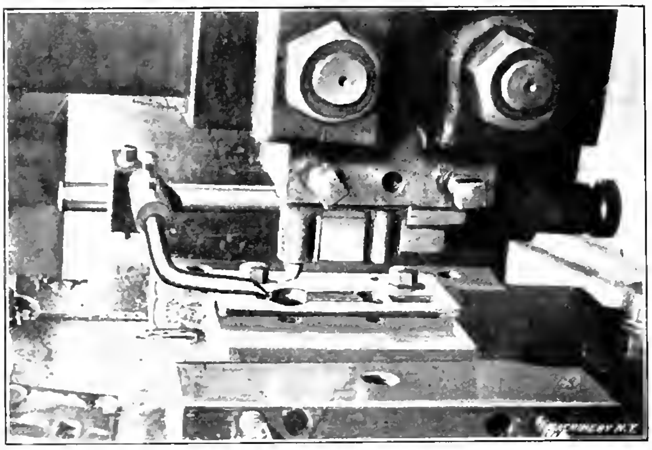

Fig. 5. Enlarged View of Automatic Stop

The general principle on which the automatic stops are made, is best shown on another press, Fig. 3, which, while a hand-fed machine, has practically the same stop used elsewhere in the shop. This press is also fitted with an automatic knock-out *A*, a pneumatic blank-blower *B*, a counter *C*, and the stop just mentioned, at *D*. By carefully examining the engraving, it will be seen that the blank knock-out works

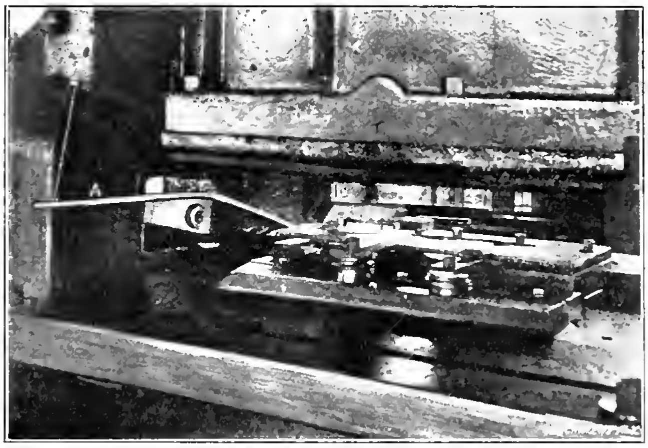

Fig. 6 Front View of Press which is equipped with an Automatic Stop that is operated by the Ram

as the ram rises, and the blank-blower throws a powerful jet of air onto the face of the die just at the instant the blank drops. The air is turned on at the proper instant by a cam and lever *E* and *F*, respectively, on the valve *G*, which automatically closes when released by the fall of the cam. The stop *D* consists of an adjustable hook which is raised and lowered by the motion of the press, through a system of levers

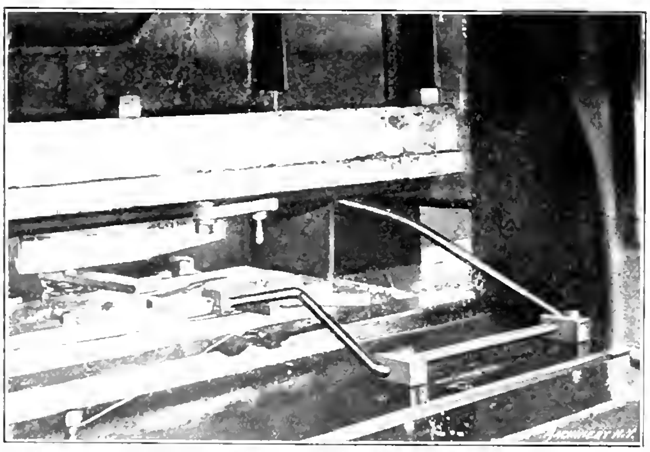

Fig. 7 Rear View of the Automatic Stop which is operated by the Ram

operated by a cam on the flywheel shaft. Fig. 4 shows how a similar stop and lever system has been fitted to another punch-press, while the stop itself is shown to better advantage in the enlarged view Fig. 5.

Another stop arrangement shown in Fig. 6 is used on a double crank-press and is operated by the bottom of the ram striking the lever *A*. A rear view of this stop is shown in Fig. 7. The letter *A* in Fig. 8 indicates where the stop comes in contact with the rear end of the punched hole. As shown, this stock is run through the press, then reversed and run through the other way to avoid waste.

The type of sub-press generally used in the shop is shown in Fig. 9. The knockout is indicated at *A*, while the felt washers used to keep the guides clean and well oiled are plainly shown. This idea of using felt washers around the

Fig. 8 View of Blanked Stock showing by letter A where Stop of Figs. 6 and 7 engages

posts is one worth copying, as it is but little trouble to put them on and they prolong the life and accuracy of the posts and guides almost indefinitely.

A very good device for lubricating stock with soap water is shown in Fig. 10; it consists of two rolls between which the stock is run, the lower roll being partly immersed in a small tank of soap water. This idea is equally good for applying oil to the stock used.

* * *

Not less than twenty governments have expressed their intention to participate in the International Exposition to be

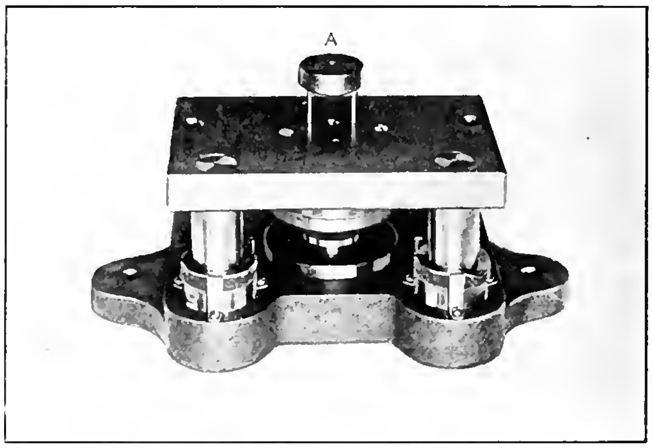

Fig. 9 View of Sub-Press showing Knock-out and Felt Oiling Washers for Posts

held at Brussels, Belgium, this year. Pamphlets and circulars relating to the exposition may be obtained from the Bureau of Manufacturers, Department of Commerce and Labor, Washington, D. C., or from the Belgian Legation in Washington.

MACHINE SHOP PRACTICE*

TURNING GAS ENGINE PISTONS IN THE TURRET LATHE

By CONTRIBUTOR

A good method of turning gas engine pistons when a turret lathe is available, is described in the following: A plan view of a piston casting mounted in the chuck of a turret lathe, is shown diagrammatically in Fig. 1. An extension is cast on the closed end of the piston to hold the casting in the chuck, so as to enable the operator to complete the turning operations at one setting of the work. This extension has the further advantage of insuring a sound casting at the solid end of the piston.

The casting, in accordance with standard practice, is set true by the inside surface, so that when the outside is turned the walls of the piston will be of uniform thickness. When the work is properly set, the turret tool or cutter *C* is brought into operation. This cutter bores the inside of the casting for a distance *A*, faces the end and rounds the inner corner. The turret is then moved back and indexed, bringing the roller *B* in position as shown in Fig. 2. This roller is inserted into the previously finished part of the bore, and as it is an accurate fit, it serves to steady the work during the turning

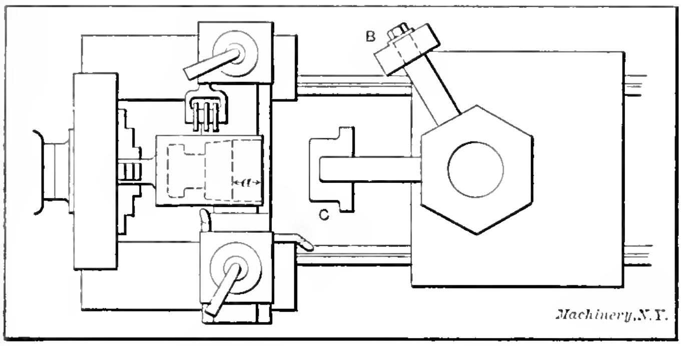

Fig. 1. Piston chucked ready for Boring

operations. The turning tool in the slide-rest is next used for rough turning the body of the piston. After the roughing cut has been taken, a bent round-nosed tool is used for facing the solid end as far as the extension will permit. This extension should not be cut away at this time, as the casting will need to be rigidly supported while the ring grooves are being cut. The finishing cut is then taken over the body of the piston, reducing it to the required size.

The grooves for the packing rings are next cut with a set of three disk tools. These tools are rigidly clamped in their holder, and are separated the correct distance by accurately made distance pieces. The holder is fastened in the toolpost of the back slide-rest. Before the grooves are cut, the car-

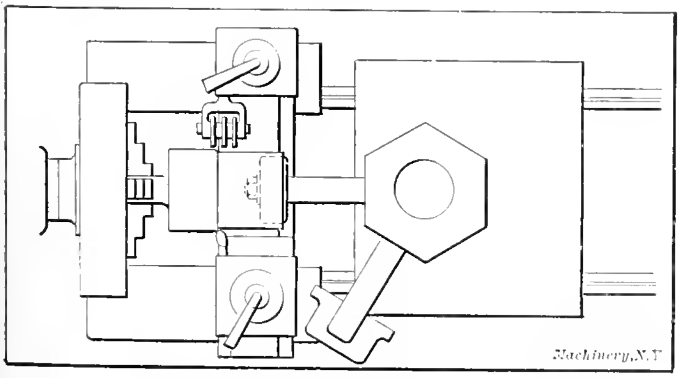

Fig 2. Rough-turning the Outside with Roller Support in Finished Part of Bore

riage is moved against a stop provided on the machine, which has been previously set so that the cutters enter the casting at the correct distance from its end. Another stop is used on the cross-slide to prevent the cutters from being fed too far into the work. After the grooves are finished, the final operation is to sever the piston from the extension piece by means of a parting tool held in the tool-holder of the front slide.

* With Shop Operation Sheet Supplement.

THE CRANK-CASE PROBLEM*

Volumes of catalogues and trade literature have been published descriptive of the operation of what is known as the enclosed crank-case two-cycle motor, but very little real information has been given relating to the principles of design and the inherent difficulties to be met in this class of engines.

Everyone knows that in this class of engines the crank-case is used as a pump to force the charge into the working cylinder; in fact, the crank-case is one end of the cylinder

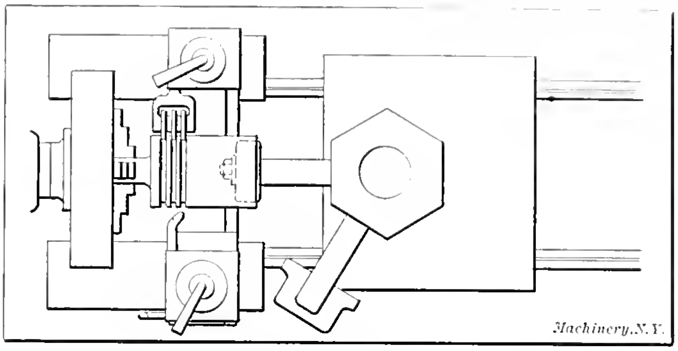

Fig. 3. Turning the Grooves

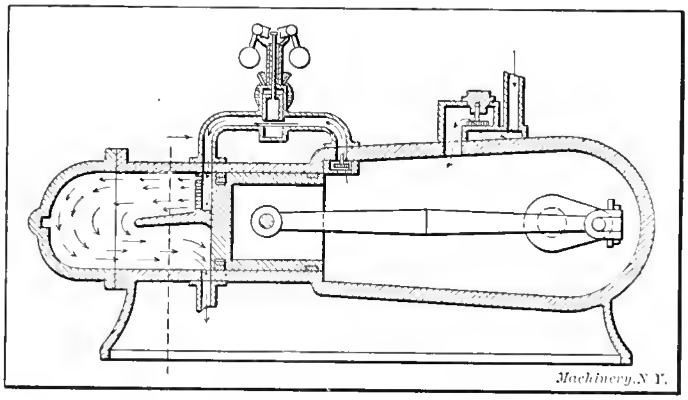
which has been enlarged enough to let the crank-shaft and connecting-rod inside and give them room to work. This makes a double-acting cylinder just like a steam engine, except that one end is an air or gas compressor with the moving parts of the engine inside of it, and the other is an explosion engine. The same piston serves for both uses and, of course, sweeps through the same volume or "displacement" at each end, this volume in cubic inches being the area of the piston in square inches multiplied by the stroke in inches.

The engine end of the cylinder has means for admitting the mixture to it, and releasing the burned gases from it, these means being two ports, or series of ports, in the cylin-



Diagrammatic View of Two-cycle Engine of the Type having a Check Valve for the Admission to the Crank-case or Pump

der walls which are covered by the piston, except for a short time near the end of the stroke. The exhaust port is wider and opens first, at a point ten to fifteen per cent before the piston reaches the dead center. This gives a chance for the hot gases to escape and reduces the pressure in the cylinder before the piston uncovers the inlet port at five to eight per cent from the end of the stroke. This is necessary to prevent the burning gases from shooting down into the crank-case and firing the new charge before it is time. Before the exhaust opens, the pressure in the cylinder may be as much as thirty or forty pounds per square inch, while the pressure in the crank-case is seldom over six pounds. One of the difficulties in two-cycle design is to get these ports right, so that the pressure in the cylinder will be lower than the crank-case pressure by the time the inlet port is uncovered. This inlet port to the engine end is the discharge port for the compressing or pump end; and for all three of the events thus far mentioned, *viz.*, admission and discharge in the engine end and discharge in the pump end, the piston is the controlling valve. The fourth event, admission to the pump end, is also controlled by the piston in the type known as three-port, or

* Abstract of article by C. A. Hawley in *The Sibley Journal of Engineering*.

valveless engine. In the two-port engine the admission to the pump is by a check valve.

In the operation of these pumps there are four main sources of loss in capacity or volume of charge: 1. Suction loss due to taking in charge at less than full atmospheric pressure. 2. Discharge loss due to failure of charge in crank-case to be fully delivered to the working end during the brief opening of the inlet port. 3. Exhaust loss due to entering charge partially mixing with exhaust gas, and going out the open exhaust port. 4. Leakage from the crank-case at bearings, etc.

Clearance space in the crank-case is often mentioned as a cause of reduced charge and is so, but in an indirect way, through its influence on suction and discharge. These latter are primarily due to fluid friction, or the resistance of the charge to passing through the inlet valve and inlet port. If there were no friction, the clearance would have no effect, but as a matter of fact it has a great effect in increasing both the suction loss and discharge loss, as will be shown.

The above losses are not all in the same direction; for instance, if an engine has a large clearance resulting in increased loss in (1) and (2) it will at the same time have a lower pressure and less leakage from the crank-case (4), and likewise, because of the reduced volume actually delivered to the cylinder, less chance of blowing fuel out through the exhaust (3). Designers nowadays do not worry so much about (3) because the other results are such that it usually is not important, but he who attempts to make his pump *too efficient* must watch out for this loss. An interesting commentary on this point was made by Mr. L. H. Nash at a recent meeting of the American Society of Mechanical Engineers. Mr. Nash exhibited the accompanying illustration which is of one of the first two-cycle engines. Note the large space in the crank-case and the enormous baffle plate on the piston with its precautions for heading the charge straight for the cylinder head. In this case the designer evidently feared nothing so much as blowing out at the exhaust.

TABLE I. SUCTION LOSS IN PER CENT OF DISPLACEMENT FOR VARIOUS CLEARANCES

Suction Pressure Below Atmospheric Pressure, Pounds per square inch	Clearance in Per Cent of Displacement			
	150	200	250	300
½	8.5	10.1	11.9	13.6
1	17.0	20.2	23.8	27.2
1½	25.5	30.3	35.7	40.8
2	34.0	40.4	47.6	54.4
2½	42.5	50.5	59.5	68.0

To return to the clearance, most designers work to keep this as low as possible. This is done by making the crank-case as close a fit as is safe, by using a short connecting-rod, by putting balance weights on the crank webs, and even by attaching false pieces in the pistons. The object of this is not merely to get a high crank-case pressure but also to reduce the suction loss. If we designate the displacement or volume swept by the piston as 100, the waste space in the crank-case will vary in different designs from say 150 to 250 additional, say 200 as a fair average; then the volume of air in the crank-case when the piston is clear up will be 300 and when the piston is clear down, 200. The pressure at the end of the down stroke depends on the pressure at the beginning of the stroke and on the nature of the compression. Theoretically there are two possible ways of compressing, known as isothermal and adiabatic. Practically, it is impossible to compress exactly by either, the usual result being somewhere between them. For comparison we may use the isothermal for figuring pressures, as this favors allowance for leakage, etc. If then we had before compression a pressure of 14.7 pounds absolute, atmospheric pressure, the pressure after compressing from 300 volumes to 200 would be 22 pounds absolute or 7.3 pounds gage, but if the suction pressure is two pounds below atmospheric, the final pressure would be only 19 pounds absolute or 4.3 pounds gage. In other words, a loss of two pounds on the suction is a loss of 3 pounds in the maximum pressure, and with larger clearance would be still more. How much this affects the volume delivered to the cylinder cannot be answered absolutely, as it depends on the inlet port and the speed. When the piston uncovers the inlet port the charge in the crank-case at once begins to enter the cylinder and the pressure starts to drop. It does not drop entirely to atmospheric pressure, however, and probably seldom to less than 1 pound gage pressure on account of the very limited time that this port is open.

TABLE II. DISCHARGE LOSS IN PER CENT OF DISPLACEMENT FOR VARIOUS CLEARANCES

Residual Pressure Above Atmospheric Pressure, Pounds per square inch	Clearance in Per Cent of Displacement			
	150	200	250	300
½	5.1	6.8	8.5	10.2
1	10.2	13.6	17.0	20.4
1½	15.3	20.4	25.5	30.6
2	20.4	27.2	34.0	40.8
2½	25.5	34.0	42.5	51.0

TABLE III. VOLUMETRIC EFFICIENCY OF CRANK-CASE FOR 1 POUND SUCTION AND 1 POUND RESIDUAL PRESSURE FOR VARIOUS CLEARANCES

	Clearance in Per Cent of Efficiency			
	150	200	250	300
Volumetric efficiency	72.8	66.2	59.2	52.4

With a clearance of 200 and a pressure in crank-case reduced to 1 pound at the point of inlet port closure, it will require 13.6 per cent of the return stroke before the charge remaining in the crank-case will expand to atmospheric pressure, and this reduces the charge delivered to the cylinder by 13.6 volumes in 100.

TABLE IV. CRANK-CASE PRESSURE (MAXIMUM) IN POUNDS GAGE PRESSURE FOR VARIOUS CLEARANCES

Suction Pressure Below Atmospheric Pressure, Pounds per square inch	Clearance in Per Cent of Efficiency			
	150	200	250	300
½	9.0	6.6	5.2	4.2
1	8.1	5.9	4.5	3.6
1½	7.3	5.1	3.8	2.9
2	6.5	4.4	3.1	2.2
2½	5.7	3.6	2.4	1.6

Going back to the suction pressure, if it is 2 pounds below atmospheric when the inlet valve or third port closes, it will require 41 per cent of the forward stroke to compress this charge up to atmospheric pressure resulting in a loss due to suction of 41 volumes. So that our net charge under these conditions will be 100 less (13.6 plus 41) = 45.4 volumes or 45.4 per cent of the piston displacement. This low capacity is frequently obtained in practice and the best practice seldom exceeds 60 to 65 per cent of the charge.

In Tables I and II the losses in capacity from both suction and discharge are tabulated for different percentages of clearance space in the crank-case. Clearances and capacities are stated in percentages of piston displacement. The tables are carried beyond the limits of good practice in order to show clearly the effect of excessive clearance or frictional pressure loss in suction or discharge. The "suction pressure" is the pressure in crank-case below atmospheric when the piston is up ready to compress and the "residual pressure" is the pressure above atmospheric when the piston has just closed the port into the cylinder and a new charge is about to be taken into the crank-case.

In Table III the net capacity is given under assumed conditions such as exist in good practice. These values are obtained by subtracting from 100 per cent the sum of the suction and clearance loss in Tables I and II. It will readily be

seen that for some of the conditions of Tables I and II the capacity would be zero or less. A study of these tables may lead one to wonder not why his engine *does not run* sometimes, but why it *does run at all.*

In estimating the suction pressure if the clearance is known or *vice versa*, the highest pressure obtained in the crank-case is a valuable aid. This can be found with a ball check valve connected to the crank-case and to a low reading gage. Table IV shows what the pressure will be under stated conditions. It may be remarked that the usual value in good engines is from 4 to 6 pounds. A leaky bearing or stuck inlet valve will at once cut this down. It will be easily seen from the tables why it is that motors choke up and refuse to run at speeds above what they are designed for, on account of the loss of charge at both ends of the stroke, and also what are the best results which may be expected of motors of this type.

CAST IRON PULLEYS

By AUGUST WACKERMAN*

A great many manufacturers, when buying pulleys, seem to think that as long as they get a round wheel, that will revolve, that is the only requirement. This policy always proves expensive, as a large amount of power is lost by giving no attention to the pulleys.

To obtain good results, it is absolutely necessary that the pulleys be well designed and perfectly balanced. The ordinary manner of balancing on parallel ways, may do for pulleys running at a very slow speed, but, for moderate and high speeds, pulleys after being balanced in this manner, must be tested at the speed at which they will actually be used when placed on their respective shafts at installation. A badly balanced pulley will destroy bearings, shaft, and, in fact, the whole transmission, in time. To have a good running power-saving line-shaft, depends as much on perfectly balanced pulleys as it does on good shafts and well-oiled bearings.

It is often claimed that when shafts break, they have been over-loaded, but investigation will sometimes show that the cause was due to imperfectly balanced pulleys. The following also should be carefully considered:

Cast iron pulleys should not be used for a higher speed than a mile a minute (5,280 feet); for a higher speed, they must be specially constructed, and, as a general rule, cannot be recommended. The accompanying table gives the revolutions per minute which pulleys of various diameters make, when the rim speed is equal to 5,280 feet per minute.

Pulleys, with a 20-inch face and over, should always have two sets of arms. The face of a pulley should be slightly wider than the width of the belt, as no belt runs absolutely true.

It is good practice to make pulleys with a 10-inch face and over, clamp hub or split; by this means the shrinkage strain in casting the pulleys is avoided, and the bore of the pulleys does not need to be especially fitted as they can be clamped firmly upon the shafts.

If the following rules are observed, they will generally save delay when ordering:

Do not order a pulley without stating whether it is to be crown or flat.

Do not measure a belt and then order a pulley the same width of face as the belt; state the width of the belt and you will receive a pulley with correct face.

If a shaft is already keyseated, give the width and depth, as the pulley must be keyed to suit. If the pulley is not to be keyed, state that it is to have setscrews only.

Do not fail to state whether the belt is single, double, triple or a four-ply; also, if of leather, canvas or rubber.

Always give the revolutions per minute if a certain horsepower that the pulleys must transmit is specified.

Always order pulley split, if it is to be used on a shaft already erected; you will have to take down the shaft if you don't.

A split pulley is always preferable to a solid pulley, as it can be easily erected or removed.

* Address: Jones & Laughlin Steel Co., Pittsburg, Pa.

* * *

According to a report from Consul Frank W. Mahin, the reported good effects of the new British patents law in establishing new industries in the country are not fully substantiated by the facts. While some foreign firms have established branch factories in Great Britain, various reasons have been assigned for this, outside of the requirement of the patent act, and in at least one of these the avowed object of benefiting English workmen has not been realized, inasmuch as many foreigners were brought by the firm to work in their English factories. The most common cause, probably, for the establishment of branch factories in Great Britain is the increased demand for certain classes of goods in Great Britain and the colonies and the preferential tariff of the British colonies towards goods manufactured in Great Britain. Thus a large Swedish industry is now establishing a branch factory in Great Britain in order to be able to export to the British colonies without having to pay the higher duties exacted on imports from other countries than Great Britain. On the whole, the report indicates that the present law has had less influence in promoting new industries than was expected, and less than it has been represented to have.

HYDRAULIC PRESS TIE-RODS WITH SOLID HEADS AND BEARINGS IN CROSSHEADS

By BENJAMIN BROWNSTEIN

The bearings for the tie-rods in the upper and lower crossheads of hydraulic presses are usually made with caps, so that the rods can be made with solid heads and can be placed in the bearings of the crosshead and taken out with

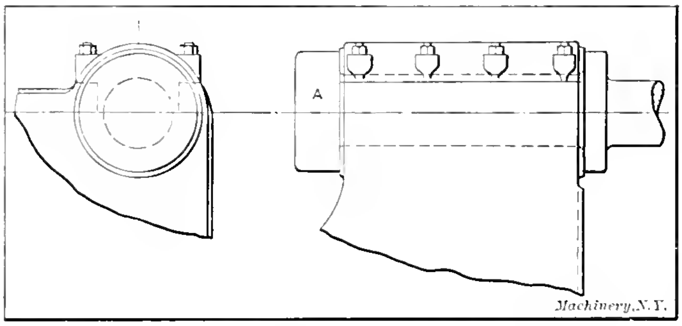

Fig. 1 Usual Method of making Crosshead and Tie-rod for Hydraulic Press

little difficulty. The method of construction is shown in the accompanying engraving, Fig. 1. While the strength of the tie-rods is increased by making them with solid heads, the strength of the crosshead bearings is lessened by the use of caps. Some manufacturers make the bearings in the crossheads solid and replace the solid head *A* of the tie-rods (Fig. 1) by nuts, and in this case the strength of the crossheads is increased while the strength of the tie-rods is decreased. Thus it will be seen that an increase in the strength of one member is always made at the expense of the strength of the other member.

A disadvantage following the use of bearings with caps is that when the hydraulic press is under heavy strain, the heads of the tie-rods are permitted to move away from the center of the strain, which action, in turn, causes the tie-rods to bend. It is for overcoming this difficulty that the bearings are made solid and the tie-rods with nuts, as mentioned, but even this is not satisfactory.

In the accompanying illustration, Fig. 2, is shown a design of tie-rod with a solid head and solid bearing in the crosshead. The joint between cap and crosshead is here eliminated, as well as the nut on the end of the tie-rod. At *E* is shown a top view of the crosshead with the tie-rods in place, and at *F* is a section through one of the bearings of the crosshead, in which *A* is the tie-rod, *B* an upper bushing, *C* a lower bushing, and *D* a nut screwed onto this bushing. The nut *D* is first put on the tie-rod, and then the tie-rod is put into the bearing of the crosshead. The bushing *C*, which is made in halves, is then put on the tie-rod and the head of the rod is pushed far enough out of the bearing at the upper end so that the bushing *B*, which is also made in halves, can be put into the bearing, after which the head of the tie-rod is brought to bear on the flange of the bushing. Now the nut *D* is screwed on the bushing *C* and tightened. Bushing *C* is prevented from turning by pin *H*. To take the crosshead and tie-rod apart, the operations are reversed. Bushings *B* and *C* are made either in complete halves, or solid and then split and provided with filling pieces put in for clearance. The one method is nearly as good as the other, but the former method is preferred.

The proportions of the tie-rod *A*, bushings *B* and *C*, and nut *D* are given in Fig. 2. The diameter of the tie-rod *A* is taken as the unit for all the other dimensions

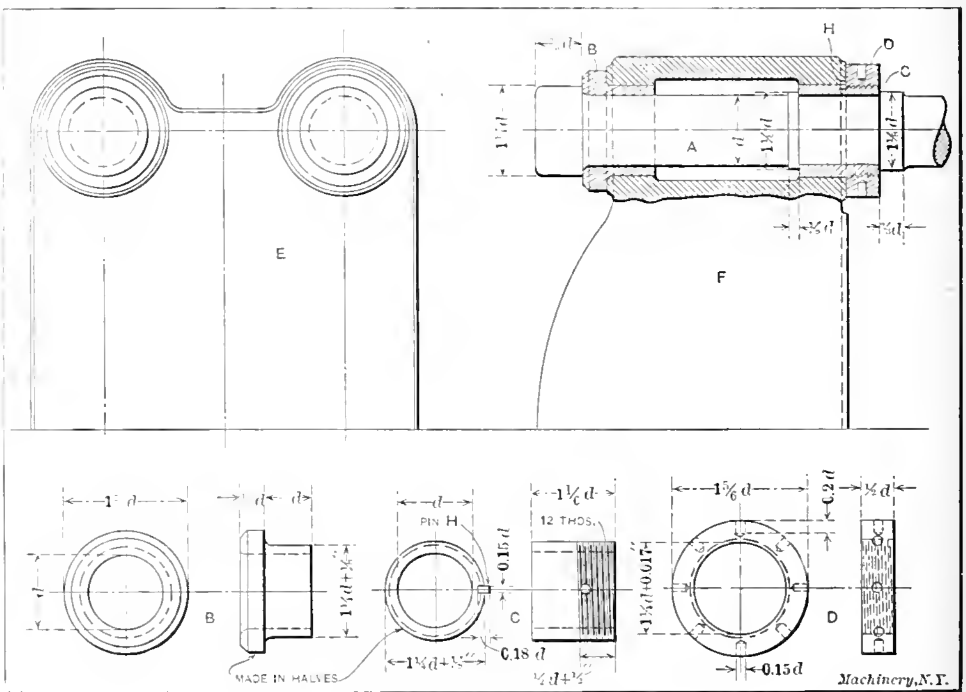

Fig. 2. Improved Method of Making Crossheads and Tie-rods

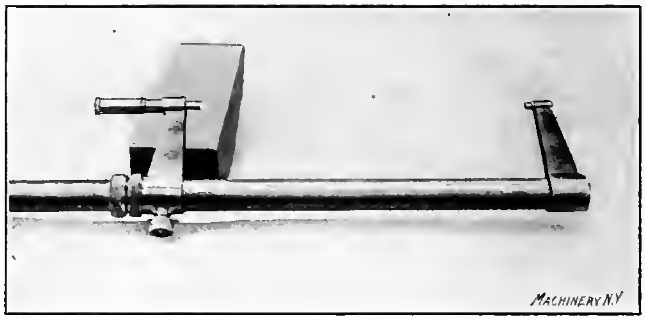
A CONVENIENT MICROMETER BEAM CALIPER

The tool shown herewith is, as may be seen, a beam micrometer caliper. It is not directly a measuring tool in itself, as it is designed to be set to end gages and then used in transferring the dimensions of those gages to other work. A micrometer screw and graduations are provided for comparing the measurements taken with the standard gage with that to which the caliper was set. It is obvious, of course, that by setting the adjustable head, with the screw reading at zero, to end gages of standard even inch lengths, the instrument may be used as a regular caliper for standard measurements.

The tool consists of a beam of tubing, carefully finished and fitted into a stationary jaw at one end and a sliding jaw at the other, the latter carrying the micrometer thimble and screw. The especial novelty of the device consists in the means secured for clamping the adjustable head at exactly



A Beam Caliper, with Micrometer Adjustment for Movable Jaws

the point on the beam desired, this being necessary, of course, as it is usually required that the graduations on the thimble shall read at the zero point when the end gage is held in contact between the screw and anvil points of the two jaws.

To the left of the movable head in the engraving will be seen two knurled nuts. It is by means of these that the fine adjustment of the head on the beam is made. When the one at the left is screwed down, it clamps to the beam, by means of a tapered and split thread, a bushing in the hub of the movable jaw. The turning of the other knurled nut with the thumb and finger adjusts the movable jaw along this bushing to the desired point. When this point has been reached (as shown by the readings on the micrometer thimble, set to the end gage), the knurled thumb-screw shown is turned, firmly clamping the movable jaw to the beam and thus preserving the adjustment. A keyway, not shown, keeps the anvil and screw points on the two jaws in line. This tool is the design of Mr. B. M. Weller, superintendent of the Colburn Machine Tool Co., of Franklin, Pa., in which plant it is in constant use.

LETTERS ON PRACTICAL SUBJECTS

ACCURATE SPRING WINDING APPLIANCE

It is often necessary in the tool-room or shop to wind both tension and compression springs that must be quite accurate as to diameter. This naturally puts one into a quandary, plus some guesswork, as to the diameter of the rod on which the spring is to be wound, owing to the enlargement of the spring after it is removed from the rod.

Fig. 1 shows an appliance which I devised and have used with success, with which a spring can be wound that will not enlarge 0.001 inch; on the contrary, it will contract in diameter when removed from the winding rod if sufficient pressure has been applied when winding, providing, of course, that the tool has been properly made. At first glance this tool may appear familiar to some mechanics, but it embodies a very important point in its construction that is not generally found in tools for this work in that it acts as a burnisher as well as a mere guide and tension appliance. The burnishing of

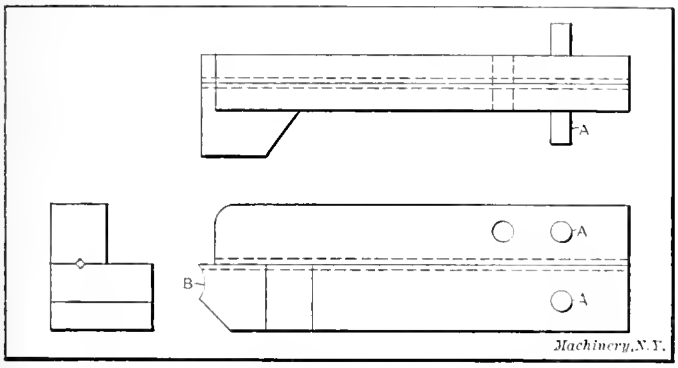

Fig. 1. Tool with which Springs may be wound to a Given Size

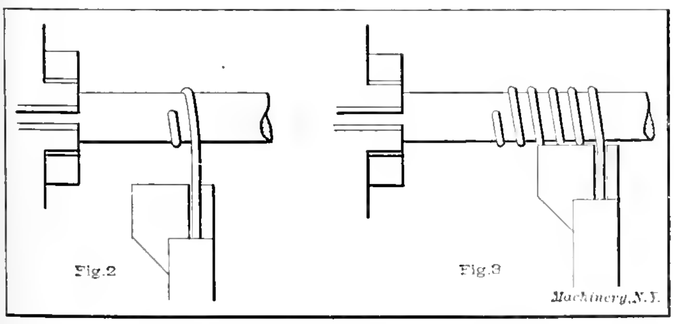
the coils while they are being wound is highly important if satisfactory results are to be obtained. This burnishing tends to expand the outer half of the wire due to the friction and heat, thereby causing the radius of the curvature of each convolution of the spring to either retain its diameter or contract when removed from the rod, depending on the pressure applied while it is being wound. The winding tool, as stated, is shown in Fig. 1. It is composed of two parts which are made of fiber for light work, or brass for heavy work. A very small V-groove is cut in the center of each piece to guide the wire. The pins *A* are to prevent the parts of the tool from being pulled through the toolpost when the work is being started. The burnishing nose *B* should, preferably, have the



Figs. 2 and 3. Method of Starting a Spring

same curvature as the spring to be wound as this will increase the friction, thus necessitating less pressure.

Fig. 2 shows the method of starting a spring. The tool, at first, is back from the winding rod a short distance; it is kept in this position until a few coils have been wound, when it is moved in against the work as shown in Fig. 3. As will be seen, the burnishing end then bears against the wire coils as they are being wound. By referring to Fig. 4 which shows a side view of the tool and a section of the winding rod, it will be noted that the upper half of the tool is set back a short distance; this is the position of the upper part when winding an open or compression spring as it permits an easy rise in the wire.

Fig. 6 shows a plan view of a spring being wound. It is advisable to gear the lathe when using this device, the same as if a thread were being cut, using gears that would give as many coils of spring to the inch as are desired.

As previously stated this tool can also be used for winding springs with initial tension. In close winding, the upper half of the tool is moved up forward as shown in Fig. 5, the

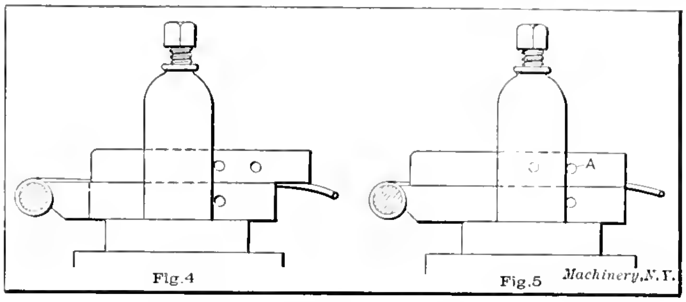


Fig. 4. Tool set for Winding Open-coil Springs. Fig. 5. Tool set for Winding Closed Springs

stop pin *A* being inserted in the rear hole; this is done to prevent the leading coil from jumping over the one adjacent to it. It is advisable, even in close winding, to use the burnishing nose, as it gives the proper diameter; in addition, burnished springs do not "set" as much as those wound with tension on the wire alone. When winding closed springs, the lathe should be run a trifle slower than for an open spring, in order to have a better control, as the carriage must be helped along by hand. The expression "helped along" explains this operation literally, as that is almost all that is necessary,

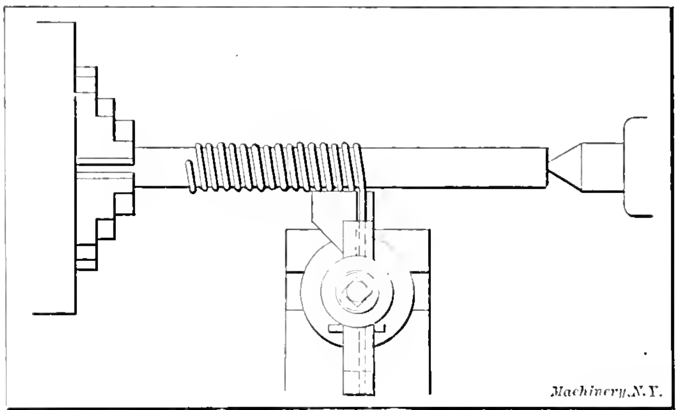

Fig. 6. Plan View of Spring being wound in a Lathe

because after a few coils have been wound, grooves are worn in the fiber or brass of the burnishing end, which act as a pusher or guide, and all one has to do is to just take up the lag in the lathe carriage. It is advisable to drill a small hole in one end of the winding rods of various sizes for holding the end of the wire, as this saves the chuck.

A very favorable feature of this device is that the rod and spring are always supported by the burnishing nose which is held against the coils by the tension caused by the friction of the wire in the slots, thus making the tool practically a traveling rest.

LOUIS E. KRAMER

Newark, N. J.

NICKED TOOTH MILLING CUTTERS

Recently I had occasion to order some nicked-tooth milling cutters and on receiving them, I found that the nicks were very narrow as compared with the length of cutting edge between them. Now as nicked-tooth milling cutters are generally used for roughing, would it not be better to have the nicks wider, say nearly the width of the cutting edge between the nicks?

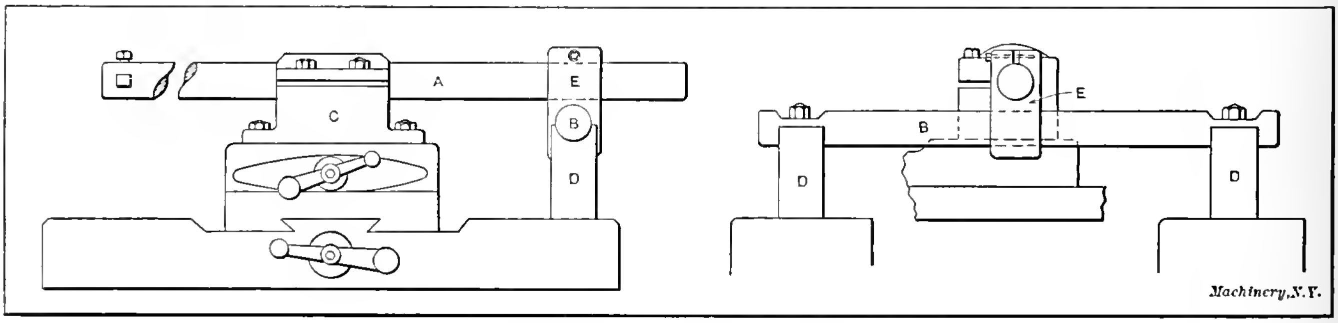
The manufacturers of cutters claim that the teeth are nicked to break up the chip, thus making an easier cut. It seems to me that they might go a step further and increase the width

of the nick. Take for example a cutter with a three-inch face, having nicks on each tooth the same width as the cutting edges between them, or one-half inch. Then each tooth will take three chips, one-half inch wide and having a thickness of twice the feed per tooth. For comparison with this cutter, take one with the same width of face but having nicks just wide enough to cause a break in the chip, the cutting edges between the nicks being, as before, one-half inch wide. Now with this second mill, each tooth will take a chip practically two and seven-eighths inch long and having a thickness equal to the feed per tooth. I think all will agree that the first mill will require less power, when milling, than the second one. Of course the cutting edge between the nicks would want to be a little wider than the nick, but not over one-sixteenth inch wider.

As a good example of a cutter with wide nicks, take the inserted tooth cutter having teeth made of round stock and inserted in a body. With this cutter the "nicks" are nearly the same width as the cutting face of the tooth and this style of mill for roughing is certainly a success. ALPHA

LATHE BORING-BAR FOR LARGE WORK

A special boring-bar that will be found very desirable for heavy duty, such as boring locomotive driving-boxes, pump cylinders, or any part requiring a long rigid bar, is shown in the accompanying engraving. This bar *A* was made for a 24-inch engine lathe. It is fitted to a toolpost *C*, which is mounted on the cross-slide in place of the regular toolpost.

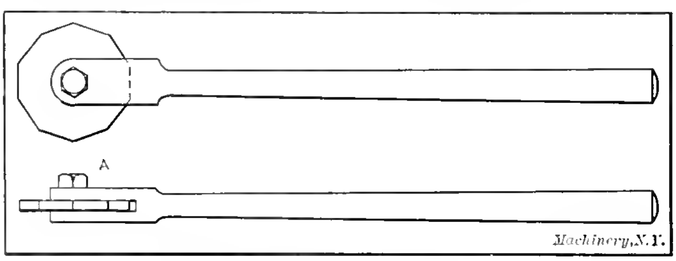


Rigidly-supported Boring-bar for Heavy Duty

The back end of the bar is additionally supported by a cylindrical cross-bar *B*, which is attached to the rear of the carriage by two columns *D*. These columns and the cross-bar are firmly bolted to the carriage as shown. Connection is made between the bar *A* and its support, by a block *E*, which is free to slide on the cross-bar, thus permitting the cross-movement of the tool-slide. The holes in this block are slotted so that it may be clamped in position, thus adding to the rigidity of the tool. The boring-bar in this case is 2½ inches in diameter, but obviously bars having reduced ends of any diameter and length to suit the work, may be made. S. W. GEORGE

SCRAPER WITH TEN-SIDED ADJUSTABLE BLADE

In a shop that I recently visited, I noticed a machinist using a scraper that was quite novel as well as useful. The blade of this scraper is in the form of a decagon; that is, it



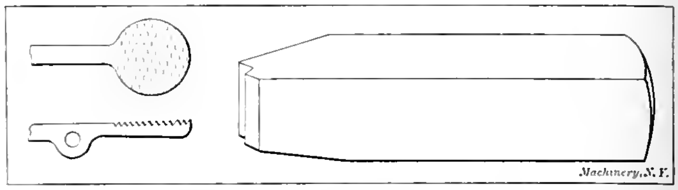
Scraper with a Blade having Ten Sides

has ten equal sides or flats, any one of which is available for use by releasing the locking or clamping screw *A* and turning the blade. This blade is made of carbon steel and is 3/16 inch thick. The flats were milled by mounting the work between the dividing head centers. The blade was hardened in a solution of water and salt and it was not tempered. The accompanying illustration clearly shows the construction of this tool. L. ROSENTHAL

Passaic, N. J.

TOOL FOR KNURLING FLAT WORK

Any toolmaker who has ever attempted to knurl or "cross-hatch" the face of a finger-plate like that illustrated herewith, will testify that it is not easy to do it regularly and easily with a three-cornered file, which is the usual way.



Flat Knurling Tool and Sample of its Work

These finger-plates are used quite frequently about jigs and fixtures, and as I had six to do the other day I hit upon the following quick and successful method: Taking a four-inch length of one-half inch square tool steel, I made a punch like the one shown in the illustration, by filing the sharp groove in the center and then filing away the metal from each side so as to leave the two 60-degree parallel ridges as shown. After hardening and drawing this punch to a dark straw color, it was driven lightly into the blank finger-plate, and by using the last impression to guide the stamp the work was gone over lightly in both directions. Going over the lines three times in all brought them up sharp and clean, thus finishing the job.

The secret of the success of this tool lies in the fact that as the punch has two ridges, it is easy to keep the spacing of the lines uniform, for one ridge locates itself in the last line struck while the other ridge strikes a new line. There is a tendency for the metal to push away around the edges of the piece during the process, and for this reason it is well to leave the blank a little large and bring it to size after knurling. CHESTER L. LUCAS

E. Saugus, Mass.

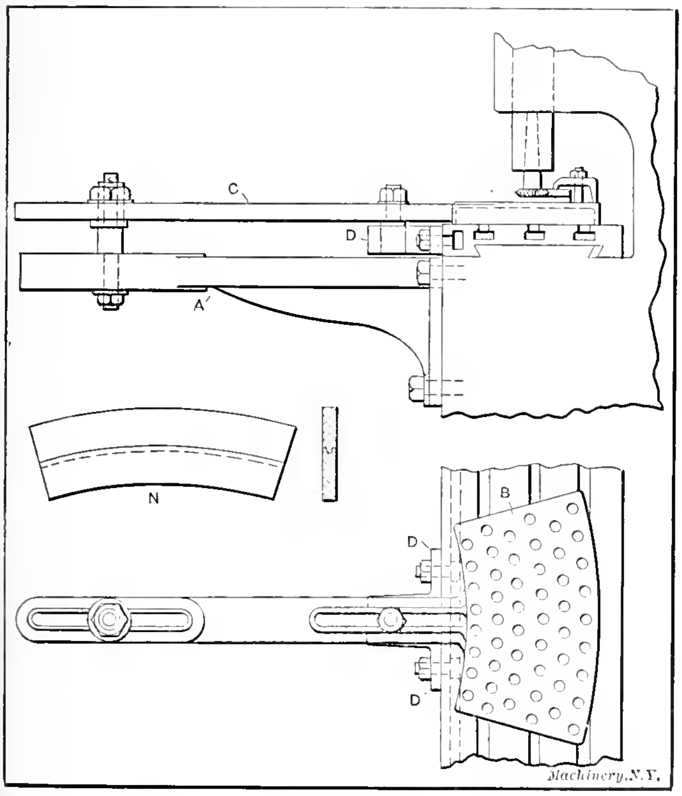
MILLING ATTACHMENT FOR MACHINING A CURVE OF LARGE RADIUS

In the December number of MACHINERY Mr. W. Alton contributes an article under the above heading. The article states that some pieces having a radius of about five feet had to be machined and that this radius was far too large for any lathe available. It must be presumed then that the curvilinear dovetail guide and saddle shown was either made by hand, entailing a very large amount of labor and expense, or it was made in another shop which had proper facilities for making the fixture and for which, no doubt, a very substantial charge would have been made.

Some years ago the writer was confronted with a similar problem, and as the method employed to arrive at the final result differs essentially from that described by Mr. Alton and has the merit of cheapness as well as efficiency, the readers of MACHINERY will unquestionably be interested in a description of the fixture.

We had always furnished and repaired the "nippers" required by a large worsted mill, which were of wrought steel and shaped as shown at *N* in the accompanying illustration, and we were able to turn them on a lathe of forty-two inches swing—the largest tool in the shop. Some new English machinery was then installed in the worsted mill and among it there was a comb which had nippers of a much larger radius, so that the lathe would not swing them by about twelve inches. The other tools in the shop consisted of a few smaller lathes, a drill press, a vertical milling machine and several minor machines.

To permit this job to go to another shop meant that probably all the other repairs of the mill would go with it. Such a contingency was not to be thought of and it was determined to rig up the vertical milling machine as quickly as possible to mill not only the pieces with the large radius, but also the smaller ones and to make the jig in such a way that there would be room for adjustment beyond present requirements. Accordingly a stand or bracket *A* was bolted to the front of the housing of the milling machine, the outer extremity of which was provided with a slot in line with the center of the milling spindle and of such a length that a stud fastened in it could be adjusted to both extremes of radius. A light table *B*



Simple Design of Milling Attachment for Curved Surfaces

of segmental form and having numerous holes drilled in it was finished parallel top and bottom and mounted upon the regular milling machine table. A radial arm *C* extended from it parallel with the bracket mentioned and at its extremity it had a slot similar to the one in the bracket. Into this slot a bush was fitted so as to be adjustable in the slot and a nut at the upper end of the bush held in place in any desired position. The bush in the radial arm oscillated upon the stud in the bracket, extra care being taken to have them swing upon each other with a good snug running fit. The front of the milling machine table had a T-slot in it running lengthwise, which contained ordinarily the lug used for the feed stop. In the present case two plain knee pieces *D* were fastened in this slot and between the two a plain stud was placed, which was adjustable in a slot in the radial arm; by this means the feed motion of the milling machine table was utilized to provide a feed for the segmental table, thus securing extreme simplicity of construction and consequently low cost.

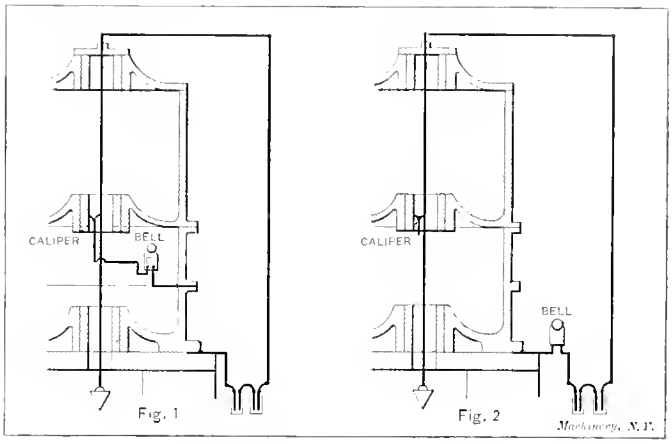
Another advantage secured by the adjustable center stud and bush was that the concentric curves on each side of the nippers could be milled by simply changing the milling cutter to one of the proper shape, and by moving the stud from or toward the milling spindle a distance equal to the width of the nipper and the diameter of the cutter. In this case the clamps for holding the nippers to the segmental table would have to be placed at the ends.

The device proved to be well adapted to accurate work within its limits and as an apprentice boy was able to run the machine, a cheaper and better article than had formerly been furnished was produced and the proprietor looked upon the fixture with the satisfied smile of the miner when he is thinking of his bonanza. CHAS. C. KLEIN

Philadelphia, Pa.

ELECTRIC CALIPERS

In the January issue of MACHINERY I noticed an article by Mr. Howard M. Nichols on the use of electric calipers for assembling vertical high speed turbines. His suggestion,



Figs. 1 and 2. Methods of Wiring for Electric Calipers

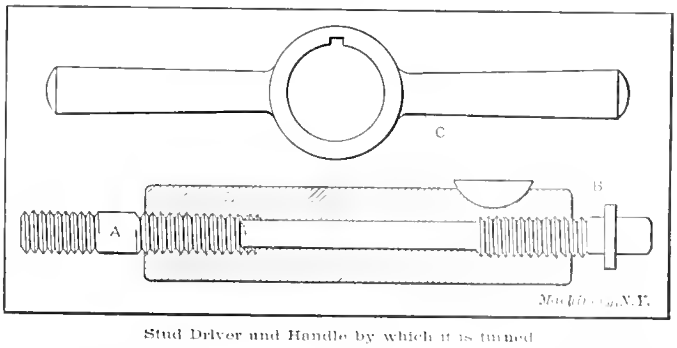
which is illustrated in Fig. 1, shows connections which would permit the bell to ring if the plumb-line were touched by the calipers without the calipers being in contact with the bearing at the same time. Fig. 2 shows how the connections can be made so that the bell will not ring unless the plumb-line and the bearing are touched at the same time by the calipers. This connection also makes its unnecessary to have a flexible connection to the calipers, which will thus be perfectly free as in ordinary work. W. F. HURLBURT

New Haven, Conn.

[The change suggested by our correspondent is undoubtedly an improvement. The arrangement shown in Fig. 1, however, would work satisfactorily, as one caliper leg would always be held against the bearing when testing the location of the plumb-line.—EDITOR.]

STUD-DRIVER

A stud-driver that is used in place of two lock-nuts and a wrench for screwing studs in the transmission cases of automobiles, is illustrated herewith. This work may be done much faster with a driver of this kind than when lock-nuts are



Stud Driver and Handle by which it is turned

used. One end of the driver is attached to the stud *A*, and into the other end a threaded locking or binding screw *B* is fitted. This screw has an extension, as shown, which passes through to the stud end of the driver. The end of this extension is cupped out so that it will have a good bearing on the stud. The pitch of the locking screw thread should be differ-

ent from that of the stud, to keep the latter from turning in the driver after it is in contact with the end of the locking screw. The driver is turned by the handle *C* which engages with the Woodruff key shown. FRANK LANG

Covington, Ky.

SHOP PHOTOGRAPHY

The article upon Shop Photography by Mr. R. F. Kiefer, in the January number of MACHINERY (engineering edition) contains some kinks that I think have been entirely dropped by British photographers.

First, why not call "non-halation plates" backed plates in order not to make people believe that they are a special brand, when they are simply ordinary plates backed with a very cheap preparation which can be easily made, or bought at any supply store. These plates may also be bought ready backed in England at threepence (six cents) a dozen extra. [The non-halation plates used in this country are not "backed plates," but a special brand having a double film which effectively prevents halation.—EDITOR.] Personally I seldom use backed plates. Reversing the plate in the holder, is a practice which I would not recommend, as the cure will generally be worse than the complaint.

The practice of brushing the plate with a camel-hair brush will put more dust onto the plate than it will take away, for two reasons: First, what is to insure the brush being clean? Second, the brushing will tend to magnetize the plate and so attract dust. The best way is to tap one corner of the plate against something; this will cause the dust to drop off.

Your correspondent advises various dodges which are very well in their way, but why not go in for an exposure meter at a very low cost and save all the bother? Mine, which I have had a number of years, cost 7/6 ($1.80), it is about the size of a watch, and it has saved its value many times over. A speed list of plates is given with the meter. I use a medium speed plate in winter, and a slow plate in summer, of the same make. My advice is to find a good plate maker and stick to one brand. If you use other brands, let it be on things which are not important until you are familiar with them. I agree with your correspondent on the factor development system, which has made developing a plate a simple job.

Before drying negatives, after washing, my advice would be *not* to use absorbent cotton, but the ball or side, of the hand. Furthermore *it is* advisable to change the position of the negatives when they are drying, because pools of water often collect at the bottom of the plate.

In conclusion I may say that photography has advanced from a mysterious operation, to calculated operation, with certain rules which, if followed, will insure correct exposure and development.

I can recommend to all photographers either a Wynnes or a Watkins exposure meter, and also Watkin's Manual of Photography. W. HAGGAS

Keighley, England.

CHART OF CROSS-SECTIONS FOR VARIOUS MATERIALS

From time to time there appear in the technical press as well as in the text books, charts of cross-sections for the various materials used in manufacturing. As the readers of MACHINERY are well aware, there is no recognized standard, and confusion often results.

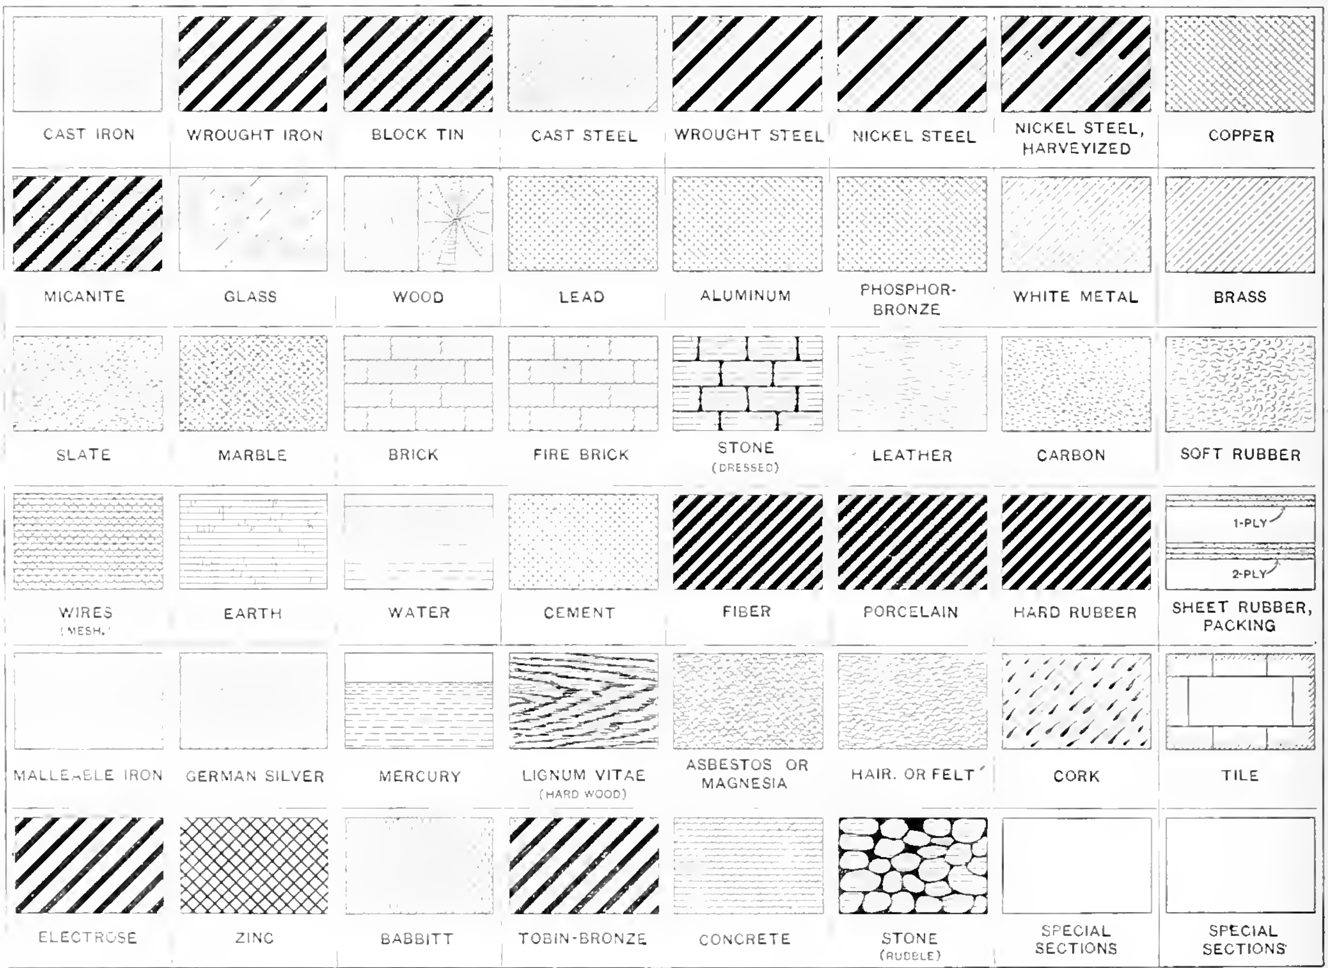


Chart showing Various Hatchings for Designating Different Materials on a Drawing

The accompanying chart was devised by the writer some years ago, and it has been adopted as a standard by a large department engaged in electrical and mechanical installations in marine work. As will be noted, many of the cross-sections are similar to those in general use, such as those for iron, steel, copper, brass, glass, etc. In addition, there are a number of other hatchings not so generally met with.

Brooklyn, N. Y. C. B. CHANEY, JR.

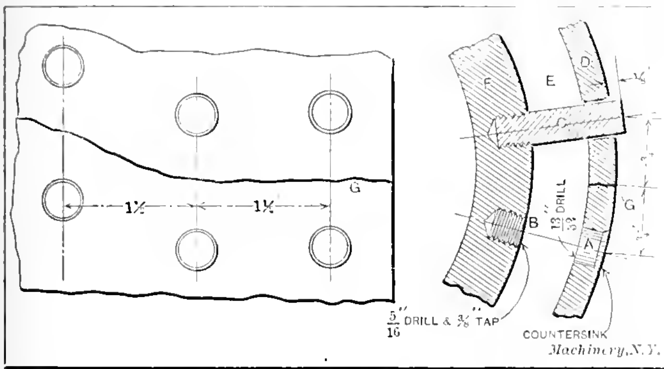
REPAIRING CRACKED WATER JACKETS

Many gas engine cylinders are thrown away as useless when the water jacket has been cracked by the water freezing in the jacket. There is, however, seldom a case of a water jacket so badly cracked that it cannot be repaired if the right methods are used. In the accompanying engraving a method has been illustrated which has been used for years

by the writer in repairing all kinds of cracked water jackets, even in cases where it has been necessary to put in pieces which have been entirely forced out. In many cases the work of repairing has been done by a blacksmith and the job has proved satisfactory in every respect. If the work is done with reasonable care, and the instructions given in the following faithfully followed, it will be impossible to tell that the cylinder has been cracked.

In the accompanying illustration the method of repairing the water jacket is clearly indicated; at *A* is a 13-32-inch hole, through the outer wall *D* of the cylinder; this hole is slightly countersunk on the outside. At *B* is shown a 5-16-inch hole, which is tapped in the cylinder wall proper with a 3/8-inch standard tap. At *C* is shown a stud screwed into the tapped hole, cut off and ready to be riveted. *E* is the water space between the outer and inner cylinder walls. At *G* is indicated the crack in the outer wall.

The method of procedure should be as follows: First lay out the holes about 3/4-inch back from the crack and about 1½ inch apart. Use first a 5-16-inch drill, drilling through *D* and into *F*, being careful, of course, not to drill through the wall *F* into the cylinder bore. Then re-drill hole *A* with a 13-32-inch drill and countersink as shown. Now tap hole *B* with a 3/8-inch tap, using first a plug tap and then finishing with a bottoming tap. From a bar of Norway iron cut off the studs one inch longer than necessary and thread one end the same distance as the depth of the tapped hole *B*. The thread should be a tight fit in the threaded hole.



Method of Repairing a Cracked Water Jacket

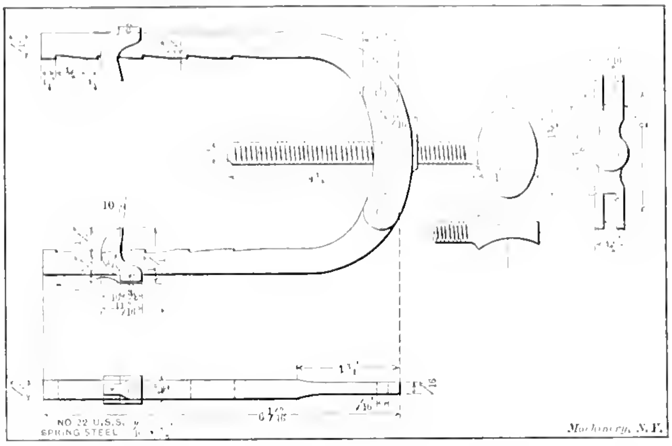
The studs are then screwed in tight by means of a pipe wrench applied to the one-inch extra length left on the end. This extra length is then cut off with a hack-saw and the stud is left projecting 1/8 inch outside of the outer wall as shown. When all the studs are screwed in and cut off, take a light ball-peen hammer and rivet down the pins. Rivet each stud a little at a time, bringing them all down together. When the studs are riveted down completely, the crack will be closed and water-tight. Then the heads of the studs are filed off flush with the cylinder wall and painted over.

Should the joint show any leakage, calk along the crack with a calking chisel or fill the water jacket with a saturated solution of sal-ammoniac and let it stand for a day. This will rust the metal in any small leaks so as to close them up. Nothing but Norway iron should be used for the studs. If the cylinder is very large, studs larger than those mentioned should be employed. GEORGE CORMACK, JR.

Rockford, Ill.

HANDY CLAMP FOR DIEMAKERS

A convenient form of crab-clamp for diemakers, that will doubtless be of special interest to those of MACHINERY'S readers who are interested in die making, is illustrated herewith. This clamp was also shown on Shop Operation Sheet No. 74, which I contributed, but the dimensions of the various parts were not given. It is particularly useful for holding a blank or templet in position on the face of a die while its outline is being scribed, or when transferring the irregular shape of a blanking die to the face of the punch, as the jaws upon which the die rests do not come near the hole in the die and therefore do not interfere with the scriber in any way. The principal feature of this clamp is that there is no time wasted in turning the thumb-screw up or down when pieces of different thickness are placed between the arms, as the sliding jaws are made so that they can be quickly adjusted on the arms which are provided with steps so that the jaws can rest at various places on them as shown. Springs which are attached to these jaws act as frictions and prevent the jaws



Diemakers' Clamp with Quick Adjustment

from dropping down when they are not resting on the steps. The arms swing on pins which are driven in the yoke, thus making it possible to accommodate various widths.

C. F. EMERSON

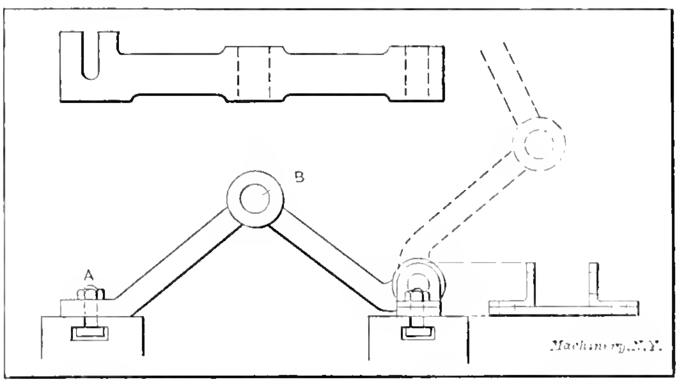
LEATHER CASES FOR MICROMETERS

In the December number of MACHINERY Mr. John F. Winchester suggests flexible cases for micrometers, protractors and other highly-finished and accurate tools. The Brown & Sharpe Mfg. Co. makes and lists in its catalogue soft leather cases for micrometer calipers, price 15 cents. They are all right and will also take caliper squares and verniers and probably some other tools, although they may not fit as well as the micrometers. J. R. RAND

Springfield, Mass.

LATHE STEADY-REST FOR DUPLICATE WORK

We had a large number of pieces which needed to be drilled while in the lathe and as it was necessary to support them during the drilling operation, the ordinary design of steady-rest proved to be very unhandy, as putting the rest in position and removing it for each part that was machined was a slow and expensive operation. The simple form of rest illus-



Convenient Form of Steady-rest for Duplicate Work in Quantity

trated herewith was then made. This rest is attached to the lathe carriage by a hinge on one side and the T-bolt *A* on the other. When the rest is not in use, it can be swung back out of the way as shown by the dotted lines. The hole *B* is, of course, in line with the axis of the lathe spindle. In machining this hole it was first drilled by a drill centered in the lathe chuck. An Armstrong boring tool was then used for boring out the hole. It was made 1½ inch in diameter, and bushed to 1⅛ inch, which was the size of the work in this particular case. Since the rest was first made, several bushings have been made for it to adapt it to work of various diameters. This attachment is not in the way and, consequently, it is very seldom removed from the lathe. It is employed for centering and drilling of all kinds, and its usefulness and value is apparent. S. W. GEORGE

SHOP KINKS

PRACTICAL IDEAS FOR THE SHOP AND DRAFTING-ROOM

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary

SOCKET FOR BELT-SHIFTER

As the style of belt-shifter socket shown in Fig. 1 was the cause of frequent trouble, the type shown in Fig. 2 was made, and it has given satisfaction. The cast iron cap *A* is fastened to the upper end of the wooden shifter-rod by two No. 14 wood

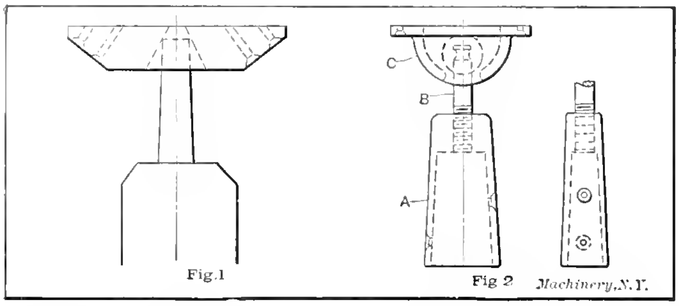


Fig.1 Fig 2

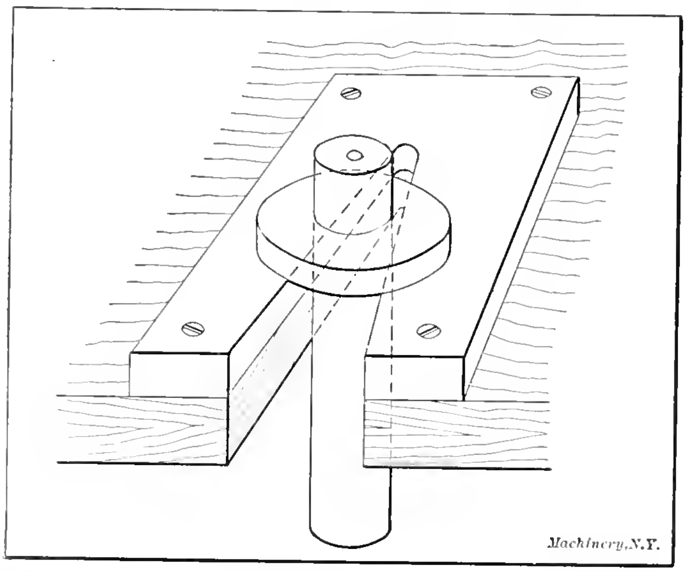
screws. An iron ball is cast on one end of the machine steel stud *B* to prevent the end of the rod from dropping out of the socket when it is assembled. The cup-shaped casting *C* is secured to the ceiling by four No. 14 wood screws. W. H. K.

A MANDREL PLATE

The engraving shows a handy mandrel plate that is intended to be screwed to the bench, close to the lathe. It has a tapered slot, and a similar one is cut in the bench for the mandrels to pass down through. The mandrel is slid inward until it

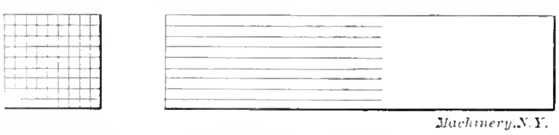


lightly touches the sides of the slot, when the work will be supported in the best manner for resisting the driving in or out. The plate may be of wrought iron, or of cast iron, if made thicker. FRED HORNER

Bath, England.

ERASER FOR CLEANING DRAWINGS

To make a cleaning eraser that will remove dirt and pencil marks from drawings, and that will not readily touch the ink marks, procure a common soft rubber pencil eraser and cut

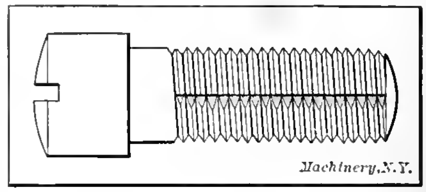


a lot of slits along the length of it, as shown in the illustration. These slits make the end flexible and this serves to keep it from removing ink marks when cleaning up a finished drawing. HOWARD M. NICHOLS

Kenyon, R. I.

IMPROVISED TAP

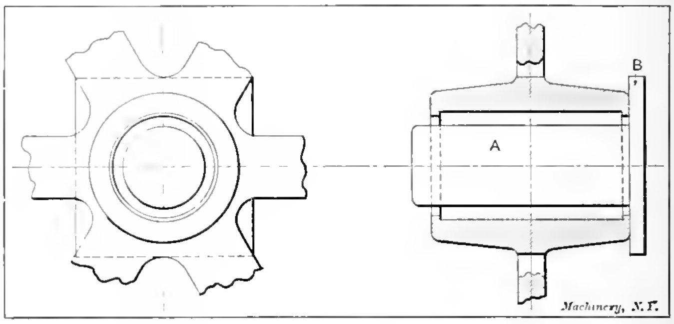
In re-assembling a machine which had been taken down for repairs, it was found that in a couple of threaded holes the threads had been, in some way or other, damaged so badly that the screws could not be replaced. These threads were of small diameter and a special pitch, and no taps were kept in stock for them. Accordingly one of the screws was annealed and three grooves were filed



in the threads lengthwise (see engraving) with a three-cornered file, thus, in reality, converting it into a tap. After being hardened, the screw was run into the holes, clearing up the threads enough to allow the screws to go back into place. F. W. B.

A LOOSE PULLEY BEARING

To bush a loose pulley, first bore it out as shown in the illustration. Then make a wooden arbor *A* somewhat smaller



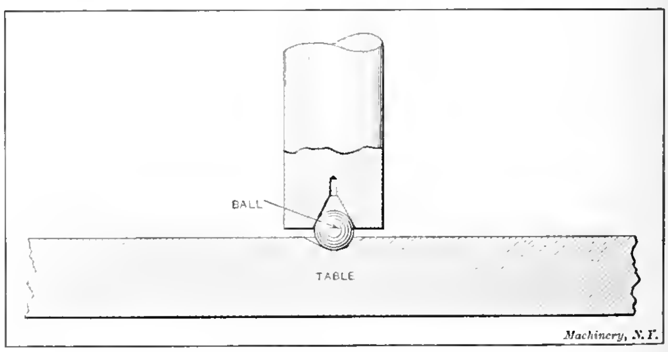
than the size of the shaft. To one end of this arbor nail a board *B*, and lay the pulley on the board with the arbor in the bore of the pulley. Adjust the pulley on the board until the arbor is central, as shown. Then get some brass chips that are well curled and fill the space between the arbor and the bore of the pulley. The hub of the pulley should then be heated and babbitt metal poured in. After this lining is bored to fit the shaft, there will be a bushing of brass and babbitt that will wear well. D. H. S.

SUPPORT FOR CENTERED WORK ON THE DRILL PRESS

A 5-16-inch steel bearing ball makes a good lower center for a drill press when handling centered work thereon. The ball is placed on a spot where a drill has marked the table, as shown in the engraving. CHARLES E. BURNS

Beverly, Mass.

[When an old drill mark is used, as described, it will

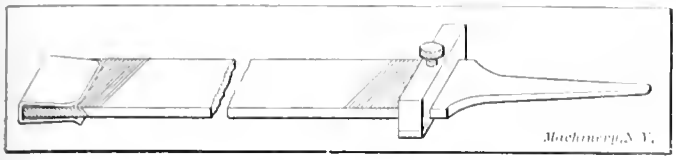


be necessary to align it with the drill spindle, assuming that the table has been shifted since the mark was made. This will, doubtless, take more time than would be required to strap a scrap piece to the table and make a new mark. Of course a competent mechanic would not deliberately mark his drill table with the drill point in order to support the work in the manner described.—EDITOR.]

EMERY CLOTH CLAMPS

The accompanying illustration shows a set of emery cloth clamps that will doubtless be appreciated by any one who has

occasion to use emery cloth on a file. The cloth is held tighter than it can be held by hand, and the hands are left free so that they may be used in a natural way. Filing may be done with the clear side of the file and the tool turned over when work is to be polished; or if desired, two grades of emery cloth

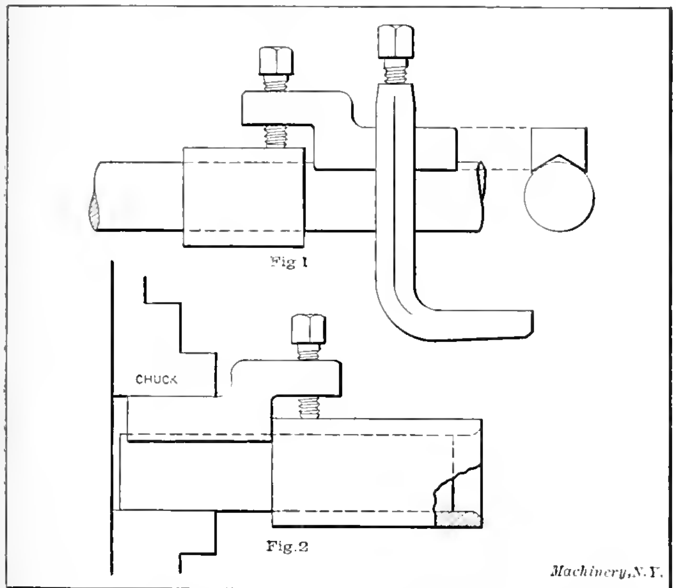


may be used, one on each side of the file. The strip of emery cloth is given a simple fold over the end of the file, the spring clip shown is pressed over it, and the other end is brought back under the clamp next to the handle; then the emery cloth may be drawn as tight as desired.

TOOLMAKER AND DESIGNER

COLLAR CLAMP

With all the paraphernalia that lies about the machine shop, often there is nothing handy that can be used to locate and clamp a cam or collar on its shaft while drilling it for a pin or spotting it for a set-screw. After many inefficient makeshifts, I made a clamp as shown in Fig. 1, and clamped



it to the shaft with a lathe dog. It worked satisfactorily. I also used it in an independent lathe chuck, as shown in Fig. 2, with a piece of cold-rolled shafting as an arbor, to face bushings to length or to round their inside corners, or any light turning where it is desired to have the work overhang the arbor.

CHARLES E. BURNS

Beverly, Mass.

WEDGE POINT FOR HERMAPHRODITE CALIPERS

Everyone who uses hermaphrodite calipers knows that the point soon loses its sharpness and makes "heavy" lines. The dulling of the point is, of course, hastened when the work on which the calipers are used is hard and rough. A style of point that will keep sharp much longer and make better lines than the conical point, is shown in the accompanying

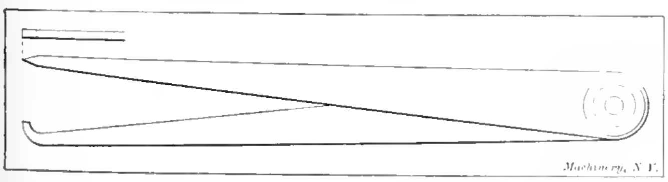


illustration. It is, in reality, an edge instead of a point, and consequently, will remain sharp for some time. It is simply an adaptation of the point a draftsman puts on his pencil for drawing lines, and practically all the work for which hermaphrodite calipers are used can be performed with this wedge-shaped end.

DONALD A. HAMPSON

Middletown, N. Y.

CASTING HOLLOW FIGURES

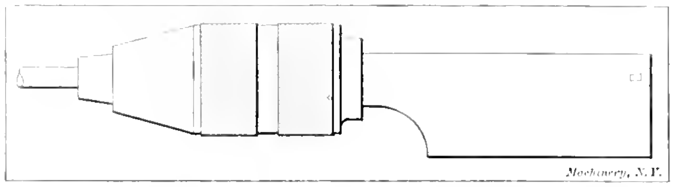
Hollow pewter figures are made by pouring them in a metal (generally cast iron) mold, where they are allowed to remain a few minutes, or until they are cooled sufficiently to form a thin outer shell of pewter. The mold is then inverted, and the molten metal in the center allowed to run out, leaving the figures hollow.

HERMAN JONSON

New York City.

BORING TOOL HOLDER FOR SMALL WORK

The accompanying sketch shows an old style of tool-holder used in possibly a new connection. The tool-holder proper is, as will be readily observed, a regular three-jawed drill-chuck. This chuck will admit any diameter of stock up to and includ-



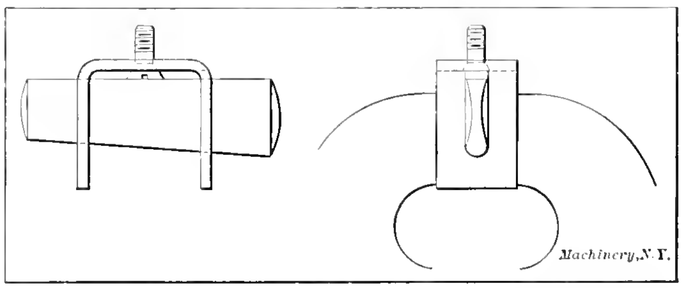
ing a half-inch, and it has a special shank fitted to it which may be clamped in the lathe toolpost. The range of work within the capacity of this tool-holder is unusually extensive, and at the same time its utility as a drill-chuck for lathe purposes is not impaired, since it may be removed from the toolpost and the shank held on the tailstock center, the center having been left in the shank for that purpose.

J. PRICE

Stamford, Conn.

METHOD OF HOLDING SMALL SCREWS

While making volume XV. of MACHINERY ready for the bindery, I noticed a method of holding small screws when filing off the ends, in the Shop Kinks page of the February, 1909, number. The arrangement shown in the accompanying sketch is successfully used for the same purpose. A suitable scrap of wrought iron is drilled, countersunk, bent and slotted for the introduction of a flat taper key straight on one face.

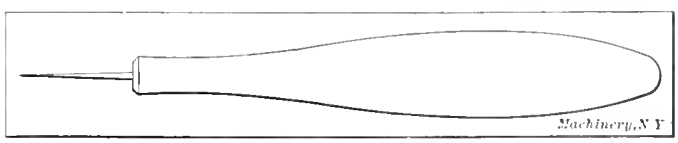


With several holes in the top of the stirrup, screws of a great variety of sizes may be held with great rigidity while being operated on, without marring them.

Holyoke, Mass. HARRY BAILEY

HANDY TOOL FOR DRAFTSMEN

A convenient tool for draftsmen's use is shown in the accompanying sketch. It is simply a burnisher made from a toothbrush handle. One end is finished with a file and fitted with a needle point, thus making a fine punch for close accurate lay-outs. The original shape of the toothbrush handle is such that the tool will not roll off the drawing-board when



it is laid aside. Any part of the handle may be used as a burnisher to polish the drawing paper after erasing part of a sketch. It is often necessary to do considerable erasing in a certain part of the drawing, and then the work does not look neat and gets soiled easily. In such cases, the paper may be given a smooth clean polish with this burnisher, which will not leave a mark on the paper or soil it.

JIG AND TOOL DESIGNER

HOW AND WHY

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details and name and address. The latter are for our own convenience and will not be published

BELTING ON PULLEYS WITH AXES AT AN ANGLE

C. J. N.—How can the belt be kept on the pulley steps on the line-shaft and on the machine in the following case? A line-shaft has a three-step cone-pulley over which a belt runs on another three-step cone-pulley on a hand screw machine. The machine is not directly under the line-shaft, but about two feet in front of it. Furthermore, it is not in line with the line-shaft, but makes an angle of about ten degrees with it. I have had trouble keeping a belt on the pulleys, and would like to know how to do it without the use of idlers, and without changing the relative position of the machine with the line-shaft.

A.—The first suggestion in reply to this question would be to provide the steps of both cone-pulleys with considerable crown. The crowning would tend to keep the belt in position on the cone-pulley steps, provided the center distance between the cone-pulleys is reasonably large and the belt not too wide. The usual rule for setting pulleys which are at an angle, which was given in the May, 1909, issue of MACHINERY in the "How and Why" department, does not, of course, apply to three-step cone-pulleys, as it is impossible to set more than the middle steps in accordance with those directions; and even this rule is applicable only when the drive is in one direction. In the case of a hand screw machine, the spindle would be reversed, so that if the machine were directly beneath the line-shaft, it would be necessary to set the middle step of the cone-pulley on the machine directly beneath the middle step of the cone-pulley on the line-shaft. In this way when the center distance between the cone-pulleys is not too short, placing the belt on the outside steps on either side of the middle steps would not be likely to cause any trouble. When the machine is moved in relation to the line-shaft either forward or backward, if the same relationship between the pulleys is maintained as that which exists when one cone-pulley is directly beneath the other, the belts should run as well on the pulleys in this case as in the former. In order to maintain this relationship, however, the machine would have to be tipped at a slight angle, that end of the machine being elevated, which is further away from the line-shaft after the machine has been moved. To illustrate this and also to find the means for calculating the amount that the machine would have to be tipped from the horizontal plane, the accompanying diagram has been drawn. In the upper part of the diagram, line KL is the center line of the line-shaft and line AB indicates the axis of the machine when its cone-pulley is placed directly beneath a cone-pulley on the line-shaft. In the lower part of the diagram is shown an elevation where H is the line-shaft, and CD the projection of the axis AB of the machine. Now, when we move the machine in front of the line-shaft, in order to maintain the same relation between the pulley on the machine and the pulley on the line-shaft, we must conceive of the lower cone and shaft as swung like a pendulum to a position in front of the line-shaft so that line HM occupies the position HN. This, however, will throw the axis of the machine at an angle with the horizontal plane, the angle being such that the line CD will occupy the position EF. To calculate the amount that the tailstock end would have to be raised in this case, assume that α is the angle which the axis of the machine makes with the axis of the line-shaft. In the diagram this angle is shown exaggerated, in order to more plainly illustrate the principle involved. Let b be the distance between the line-shaft and the center of the cone-pulleys on the machine, a the distance which the machine is moved forward in relation to the line-shaft, and l the length of the bed of the machine.

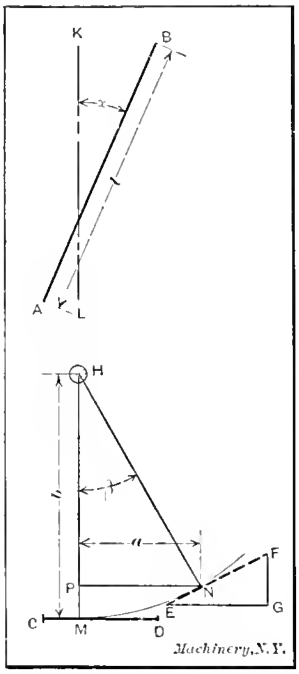


Diagram for Belt Problem

Now the length CD or the projected length of the bed of the machine equals $l \times \sin\alpha$. Further $\sin\beta = \frac{a}{b}$.

Line FE, of course, equals line CD, both being projections of the length of the machine bed on the same plane. Thus $FE = l \times \sin\alpha$. Line FG indicates the amount that the tailstock end of the machine should be raised relative to the headstock end in order to preserve the relative position of the cone-pulleys. Angle $FEG = \beta$.

$$\text{Hence, } FG = FE \times \sin\beta = l \times \sin\alpha \times \frac{a}{b} = \frac{a \times l \times \sin\alpha}{b}$$

Hence, if the distance between the line-shaft and the pulley on the machine, the distance that the machine is moved in front of the line-shaft, the length of the machine bed, and the angle between the axis of the machine and the line-shaft, are known, the formula above gives us the amount to raise one end of the machine to preserve the relationship between the cone-pulleys. If the belt runs properly when the machine is set directly beneath the line-shaft, it should run as satisfactorily when the machine is set in the manner described in front of the line-shaft.

As an example, assume that $a = 2$ feet, $b = 8$ feet, $l = 6$ feet, and $\alpha = 10$ degrees. Then:

$$FG = \frac{2 \times 6 \times \sin 10^\circ}{8} = 1.5 \times \sin 10^\circ = 0.261 \text{ foot, or}$$

$0.261 \times 12 = 3\frac{1}{8}$ inches, about. This is the amount that, in this case, the tailstock end of the machine should be elevated above the headstock end.

* * *

NEW GERMAN TARIFF RATES ON MACHINERY

According to the new agreement between Germany and the United States, American metal and wood-working machinery may be imported into Germany at a considerably lower rate of duty than heretofore. Instead of the general or maximum rate being imposed, the minimum rates will apply. The old rate of duty on machines or tools weighing 550 pounds (250 kilograms) or less, was \$4.76 (20 marks) per each 220 pounds (100 kilograms). The new rate is \$2.86 (12 marks). For weights over 550 pounds, and up to 2,200 pounds the old rate was \$2.86 (12 marks) per 220 pounds. The new rate is \$1.91 (8 marks). When over 2,200 pounds, up to 6,600 pounds, the old rate per 220 pounds was \$1.91 (8 marks), and the new rate is \$1.43 (6 marks). For weights between 6,600 and 22,000 pounds the old rate was \$1.43, while the new rate is \$1.19. For machinery heavier than 22,000 pounds the old rate of \$0.95 per 220 pounds is unchanged.

* * *

The Swedish Institution *Järnkontoret*, representing the Association of Swedish Iron Manufacturers, has decided to build an electric blast furnace at Trollhättan for experimental purposes. An electric blast furnace has been in use for some time at Grängesberg in Sweden, but the efficiency of this furnace with electricity generated by a hydro-electric plant has so far reached only 58 per cent, while in the ordinary blast furnace the efficiency can be raised to 80 per cent. It is expected, however, that the new furnace will materially reduce the loss through various alterations in the construction. Should the experimental working prove successful, a considerable portion of the water power owned by the government in the northern part of the country, in the vicinity of the large iron deposits, might be exploited in the production of pig iron by the electric process. As a matter of fact, the possibilities of developing a large iron industry in the northern part of Sweden is entirely dependent upon the success of the electric process, as this eliminates the coal otherwise required.

NEW MACHINERY AND TOOLS

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP

LE BLOND HEAVY DUTY MANUFACTURING LATHE

In the September, 1909, number of MACHINERY, we illustrated and described a heavy duty engine lathe, designed and built on original lines by the R. K. Le Blond Machine Tool Co., 4609 Eastern Ave., Cincinnati, O. We herewith illustrate a further modification of this design of lathe, especially adapted to manufacturing operations. The special features in this case are a geared headstock of unusually direct and durable construction, and a multiple stop arrangement for both cross and longitudinal feeds. The accompanying engravings illustrate these mechanisms very clearly.

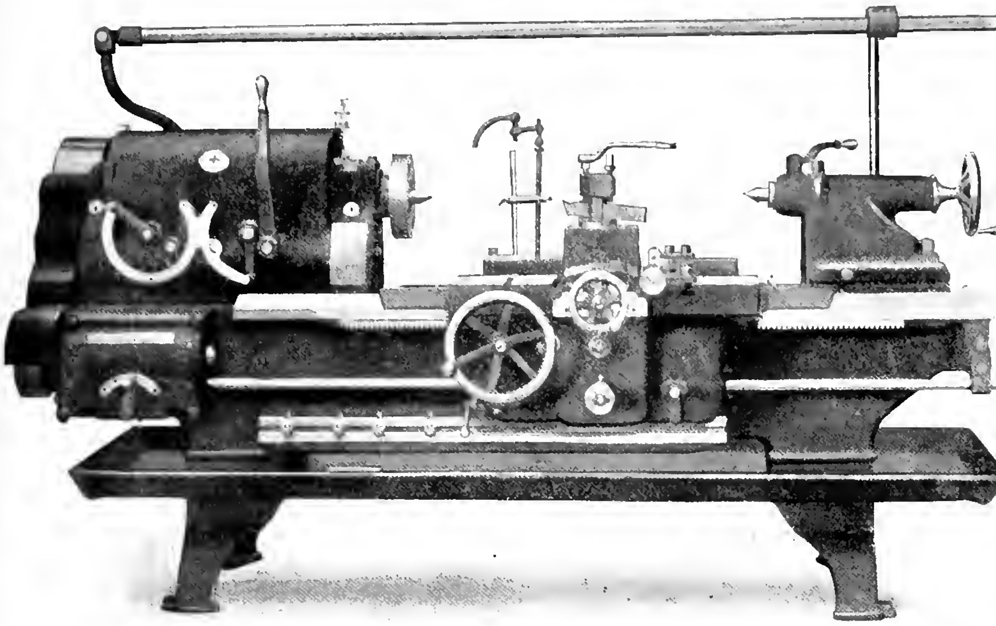

Fig. 1. The LeBlond Heavy Duty Lathe, with Geared Head and Multiple Cross and Longitudinal Stops

Fig. 1 shows a general view of a 21-inch lathe of this type, fitted with oil pan, pump, plain rest and plain geared feed. The ruggedness of the machine is plainly shown. The convenience of the hand levers for controlling the speeds and feeds, and the complete guarding of the gear mechanism, should also be noted. Fig. 2 shows an end view of the headstock, while Fig. 3 is from a photograph taken looking directly down into the mechanism, with the cover removed. This latter engraving shows the drive to the best advantage.

Driving pulley *A* runs at constant speed, and may be directly belted to the countershaft if desired, as it is connected with the driving shaft through a powerful friction clutch. This is controlled by lever *B*, and operated by the shifting rod shown extending over the machine in Figs. 1 and 2, an arrangement which has become deservedly popular for geared head lathes. This clutch for connecting and disconnecting the driving pulley *A*, is also provided with a brake mechanism which goes into operation when the power is thrown off, thus bringing the lathe spindle instantly to a stop and avoiding loss of time in taking measurements or changing work.

Gears *D* and *E* on shaft *C* are mounted on a sleeve, which may be shifted longitudinally so that *D* meshes with gear *H*, or *E* with gear *F* as shown in Fig. 3. *F* and *H* are keyed to intermediate shaft *G*, which carries a second sliding sleeve on which gears *M*, *N* and *O* are mounted. This sleeve may be shifted to three positions, so that *M* may engage with gear *P* as in the case shown, *N* with *S*, or *O* with *T*. Gears *P*, *S* and *T*, as well as *Z*, are mounted on a third sleeve which revolves loosely on the spindle *R* of the lathe, but has no end movement. Gear *Z* is connected under the spindle through back-gearing with main driving gear *Y*, one back gear being shown at *Q*. The spindle may be clutched to either *T* or *Y* by means of clutch *X*, which furnishes a friction back-gear control.

These combinations, it will be seen, give twelve changes of speed—two by the shifting of *D* and *E*, multiplied to six by the shifting of *M*, *N* and *O*, and again doubled to make twelve by the operation of the back gears. The controlling levers for these twelve changes are shown at *U*, *K* and *W*. Lever *U*, through the operation of segment gears and rockshaft *V* shifts *M*, *N* and *O*; lever *K*, also through segment gears and rockshaft *L*, shifts *D* and *E*; while lever *W* controls the friction back-gear clutch at *X*.

The headstock casting itself will be seen to be of closed box construction, braced with cross-ribs. It forms a reservoir for a bath of oil in which the gears run constantly, with obvious advantages in the way of reduction of wear. Oil gages are provided for determining the height of the oil. The makers call attention to the simplicity and durability of this geared head. The changes are all made through sliding gears, and the drive in every case is in straight lines. The number of parts has been reduced to a minimum. The twelve speed changes are carefully calculated, and cover the proper range for which each size of lathe is designed. Each gear is made of the material suited to its peculiar requirements, and in no case are two soft steel gears run together. The sliding gears have rounded teeth, permitting easy engagement.

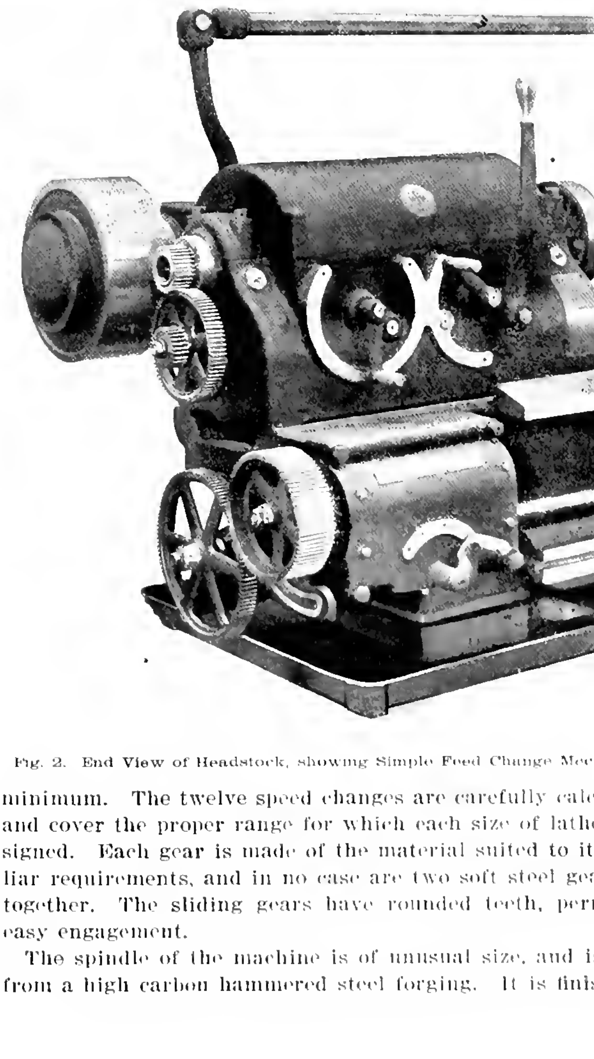

Fig. 2. End View of Headstock, showing Simple Feed Change Mechanism

The spindle of the machine is of unusual size, and is made from a high carbon hammered steel forging. It is finished to

size by grinding, great care being taken to bring it close to standard gage. The front spindle bearing is hardened and ground, and runs in a cast-iron box of special close-grained material. The particular design is somewhat expensive, but has been found to give the best results under severe strains at high speeds—these being the conditions under which the lathe is expected to operate when using tools of modern steels. This combination of materials for the main bearings should not be confused with the more common combination of soft steel spindles running on cast iron. The bearing is lubricated by generous oil wells, through felt pads which filter the oil and supply it slowly but continuously to the wearing surfaces.

Besides the provision of a quickly changed, powerful and simple drive, as just described, the machine has been specially adapted to manufacturing by the provision of an elaborate but simple system of stops, for both cross and longitudinal feeds. The cross-feed stops are of the positive type and are best seen in Fig. 4. A four-faced stop bar is used, as shown, extending across the carriage from front to back. On each face of this stop bar is adjustably mounted a stop, as shown; these stops may be set to give different depths of cut for different diameters. The bar is rotated to bring one stop after another in line with the abutment on the tool-slide, by means of the knurled handle shown at the front. The stop-bar could doubtless be provided with more than four faces, if required for complicated work.

The longitudinal stops, as shown best in Fig. 1, are adjustably mounted in a T-slot in a long cast-iron bracket, rigidly mounted on the bed. When the trip lever on the apron strikes one of these longitudinal stop dogs, a square tooth clutch on the feed drive of the apron is disengaged, thus stopping the feed. Raising the trip lever, re-engages the clutch and the feed is automatically thrown back into action again, until the next stop is reached. This operation may be repeated as many times as there are shoulders on the work at hand. These rigidly-mounted dogs also form positive stops, permitting the duplication of shoulder distances with great accuracy. The

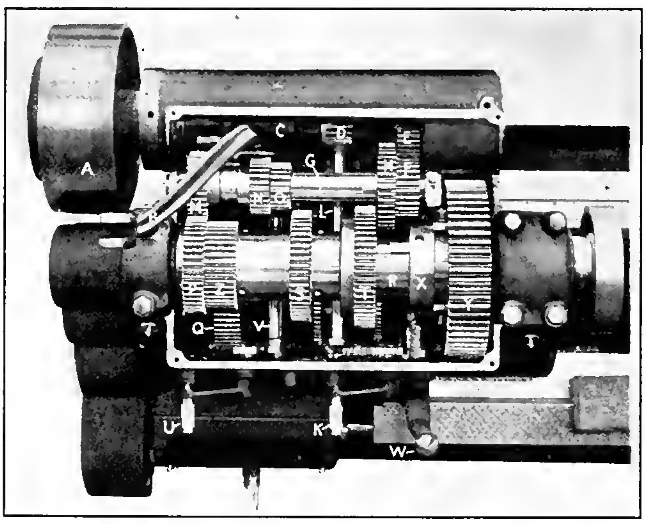

Fig 3. Top View of Headstock with Cover Removed, showing Speed Change Connections

trip lever is of such shape that it rides over the dogs when the carriage is being returned, making it unnecessary for the operator to give the mechanism any further attention.

The usefulness of this combination of cross and longitudinal stops will be readily appreciated. With four dogs for each movement it is possible, for instance, to rough out with a single tool a lot of similar pieces, each of which has four different shoulders to be turned to the proper diameter and length of cut. The tool is set to the diameter indicated by the first cross-slide stop, is fed up to the first longitudinal dog, and stops. The tool is drawn back, the cross feed stop bar is turned, and the tool is fed down to the second stop for the second diameter. The feed lever on the apron is raised, allowing the carriage to feed forward to the next longitudinal stop and so on. Overhanging parts are avoided, so that diameters can be duplicated with great surety. The whole construction is very rigid. The mechanisms are simple in construction, and when not required, can be quickly set so that they do not interfere in any way with the movements of the lathe. These features should be appreciated in manufacturing work.

The other improvements in this design of lathe were described in connection with the article of September, 1909. They included a novel design of ways, intended to give the advantages offered by both the English and American types; a double-walled apron; and an improved quick-change gear-feed device, which will also be furnished with these manufacturer's lathes if desired. The arrangement shown provides eight changes of feed, ranging from 0.0045 to 0.100 inch per revolution of the spindle. Of these, four changes are obtained by gearing in the feed-box, while a further fast and slow change

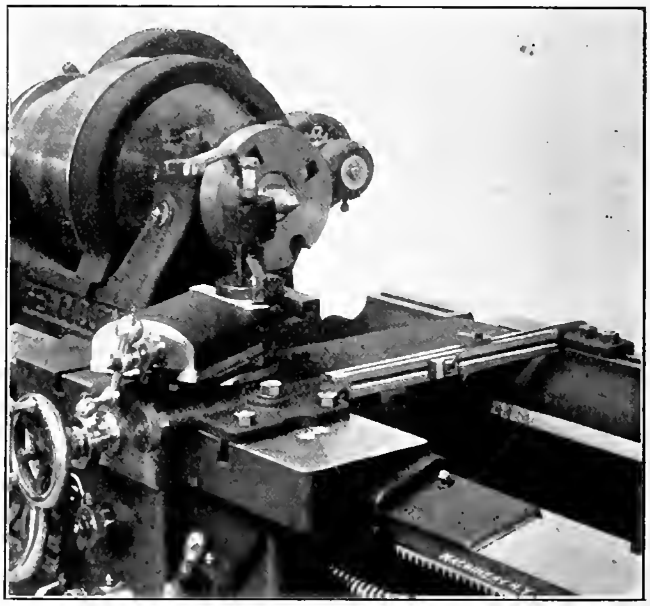

Fig. 4. Multiple Cross Feed Stops mounted on Carriaga

is given by shifting the intermediate gear shown in Fig. 2, from the large gear to the pinion shown on the headstock stud.

In connection with this design, it will also be remembered that the headstock is set two inches back of the center line of the bed, making it possible to turn the full swing of the lathe without any overhang of the tools beyond the ways. The stiff construction of the tailstock, as well as of the other structural members of the machine should also be noticed.

This manufacturer's lathe is built in seven sizes, 17, 19, 21, 25, 27, 30 and 33 inches swing, respectively. It should be especially useful for the duplication of shafts and other work having one or more shoulders.

IMPROVED TABLE SUPPORT AND FEED FOR QUEEN CITY SHAPERS

In Fig. 1 is shown an example of the line of shapers made by the Queen City Machine Tool Co., Cincinnati, O. This design incorporates two improvements which are plainly shown in the engraving. One of these is outboard support for the table, which controls the table rigidly, yet permits it to feed with the utmost freedom even when the base of the machine is distorted in clamping to the floor. The other improvement relates to the feed, and provides unusual conveniences in the matter of the making of changes in rate and direction while the machine is in operation.

The outer edge of the table is supported, as shown, by a projecting lip, which bears in a horizontal gibbed slide, vertically adjustable on the standard bolted to the base. This vertical adjustment covers the full vertical movement of the table, so that the support may be used at all times. The slide is provided with a gib, so that the bearing of the table will be at all times closely controlled, and yet be free to feed horizontally. Owing to the length of the slide the bearing surface on the lip is at all times protected from chips, giving a durable surface which does not require to be constantly cleaned. This length of slide also furnishes full support at extreme adjustment in either direction.

The same wrench that loosens the straps for binding the cross-rail to the face of the column, loosens the slide support in the standard at the front of the table, allowing the slide to move freely with the vertical adjustment. Since only two screws are used for the clamping of the slide to the bracket, this adjustment is self-aligning. Even though the base of the machine may be badly twisted out of shape from being clamped down unevenly, the slide will always be true with the lip on the edge of the table, as its alignment is determined entirely by that lip.

The improved feed is shown in a close on view in Fig. 2, and in detail in Fig. 3. The cross-rail is at A and the cross-feed screw at B. This latter is connected by gearing, as shown, with sleeve F, which revolves loosely on stud C. The power feed, is received from the crankshaft by a mechanism which operates in the usual manner, on ratchet-wheel D. One of the points of improvement is the provision of a friction washer E between D and the collar on F, to permit this ratchet to slip on the sleeve whenever excessive resistance is met with in the feeding of the table on the cross-rail. This makes the feed fool-proof, providing enough power for legitimate purposes, but not enough to break any of the parts in case the workman feeds during the cut or allows the saddle nut to strike against the rail at either end. It is preferable

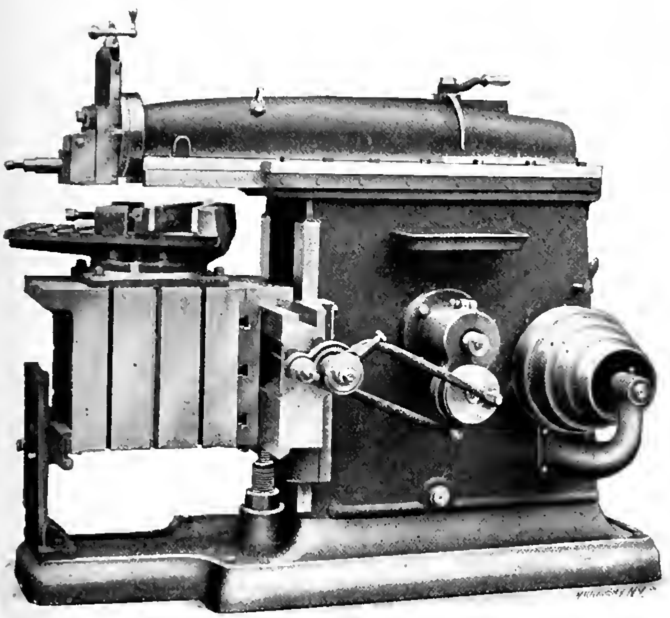

Fig. 1. A Shaper with Self-aligning Outward Support for Table, and Quick-change Feed Mechanism

to the design in which the friction is placed on the feed rod itself, because it is not affected by the vertical adjustment of the rail, and is entirely automatic.

The control of the feed change is unusual. In place of the regulation slotted adjustable crank disk, a simple revolving plate is used, shown at M, which is geared with the main shaft O of the shaper. This is mounted in a swinging case which is connected with the cross-rail by distance rod H, so that the mechanism is unaffected by the vertical adjustment of the work-table. Feed-rod K is pivoted to the revolving plate M, by a latch whose lever is shown at L. By raising this latch the pin is withdrawn from the hole in revolving disk M, though it is still supported by a loose outer cover disk mounted on the same center. The continuous revolution of M brings a second pivot hole N under the latch, which then drops in. This evidently causes the feed to take place on the opposite end of the stroke. Thus, whenever it is desired to change the time of feeding from one end of the stroke to the other, the latch L is quickly pressed and released, when the pin will automatically change its position from one side of the disk M to the other, producing the desired effect.

Feed-rod K, as shown, operates a swinging arm carrying latch J, which may be turned to face in one direction or the other, depending on which direction it is desired to feed the table. A new method of varying the rate of feed is employed. Instead of doing this by varying the arc through which latch J swings, the movement of this part remains unchanged, but it is allowed to pick up more or less teeth of the ratchet through the action of cam G. This is cut away for part of its length, as shown, to permit the latch to engage with the ratchet. It may be so adjusted, however, that it will raise the latch for a less or greater number of teeth, or indeed for the entire portion of the stroke, through the action of its cam surfaces on the pin shown projecting from the side of the latch, and most plainly seen in Fig. 2. Thus,

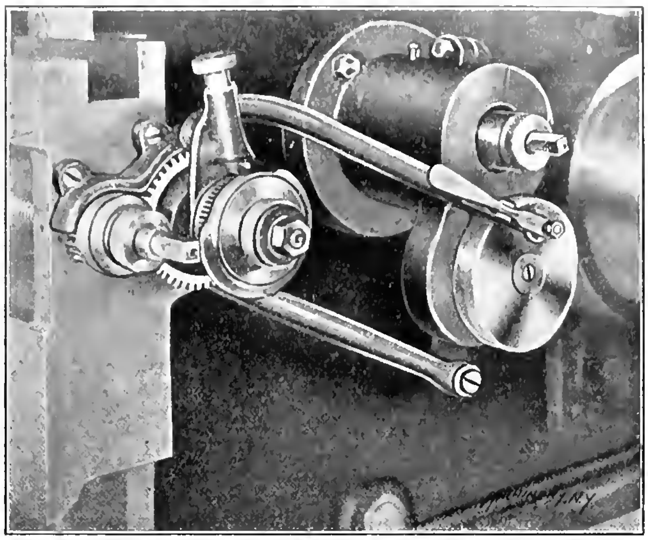

Fig. 2. Near View of Feed Mechanism

by adjusting this cam to different angular positions, it is possible to have from 1 to 16 teeth of movement at each stroke of the ram. When adjusted, it may be locked by means of the nut shown.

This teed mechanism gives 16 changes, varying from 1/64 to ¼ inch stroke on the 24-inch machine, which is here shown. Thus from zero to full feed or reverse, or to and from any number of notches in either direction, can be made instantly

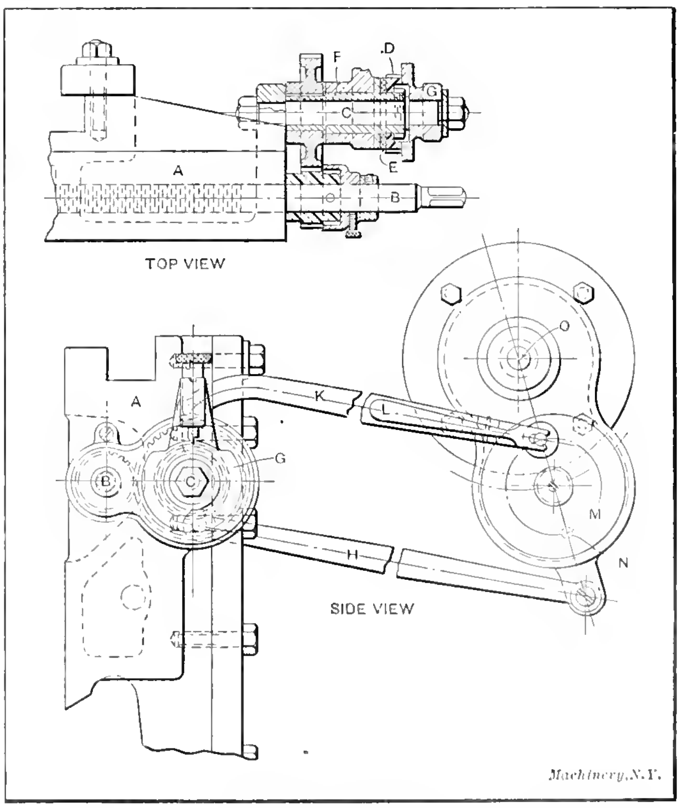

Fig. 3. Details of Arrangement for quickly altering Rate, Direction and Time of Feeding

and with precision while the machine is running. It is the makers' statement that changes can be made on the average in one-fifth of the time required with the ordinary design of feed change, without the danger to the fingers often met with in using the slotted disk arrangement

BEAMAN & SMITH VERTICAL TWO-SPINDLE CYLINDER BORING MACHINE

The accompanying illustrations show a two-spindle vertical boring machine built by the Beaman & Smith Co., of Providence, R. I. It is designed particularly for boring automobile cylinders and is provided with special facilities for

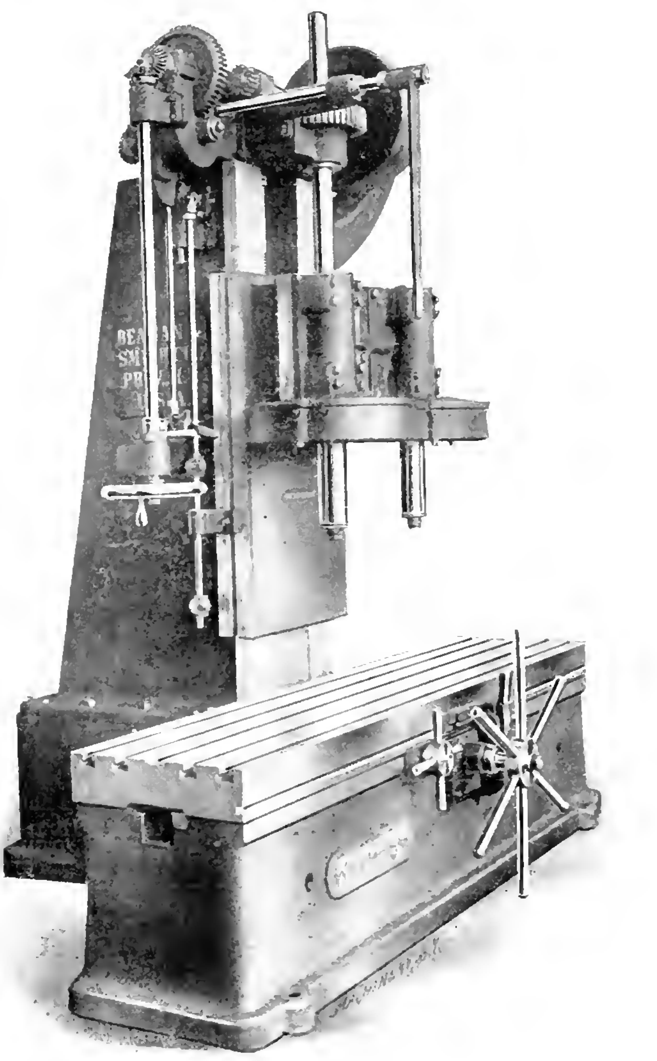

Fig. 1. A Vertical Boring Machine, having a Novel and Effective Spindle Construction

that work, though it will, of course, prove useful for similar operations on other work.

An examination of Fig. 1 gives the impression of simplicity, rigidity and convenience of arrangement; but in addition to these features there are certain important improvements which do not appear on casual examination. One of these is the table adjustment, which facilitates the setting up of the work at one end of the table while the boring is in progress at the other. It also furnishes means for shifting the table to either of two positions at each end, as it is intended that two cylinders of a block of four shall be bored at a time, whether those four be in a single casting or in two double castings. The convenience of the automatic feed and the power quick return, each of which is provided with automatic stop, should also be noted. Special attention is called, however, to the construction of the spindle and the spindle drive, which is entirely new so far as we know. This improved design gives promise of unusual effectiveness in the work for which it is intended.

First, as to the general construction of the machine: The base is of T-shape with long ways in front, along which the work table is adjusted to bring the work into position under the spindle. To the rear extension of the base is bolted a heavy column, on the face of which the double spindle-head is gibbed for its vertical feed. This head has the spindles set to a fixed center distance, but changes in this center distance could doubtless be made, if required, without radical alterations in the rest of the machine. Such a change, of course, would only need to be made for more than two cylinders cast *en bloc*. For single or double cylinder castings, the work itself is adjusted on the table.

In regard to the construction of the spindle head and spindle, it will be seen, first, that a principle used on all similar machines of the same make has been followed—namely, that of extending the sliding surfaces of the head forward (or downward in the case of a vertical machine like this) to or beyond the cutting edges on the spindle. We have referred to this previously; see, for instance, the description of the duplex horizontal boring machine in the October, 1908, number of MACHINERY. This arrangement gives a stiffness of support to the cutting edges which would otherwise be impossible. To express it in colloquial language, the cutting edges have no "leverage" on the slide, and the freedom necessary for the oil between the sliding surfaces is not multiplied so as to permit destructive vibration at the tool point. The cutting edges have a support on the face of the column directly in back of them on a vertical machine, or directly under them on a horizontal machine. This also avoids excessive wear at the forward end of the slide.

This same idea of directness of support has been still further carried out in this machine in an important improvement clearly shown in Fig. 2. Instead of having the spindle solid, revolving in bearings in the sliding head, it is made in the form of a hollow sleeve as shown at *A*, provided with bronze liners *BB*, and revolving on a stationary spindle stud *C*, which is firmly clamped into the bearing head as shown in Fig. 1.

The spindle sleeve *A* is held from dropping off by its attachment to driving gear *D*. This latter is supported by a ball thrust bearing *E*, resting on the shield or gear guard *F*, seen also in Fig. 1. The thrust of the cut is taken directly between the nose of the spindle *H* and the end of stud *C*, through the ball bearing *G*. Adjustment for removing the end play is made by drawing up gear guard *F* by screws provided for the purpose as shown in Fig. 3. This raises driving gear *D* and with it spindle sleeve *A*, leaving the proper

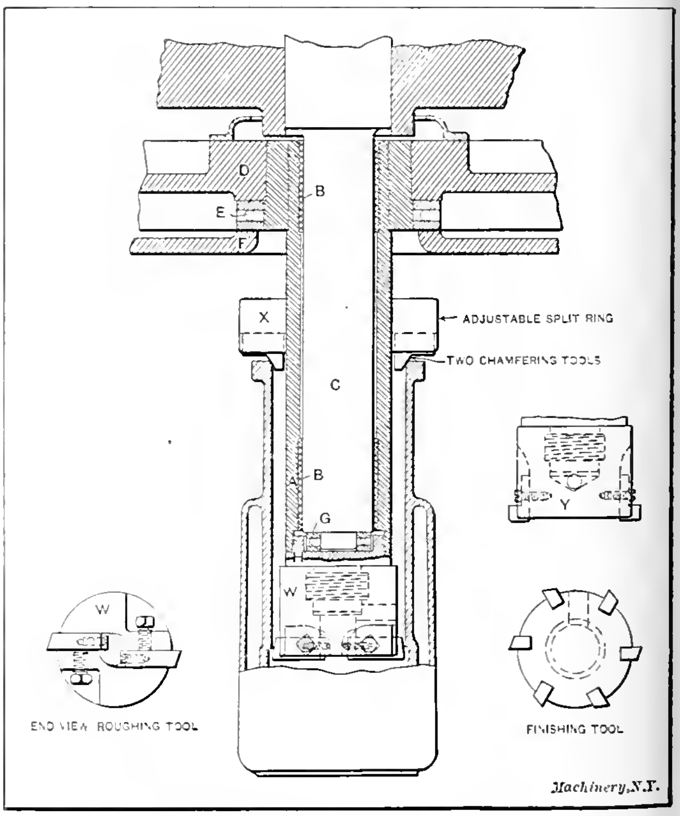

Fig. 2. Sectional View of Spindle Sleeve on Stationary Stem; also shows Cutter Heads used for Cylinder Boring

amount of play for thrust bearing *G*. The two spindles have each their separate driving gears *D*, and are each driven from the same pinion on the lower end of shaft *J*, which is connected by the gearing shown, with the three-step driving cone *K*.

The advantages of this spindle design, for which patent is pending, are obvious. It permits boring with an overhanging spindle which has no overhang to speak paradoxically. By making it in the form of a sleeve, and giving it an internal bearing, this bearing is brought close up to the cutting point, so that the necessary freedom for lubrication is not multiplied at the cutting point, thus carrying out the advantages of the extended slide construction previously described. It would be difficult to imagine a more satisfactory construction for work of this kind. It should also be noted

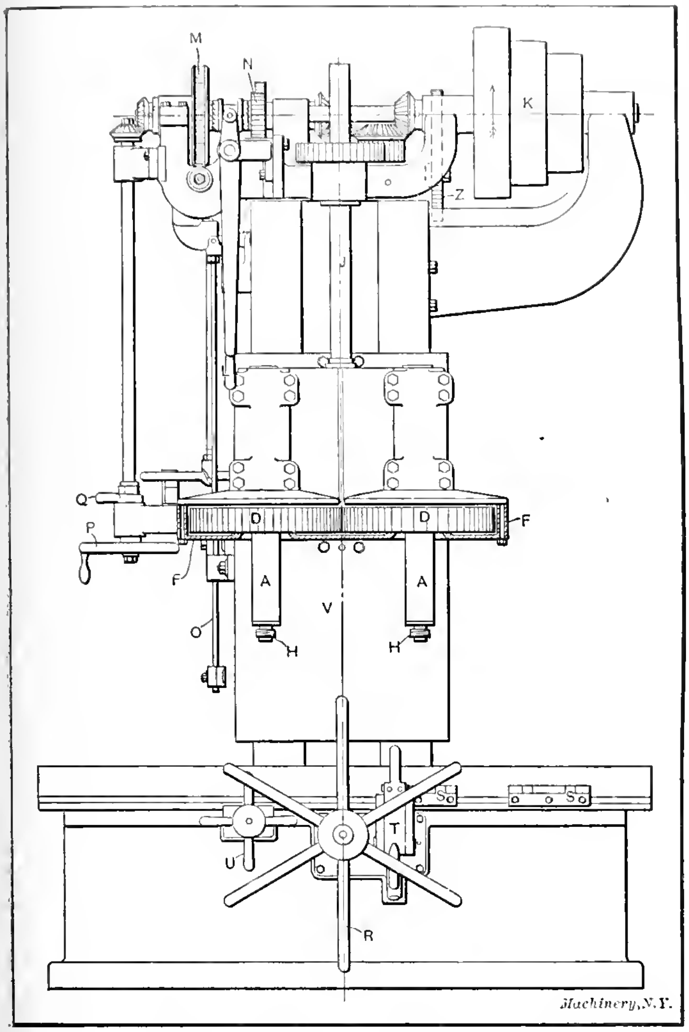

Fig. 3. Front Elevation, showing Feed and Drive Connections, and Arrangement of Table Setting for Changing Work while Machine is in Operation

that the arrangement permits the use of driving gears of large diameter, connected with the spindle close up to the work, so that the power is led to the cutting point by the most rigid and direct means.

As stated, power down feed and power quick return for the spindle head are provided. These movements are controlled by lever *L* (see Fig. 3), which operates a clutch connecting either slow feed worm-wheel *M* or rapid traverse gear *N* with the feed screw driving shaft. Rod *O* is provided with dogs operating automatic stops for both the upward and downward movements. Handwheel *P* may be thrown in or out of engagement by means of lever *Q* for giving a fine hand movement for facing, etc. Thirteen changes of speed are provided, controlled by a change gear box not plainly shown in any of the engravings. The boring head is counterbalanced, making hand and power manipulation easy.

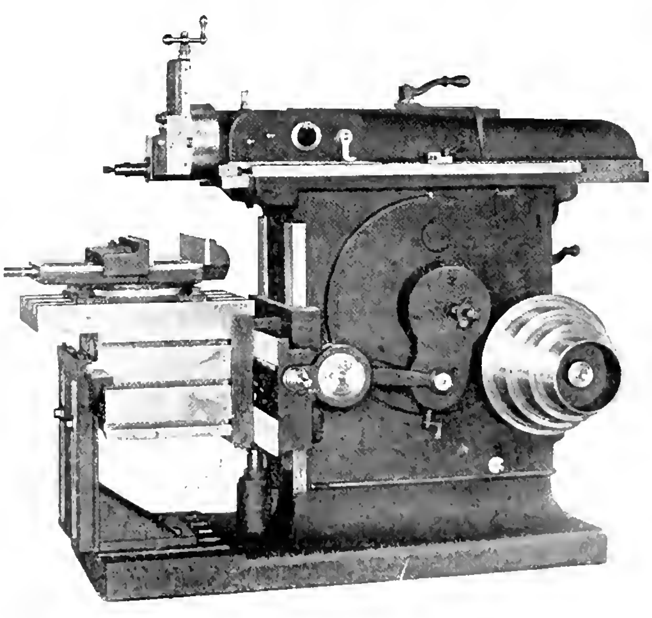
The work-table is shifted to different positions along the bed by the large pilot wheel *R*, which operates a rack and pinion movement. The various positions for lining up the boring spindles with the work are located by templets *SS*, having slots which fit a tongue on latch *T*. By this means, as explained, the table is shifted and located when moving from one pair of a set of four cylinders to the other, or when shifting the table for nearly its full length in moving from a complete set of cylinders to one newly clamped in place. These arrangements permit the changes to be made accurately without measuring, thus reducing the idle period of the machine to a minimum, keeping it constantly employed in actual cutting. Small pilot wheel *U* operates a clamp for locking the table, when it has been located by the pilot wheel and latch.

Fig. 2, besides showing the construction of the spindle, illustrates the style of tools used and the order of operations. The roughing tool is shown in two views at *WW*, mounted in place in the spindle and in an end view. It will be seen to have two boring blades held in place by set-screws, and provided with adjustable abutment screws at the back for setting them out to the right diameter. The head in which they are held is screwed onto the end of the spindle nose *H*, on a 1½-inch lead, triple, right-hand U. S. standard thread, and is provided with a hole for inserting a bar to permit its ready removal in changing tools. On the exterior of sleeve *A* is clamped the split ring *X* (which may be adjusted to any required position on the sleeve), which carries blades for chamfering the outer end of the cylinder as shown. Finishing head *Y* carries six inserted blades held in place by screws and mounted in a body similar to that provided for tool *W*, and held on spindle *H* by the same means.

The work table is 20 inches wide and 6 feet long. The spindles will be spaced to any distance required for special work, and the improved construction readily allows the spindles and spindle studs to be made of a size which will best suit the work in hand.

TWENTY-FOUR INCH STOCKBRIDGE SHAPER

The accompanying half-tone illustration shows a new design of the 24-inch shaper built by the Stockbridge Machine Co., Worcester, Mass. In general, the previous designs of the Stockbridge shapers have been followed, but some important changes have been made in the construction, with an idea of making the machine simpler and stronger, and thus increasing the capacity of the machine. The new shaper is more powerful than the previous designs, which can be judged from the back-gear ratio, which is 30 to 1. Although intended for high duty, the high standard of accuracy of former designs has not been sacrificed, but this feature is combined with that of increased power. The most important improvements are described in detail in the following.



Twenty-four Inch Shaper built by the Stockbridge Machine Co., Worcester, Mass

In previous designs a taper packing was used to take up the wear of the side thrust of the ram, but in the new design a solid gib is used. This gib is bolted to the column. It presents a solid working face for taking the side pressure of the ram when taking a cut, any wear of the gib being taken up by adjusting screws so arranged that they do not interfere with the gib being solidly bolted to the column.

The cross-feed mechanism has been simplified and strengthened. The feed rod is automatically adjusted to any position

of the bar, and without changing its position, the table can be fed in either direction and can be automatically stopped at either end of the required feed.

The method of supporting the driving cone gives exceptional rigidity. The cone is carried on a sleeve which is supported by a large self-oiling bearing, which takes the strain of the driving cone off the driving shaft, and permits the use of a very large bearing. This, in connection with the self-oiling feature, eliminates the probability of the box becoming heated, and the consequent troubles arising.

The direct drive is in the ratio of 6 to 1, and with the back-gears in, the ratio is 30 to 1, as mentioned. The cone drive provides for eight changes of speed to the ram, and the range in strokes obtainable is from 8 to 90 per minute. The change gears are all made of steel, and the driving shafts are carried through on both sides of the machine, having a bearing at both ends. If a gear-box and single-pulley drive is preferred instead of the cone drive shown on the machine illustrated, it can be supplied and attached without difficulty, the parts being interchangeable. In common with all the shapers built by the Stockbridge Machine Co. the machine is equipped with the company's patented two-piece crank motion, which provides for a uniform cutting speed the entire length of the cut, as well as a quick return motion.

Some of the principal dimensions of the new 24-inch shaper are as follows: maximum length of stroke, 24¾ inches; vertical traverse of table, 15 inches; horizontal traverse of table, 30 inches; size of top of table, 16 × 24 inches; length of ram bearing in column, 36 inches; width of ram bearing in column, 12 inches. The countershaft for the machine runs at 300 revolutions per minute, the floor space required is 102 × 52 inches, and the net weight 4400 pounds.

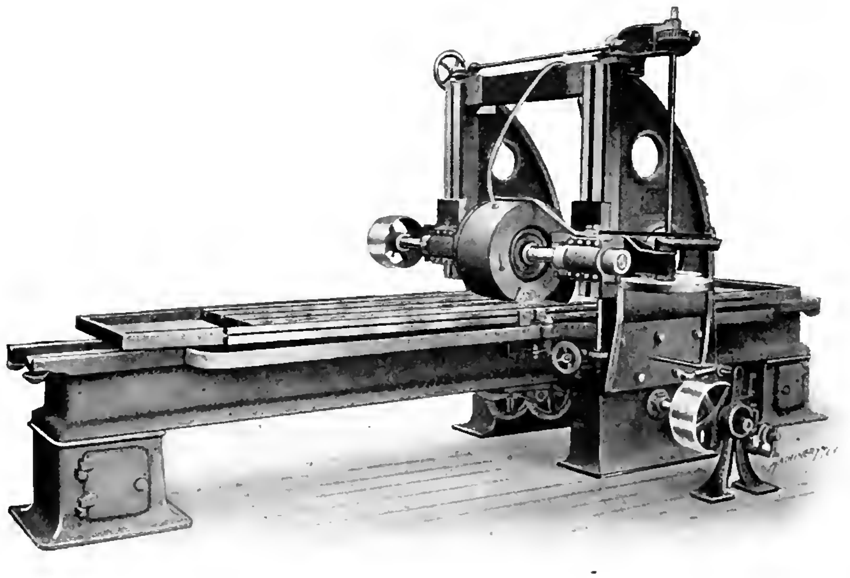


Fig. 1. Oscillating Surface Grinder for Rapid Reduction

TWO STYLES OF SPRINGFIELD SURFACE GRINDERS

The engravings illustrate two new designs of surface grinders, of styles that have been built for some time by the maker (the Springfield Mfg. Co., Bridgeport, Conn.), but which have recently been re-designed throughout to bring them in line with modern requirements for surface work with the emery wheel. The first of these, shown in Fig. 1, is of the "oscillating" type. The second is a motor-driven machine built on the lines of the standard metal planer.

The oscillating surface grinder is the No. 3 automatic size, having a reversing mechanism and other parts similar to the metal planer, with table driven by rack and gearing. It is also made with a screw driven table if the customer prefers. The oscillating feature of the machine will be readily understood from Fig. 1. The wheel, which is 20 inches in diameter by 12 inches wide, is carried on a large and substantial spindle, mounted in two phosphor-lined boxes which oscillate in slides mounted on the cross rail. The oscillation is continuous, and is effected by the crank shown, which receives its power through worm gearing from a shaft on the upright, belted to the countershaft. The crank is slotted so that the width of oscillation can be adjusted to suit the width of work. It will be seen that, as the work table reciprocates back and forth under the wheel, the latter is moved back and forth over the work, cutting a zig-zag path. As the work continues to reciprocate, these zig-zag paths overlap, covering the entire surface in a manner which removes the stock at a very rapid rate. The down feed is effected by a hand-wheel.

The machine is arranged to take care satisfactorily of the cooling compound used for such work. This compound is supplied by a centrifugal pump, shown on the floor in the rear of the driving pulley. Guards, return spouts, settling tanks, etc., are provided, as required. This machine grinds up to 24 inches wide, 18 inches high and 10 feet long. In the particular machine shown the height is special. The standard height takes but 9 inches under the wheel, but will be made to grind a width of from 15 to 30 inches and a length of from 4 to 12 feet.

The motor driven grinder shown in Fig. 2 is known by the makers as the No. 2 automatic planer surfacer. This machine, as may be seen, has the original feature of being entirely self-contained. The motor for driving the wheel is mounted directly above it on the saddle. Proper mechanical means are provided for keeping the belt under suitable working tension. The motor on top of the uprights drives the platen and feeds. This machine also is neatly arranged to take care of the cooling compound, having a centrifugal pump operated from the lower driving shaft. The water supply tube leads directly into the wheel case, so that it is used effectively and without splashing.

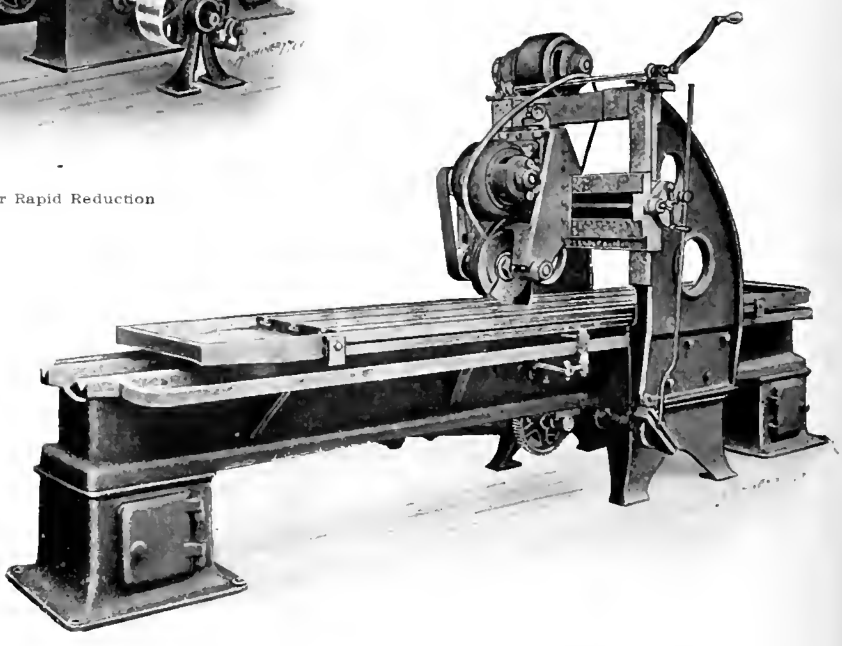

Fig. 2. Plain Type Surface Grinder with Self-contained Motor Drive

This machine, in the size shown, has a capacity for grinding work 8 feet long and 24 inches wide. It is also made in various other lengths, ranging as may be required from 4 to 12 feet. The motor driving the wheel is of 3 horsepower capacity, while that for operating the table mechanism is 2½ horsepower. Both are wired, in the case shown, for 230 volts. The emery wheel is 12 inches diameter, 2 inches face, and has a 2-inch hole.

WATSON-STILLMAN HYDRAULIC BENDING MACHINES

Two new hydraulic bending machines especially adapted for the bending of large pipe, structural sections, automobile parts, etc., have recently been brought out by the Watson-Stillman Co., 192 Fulton St., New York.

The smaller machine, shown in Fig. 1, is capable of exerting a power of 25 tons with a hydraulic operating pressure of 2,200 pounds per square inch. The table of this machine is 2 feet by 3 feet 4 inches, and is provided with 18 round holes staggered in rows as indicated, but systematically placed with regard to the ram. Round pins of 3½ inches diameter can be placed in the holes, and the work to be bent may be further held by bolts set in any of the T-slots provided on the top and sides of the table. Modifications of the table may be made when necessary for special requirements. The ram of the machine has a travel of 8 inches, and is brought back to the starting position by the counterweight shown. The center line of the cylinder is 2¼ inches above the table, but the bending block can be raised higher above the table if required. By making the ram travel in guides, its center line may also be brought below the table. The cylinder head is removable and provided with air passages for removing entrapped air or draining, if required in cold weather. The ram is controlled by a stop and release valve on the side of the cylinder. The frames and cylinders of both this and the larger machine are of cast iron and the cylinders copper-lined. The rams and bending pins are of machine steel, and a positive stop is provided for preventing the ram from passing out beyond the safe limit.

The machine shown in Fig. 2 is capable of exerting a pressure of 30 tons. It is provided with a table 4 by 6 feet, and with two opposed 7-inch cylinders having a 12-inch stroke, arranged to operate in either direction with a double-headed ram extending between them. The table shown in the illustration has 21 holes on each side of the ram, staggered in six rows. The removable pins are 4½ inches in diameter. A large bending pin, shown in the center, is attached to the ram which works in machined guides and is covered, so as to prevent scale or dirt from reaching the contact surfaces. The cylinder heads are removable in this machine, the same

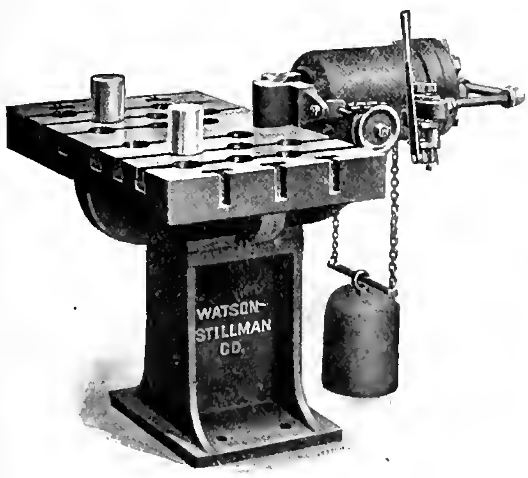

Fig. 1. Twenty-five Ton Watson-Stillman Hydraulic Bending Machine

as in the smaller one, and provided with air passages. The valves, which are all located in one place under the table as shown, may be operated by any of the four levers at the corners of the machine. The arrangement is automatic, so that the opening of the pressure or release valve for one cylinder opens the opposite valve in the other cylinder, the movement being stopped by removing the hand from the operating lever. If required, a pair of bending blocks with hardened steel faces can be substituted for the ram bending pin. The cylinders may be placed higher in relation to the surface of the table, if desirable. In such a case, the rams are usually made independent and single-acting, and returned by counterweights the same as in the smaller machine.

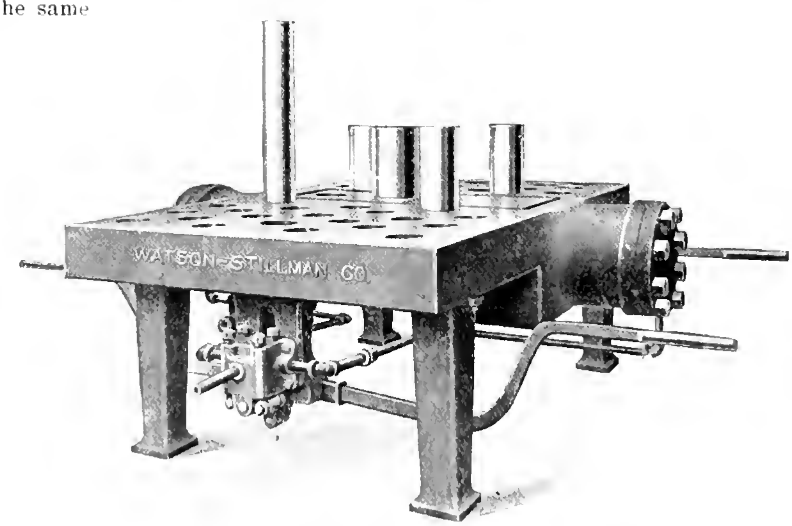

Fig. 2. Watson-Stillman Bending Machine of Larger Capacity than that shown in Fig. 1

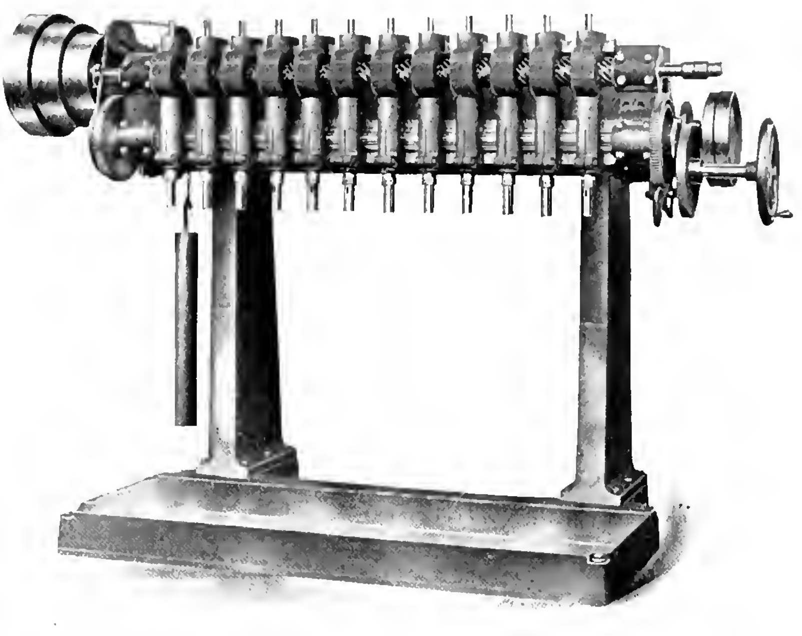
MOLINE MULTIPLE SPINDLE DRILL WITH BASE PLATE AND SPINDLE FEED

The multiple spindle drill shown herewith is No. 31 of the line made by the Moline Tool Co., Moline, Ill. It employs the same driving principles as used on other machines of this line which we have previously illustrated (see, for instance, the two machines described in the department of New Machinery and Tools of the February, 1910, issue of MACHINERY) but differs from them in that no work-table is provided, requiring the feed to be applied to the spindles. The machine is, therefore, intended particularly for medium or large-sized work mounted on special fixtures, or clamped directly on the base-plate of the machine.



No. 31 Moline Multiple Spindle Drill, with Feed applied to Spindles

The spindles are carried in steel quills, bronze bushed, with feed racks cut in the solid metal. These racks mesh with a pinion extending the whole length of the cross-rail of the machine, permitting the spindle heads to be adjusted freely without disturbing the connections, in the same way that the helical driving gears for the spindle are shifted to any position on the long helical driving gear on the cross-rail. A feed of 6½ inches is provided for, and each spindle has an independent vertical adjustment of 2 inches, permitting the use of drills of various lengths in the various spindles.

A three-step cone drives the machine. A pair of two-step cones at the right of the machine operates the feed; the driving cone of the pair is of very small diameter, as shown, and is mounted on the right-hand extension of the driving shaft. The geared connections will be readily followed in the engraving. The long feed pinion is driven by gears at each end, to lessen the torsional deflection resulting from its great length. An automatic feed stop is provided, operated by a dog adjustably mounted in a circular groove, cut in the rim of the feed gear on the right end of the pinion shaft. This operates the levers shown, to throw out the feed clutch, when the desired depth of hole has been drilled.

The machine will be built in any reasonable width, with any number of heads. The greatest distance from the spindle to the base is 41 inches, and from the face of the column to the center of the spindle, 12½ inches. These spindles can be adjusted to within 3 inches of each other; the maximum length of layont in this particular case is 5 feet. The machine will drive any drill up to ⅝-inch diameter. It will be furnished with adjustable table when desired.

ADJUSTABLE SCREW CUTTING DIE

An improved design of adjustable screw cutting die has recently been brought out by the Remington Tool & Machine Co., Boston, Mass., the die being known as the "Perfection" screw cutting die. As shown in the accompanying illustration Fig. 1, the die is made in two sections, with a hinge formed integral with one of the parts. The adjustment is accomplished by means of a taper pin entering into a tapered hole, one half of which is located in each of the die halves as shown. The taper pin is placed on the end of the adjusting screw passing through the die holder shown in Fig. 2, so that the size of the die can thus be adjusted without removing it from the holder. When properly adjusted and clamped in the holders, shown in Figs. 2 and 3, it can be considered practically as a solid die.

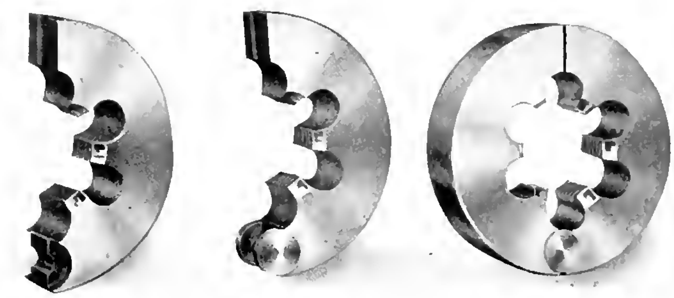


Fig. 1. The Remington Tool and Machine Co.'s Adjustable Threading Die

One of the most prominent features of the die is that it can be ground on the cutting edges after hardening, the teeth being easily accessible. There is ample clearance for an emery wheel or for lapping with diamond powder. In case particles of metal become lodged between the teeth of the die, it can also be easily cleaned. The advantage of being able to grind the cutting faces of the die adds both to its efficiency and economy. The tearing of the thread of the piece to be cut, which is an evidence of a dull die, is avoided when this die is kept in proper condition, and the life of the die is increased considerably by being able to sharpen it whenever dull. On account of its construction, breakage due to extreme adjustment is also impossible, and this loss thereby eliminated.

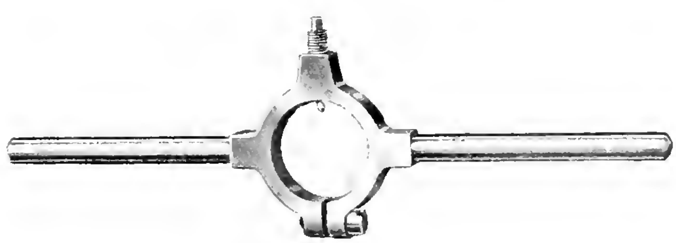

Fig. 2. The Remington Elastic Die Holder

Figs. 2 and 3 show two holders adapted for use with these dies. The dies can, of course, be used in ordinary standard die holders, but the so-called elastic holder shown in Fig. 2 is especially adapted for this die. A holder for use in the lathe, embodying the same features as this holder, is shown in Fig. 3.

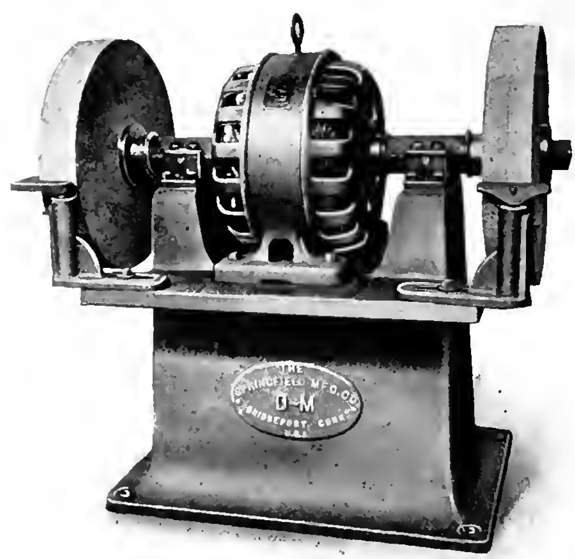
As an interesting example of the capacity of these dies, the makers state that one of them has been in daily use for over four years cutting the threads on over 6,000 chuck heads in that time, and this die is still performing satisfactory service.

Fig. 3. Die Holder for Use in the Lathe

THE SPRINGFIELD MOTOR-DRIVEN DRY GRINDER

The emery wheel stand shown herewith is an original design, developed by the Springfield Mfg. Co. of Bridgeport, Conn. The special feature is the arrangement which permits using a standard, stock motor with a regular armature, the only change being in the shaft. The shaft is mounted in self-oiling bearings, 2 inches diameter and 8 inches long.

The motor used is a Westinghouse alternating-current 5-horsepower machine ,of suitable speed for wheels 24 inches diameter and 4 inches face. It will be noted that an open type machine is used. This is possible only with the alternating motor, where there are no delicate parts such as commutators, etc., to give trouble from grit and dust. In cases where the purchaser prefers it, an entirely closed motor will be furnished, either of the alternating- or direct-current type. The makers of the particular motor shown claim that it does not require expensive starting apparatus, a regular knife-throw switch being all that is needed.



Electrically-driven Grinding Stand adapted for use of Stock Sizes of Alternating Motors

ROBBINS NEW MODEL 14-INCH ENGINE LATHE

Fig. 1 shows a new engine lathe made by the Robbins Machine Co., of Worcester, Mass. As may be seen, it is of plain, straightforward design, with simple lines, and is devoid of complicated mechanism. These features were intentionally followed, as it was the desire of the manufacturers to produce a lathe of the simplest possible construction, departing in no

important respects from designs whose value has been proved by time; along with this, however, it was desired to produce a lathe which should have a greater cutting capacity than any other machine of its size on the market. The manufacturers have been very well pleased with the results of their endeavor in this direction.

It is needless to say that great stiffness has been given to the main castings. The V's, centers, lead-screw and other parts are the same size as previously used on the makers' line of 18-inch standard engine lathes. It is strongly back-geared, and the proportions are such as to obviate chattering. The spindle is made from crucible steel, accurately ground and fitted to scraped bearings of the best phosphor-bronze. The tailstock also has a crucible steel spindle, and is cut away to permit using the compound rest parallel with the ways. The carriage is of rigid design with long bearings on the ways, and has the compound swivel and screw graduated for convenience in adjusting. The bed is of box design, heavily braced with cross-girders.

Coming down to the details of the mechanism, the provision of a geared feed of suitable range, with quick-change control, is an important point in keeping the machine up to its full output. As may be seen in Fig. 2, which shows the gear-box from the rear removed from the lathe, the mechanism is of the tumbler gear type, and provides for four changes of feed. The driving gear is mounted on the lead-screw driving shaft, so that the changes apply to the feed only. An automatic stop for the feed is furnished. An adjustable collar is mounted on the feed-rod. When the feed-rod bearing in the carriage strikes this collar, it moves it endwise, disengaging the clutch shown at the lower right-hand corner of the opening in Fig. 2. As may be seen in Fig. 1, the lead-screw may be disengaged from the feed box when using the rod feed. For setting up for screw cutting, the regular change gears are used, of course.

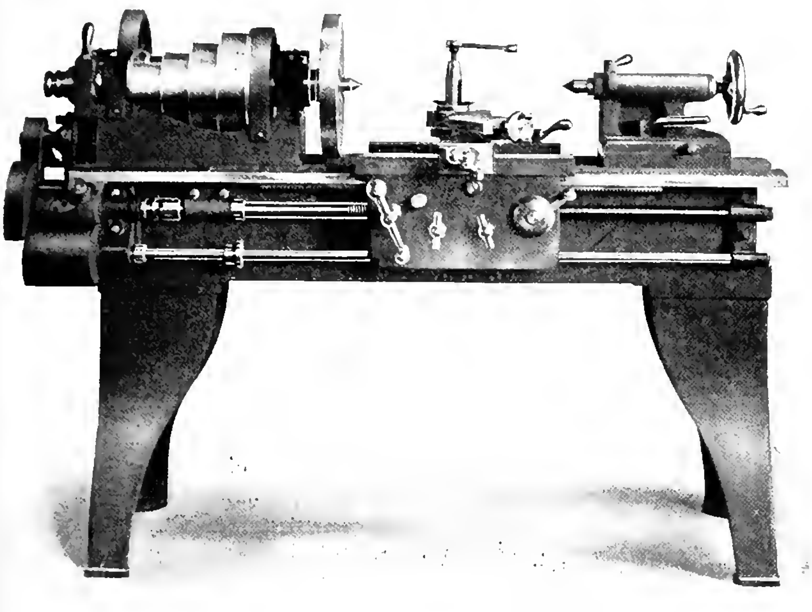


Fig. 1. An Engine Lathe of Standard Lines, designed for Rapid Reductions

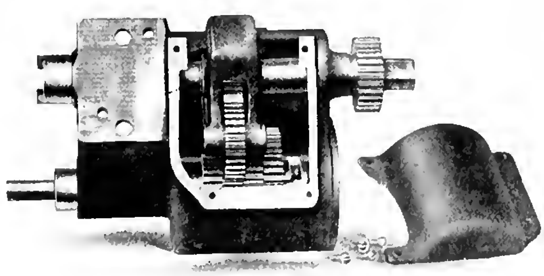

Fig. 2. The Quick-change Feed Box, which gives Four Ratios

This feed box has been so designed in its ratios as to give the range of feeds required for ordinary turning operations. Owing to the positive connections, these feeds are maintained in a way that is not possible with the ordinary belt drive. The feed changes can be easily operated while the lathe is in motion, and in the middle of a heavy cut. It is constructed in a substantial manner, using steel gears cut from solid stock.

Fig. 3 shows a rear view of the apron. The construction is noticeable for its simplicity. Separate worms are used for the carriage and cross-feeds, that for the latter being double-threaded. The construction of the feed frictions is plainly shown. The cams and fingers for expanding the friction rings are made of hardened steel. A screw is provided at the base of the expansion fingers for taking up the wear, or increasing the gripping power of the ring. The rack-pinion can be pulled out and disengaged when cutting screws. It will be noted that this pinion is supported in a double bearing, close to its point of engagement with the rack.

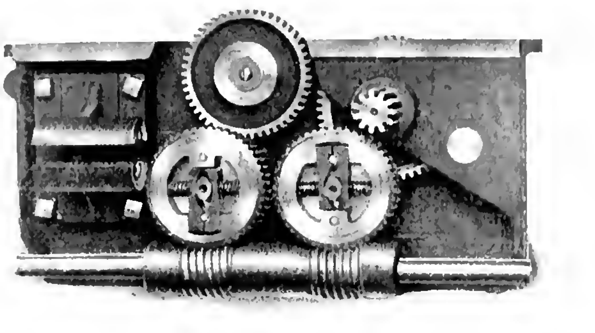

Fig. 3. Rear View of Apron, showing Simplicity and Directness of Mechanism

The headstocks will be furnished with a three-step cone if desired; in either case the speeds are arranged in geometric ratio. In the three-step design, the diameters on the cone pulley range from 5 to 9¼ inches; in the four-step design from 4 to 9⅝ inches, using 3½- or 2½-inch belts, respectively. The back-gearing ratio is 9 to 1. The front spindle bearing is 2¼ by 4¼ inches. The lathe has a 1 1/16-inch hole through the spindle, with a No. 4 Morse taper hole for the center. Change gears are provided to permit the cutting of threads from 3 to 30 per inch. The lathe with a 6-foot bed takes 36 inches between centers, and weighs complete 1600 pounds. This lathe swings 15 inches over the bed. It will also be furnished to swing 16 inches over the ways with an extra heavy headstock, tailstock and carriage, and with a four-step cone for a 3-inch belt.

The makers have found, after severe tests, that this tool has a reduction capacity great enough to use modern high-speed steels on cuts as great as the manufacturer can afford to use without wasting stock. The lathes are carefully tried out when completed, and are guaranteed in every respect.

CINCINNATI PORTABLE ELECTRIC RADIAL DRILL

The accompanying engraving shows a portable electric drill (made by the Cincinnati Electrical Tool Co., Cincinnati, O.), so mounted as to form a drilling machine of the "Scotch" radial type. When mounted in this way, it is evident that the machine is well adapted to portable use, on work up to the very largest size, to the top and sides of which it may be conveniently clamped by the slotted base in which the column is seated.

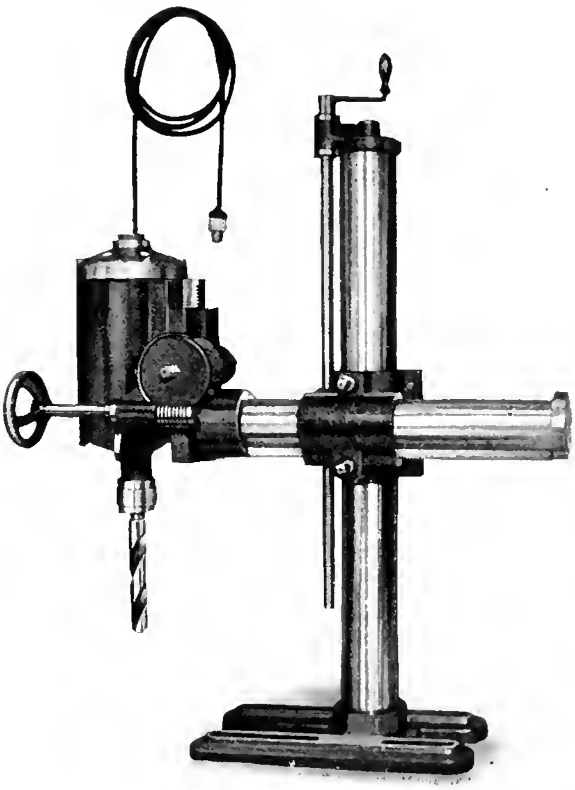
The arrangement consists essentially, as may be seen, of a standard design of geared electrical drill, mounted on a rack and pinion slide at the end of a horizontal arm, which is itself horizontally and vertically adjustable on the main column of the attachment. The columns are made of heavy seamless Shelby tubing, ground accurately to size, thus giving good fits and making the adjustments easy.

The vertical adjustment is effected by the screw shown which is suspended from a ball bearing bracket at the top,

which permits the whole drill to be swung around the central post in a way similar to the regulation radial machine. The in-and-out adjustment of the horizontal arm through the saddle is effected by a rack and pinion movement, as shown. The rack and pinion vertical feed of the machine at the end of the horizontal arm is controlled by a handwheel and worm connection, which permits a steady even feed. The worm gear-box swivels so that the handwheel may be set to any position throughout the circle, as may be most convenient for feeding. The worm may be thrown out of engagement at any time to permit the rapid adjustment of the drill.

The motor is shunt wound, and thoroughly ventilated by means of a self-contained fan mounted on the armature shaft. Ball bearings are used for the shaft, as the makers have found them to give results superior to bronze bushings in the matter of wear, the latter having been found to allow the armature and pole pieces to rub in a comparatively short time. The reduction gearing is made of hardened steel, and is enclosed in a gear box at the lower end of the machine. This is filled with lubricating grease, which reduces the friction and the wear on the machine to a minimum. A balanced internal gear drive is used, overcoming any cramping strains on the motor.

The machine can be quickly attached to a lamp socket by



A Portable Electric Drill of the "Scotch Radial" Type

means of the cable shown. It will be found useful particularly for bridge work, boiler shops, and all kinds of drilling and reaming on heavy work. It is made in three sizes, capable of driving 3/4, 1 1/4 and 2 1/4-inch drills, respectively. The illustration shows the 2 1/4-inch size. This machine has a vertical adjustment of 42 inches on the main column, a horizontal adjustment of 24 inches, and a feed of 4 1/2 inches.

OESTERLEIN NO. 25 UNIVERSAL MILLING MACHINE

We herewith illustrate and describe a new design of universal milling machine developed by the Oesterlein Machine Co., Cincinnati, Ohio. The machine has been changed in a number of particulars, principally as to the column, the quick change feed box, and the dividing head. Figs. 1 and 2 will serve, without extended explanation, to give an idea of the simplicity of the machine, the large proportions of all its main parts, and its rigidity. We can, therefore, pass to a description of the improvements in detail, without further preliminaries.

The feed box is on the right-hand side, back of the column, as shown in Fig. 2; the line engraving Fig. 3 gives details of the mechanism. It is connected with the spindle through a roller chain which drives sprocket wheel *A*. This in turn, drives, through shaft *B*, the sliding gears *C*, *D*, and *E*, which can be shifted axially as a whole to either of the three positions, so that *C* engages gear *F* on shaft *G*, or so that *D* engages *H*, or so that *E* engages pinion *J* on the same shaft. Three rates of speed are thus given to shaft *G*. These changes are effected by handle *K* on the front of the box which, through the rock shaft and lever shown, operates pin *L*, engaging a recess in the hub of pinion *C*. On shaft *G* are mounted four gears, *F*, *M*, *N*, and *O*, any one of which may be engaged by a sliding tumbler *P*, controlled by handle *Q* on the outside of the feed box. This transmits the motion to the telescopic shaft *R*, through which the feed is taken to the work table in the usual manner.

The three changes given by handle *K*, and the four by handle *Q* thus combine to give 12 rates of feed, any one of

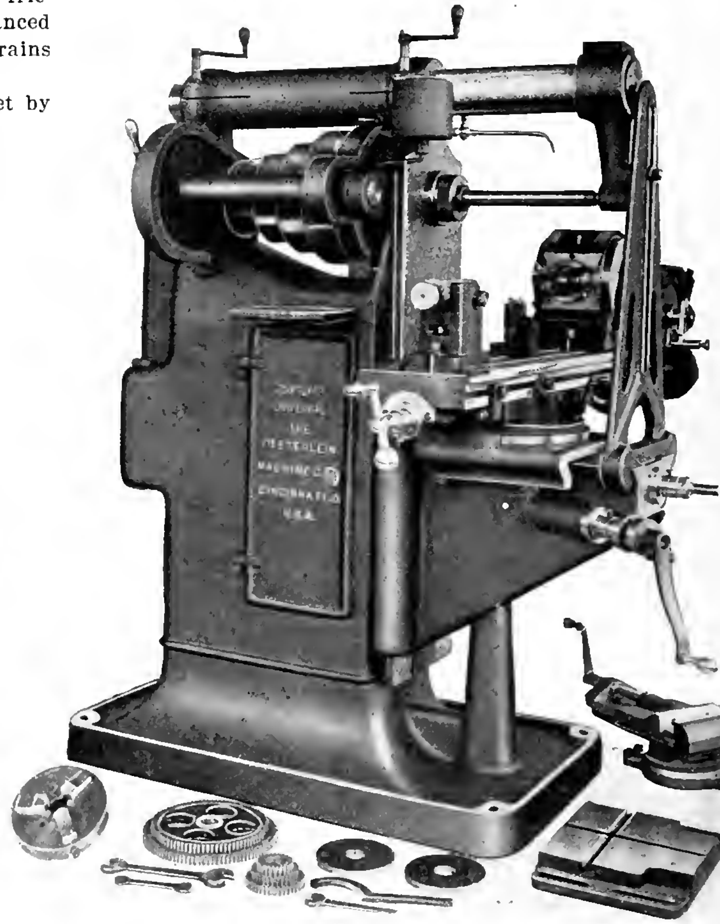


Fig. 1. No. 25 Oesterlein Universal Milling Machine

which is instantaneously obtainable. The gears in the feed box run in oil; provision is made to readily drain this oil when a clean supply becomes necessary. A direct reading index plate is attached to the feed box, from which the exact amount of feed per revolution of the spindle is read.

Fig. 4 shows the dividing head as arranged for plain indexing, without the spiral attachment. Fig. 5 shows a rear view of the head geared up for spiral cutting; a front view with the same setting is shown in Fig. 2. Fig. 6 is a sectional view of the head showing the internal mechanism. The design provides for dropping the worm out of contact with the wheel for direct indexing. It also provides for making adjustments between the worm and wheel for taking out the back lash. Means for clamping the work spindle in any desired position is also furnished. Suitable clamping arrangements for the index plate permit the use of either plain indexing or spiral cutting. The way in which these various features are provided for will be understood from the following description.

The main head casting or swivel block *S*, has a range of angular adjustments from 10 degrees below the horizontal

to 10 degrees beyond the perpendicular. It is clamped in any position between these two extremes by means of bolts T (the nuts for which are seen in Fig. 5), which engage V-blocks turned to fit the V's shown at a. These bolts are sufficiently far apart to hold the adjustments very rigidly.

The spindle U is of crucible steel, and has a taper bearing for its entire length except on the seat required for the dividing worm wheel V. It may be firmly clamped in any position by a wedge pin having a 60-degree angle milled on one end, to fit the sixty-degree groove in the spindle, shown at b. This wedge pin is operated by the small cross handle screw seen on a level with the axis of the swivel block in Fig. 5. The spindle is furnished with means for taking up wear in its journals.

The worm wheel V is made of bronze, and the worm shaft and worm W are made of tool steel, in one piece. The worm has a bearing at one end in trunnion X, which is hinged at c, while the inner end is supported by bearing Y. The latter rests in a suitable sliding support, hung to the pivot of engaging crank Z, which, as shown in Fig. 5, projects through the back side of the head, where it is provided with a cross-

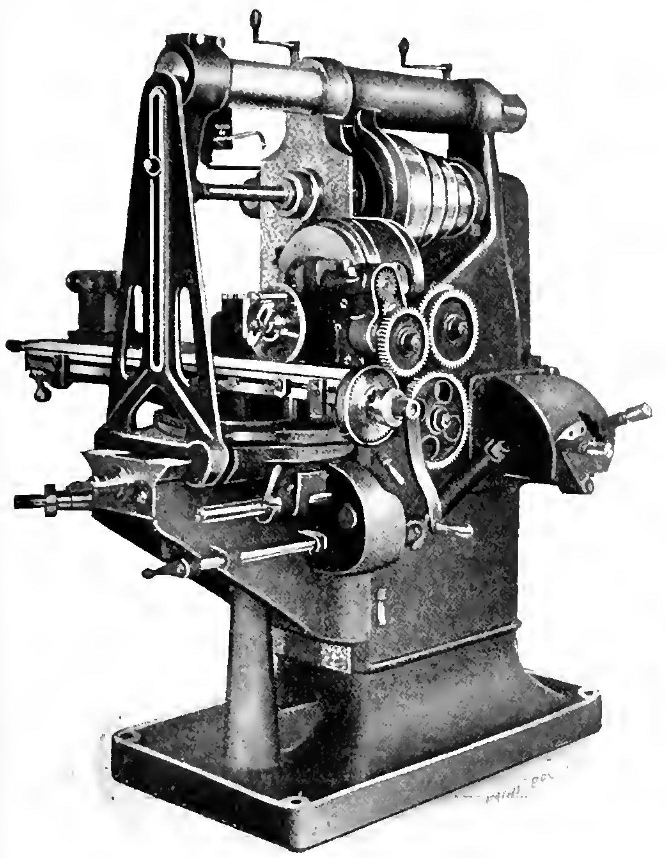

Fig. 2. Right-hand Side of Oesterlein Universal Milling Machine, showing the New Feed Box

pin for operating. By turning Z, worm W may be rocked about trunnion center c to bring it into engagement with wheel V, or dropped out of engagement so that V revolves freely.

The purpose of this is to permit direct indexing on worm wheel V, which is as shown, provided with a row of holes at d, which are in line with direct index pin A_1. This latter is entered into the holes or withdrawn from them by eccentric handle B_1, which projects through the top of the swivel block in front, as shown in Fig. 4. By using this, when worm W is thrown out of engagement, quick indexing is provided for 1, 2, 3, 4, 6, 8, 12, and 24 divisions. The front shoulder of spindle U has 24 graduations in plain view, corresponding with the small holes d on the worm wheel. Pin A_1 is hardened, and the point is tapered so that the indexing is done accurately and securely.

The engaging crank Z, for raising or dropping worm W, is itself fitted in an eccentric bushing C_1 which may be rocked slightly to take up any back lash between V and W, thus making allowance for wear as fast as it may occur. The adjustment raises the engaging crank, and consequently the worm, and brings it more closely into engagement with the wheel.

A point that should be noted in this dividing head is the

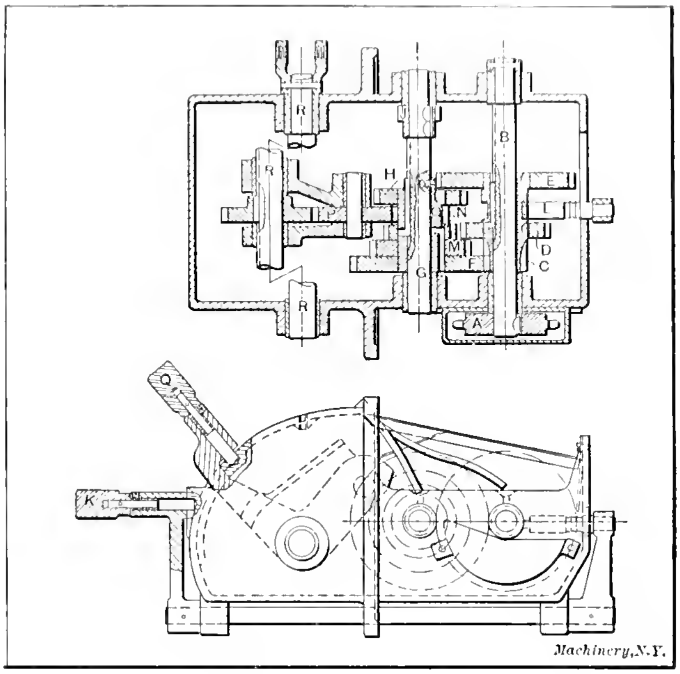

Fig. 3. The Mechanism of the Feed Box

fact that the index crank E is mounted directly on worm shaft W, instead of being connected through gearing, as is sometimes the case. This makes for accuracy in the indexing. Index plate F_1 is screwed firmly to sleeve G_1. Provision

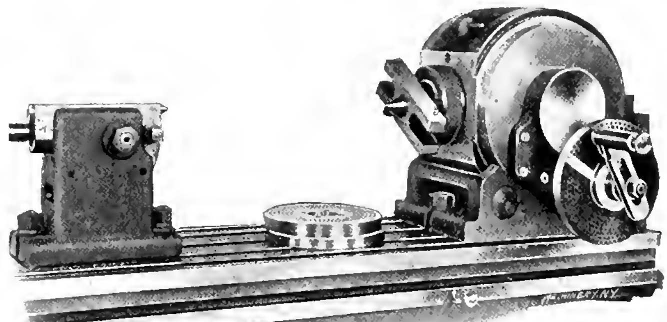

Fig. 4. Plain Dividing Head adapted for all Forms of Indexing Work except Spiral Cutting, and used on the Plain Milling Machine

is made for locking G_1 to trunnion X for direct indexing. When cutting spirals G_1 is, of course, free, being rotated through gears H_1, J_1, and the connections shown in Figs. 2 and 5. The change gear mechanism connecting with the

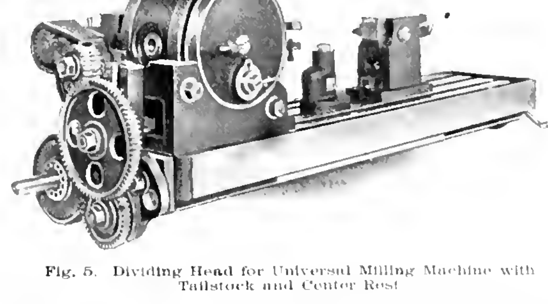

Fig. 5. Dividing Head for Universal Milling Machine with Tailstock and Center Rest

lead screw gives provision for compounding, and for reversing the motion as well in cutting right or left-hand spirals. The support for the gears is very rigid, as may be seen. This assists materially in taking substantial cuts on spiral work.

With this new design of dividing head is furnished a set

of change gears, three double dividing plates, a tailstock and a center rest. The three plates will index up to 100 on even divisions, and on those divisible by 5 up to 200, and many others besides. The tailstock is so arranged that it can be swiveled to any angle that may be required for milling tapered work. An efficient clamping device for the center is furnished.

REED 14-INCH EXTRA HEAVY LATHE

The F. E. Reed Co., of Worcester, Mass., has recently built an extra heavy 14-inch lathe, with plain rest and power cross-feed. This tool is shown herewith. It is particularly adapted to the rapid production of automobile, motor boat, engine and similar parts. The makers state that the construction throughout is the heaviest ever used for a lathe of this swing, and that it has all the power and stiffness of the commercial 20-inch lathe.

The head is back-geared and driven by a 3-step cone, having diameters, respectively, of $7\frac{1}{2}$, $9\frac{3}{4}$ and 12 inches, for a $3\frac{1}{4}$-inch belt. The back-gears are made with corresponding strength. The ratio is 3.62 to 1, which gives a range of spindle speed well adapted for the work to be done. The spindle itself is a crucible steel forging with a $1\frac{1}{8}$-inch hole bored through it. The spindle boxes are of cast iron, lined with genuine babbitt metal, firmly seated in dove-tail slots. The front bearing is $2\frac{3}{4}$ inches diameter by $6\frac{5}{8}$ inches long. All the bearings are provided with ample oiling facilities.

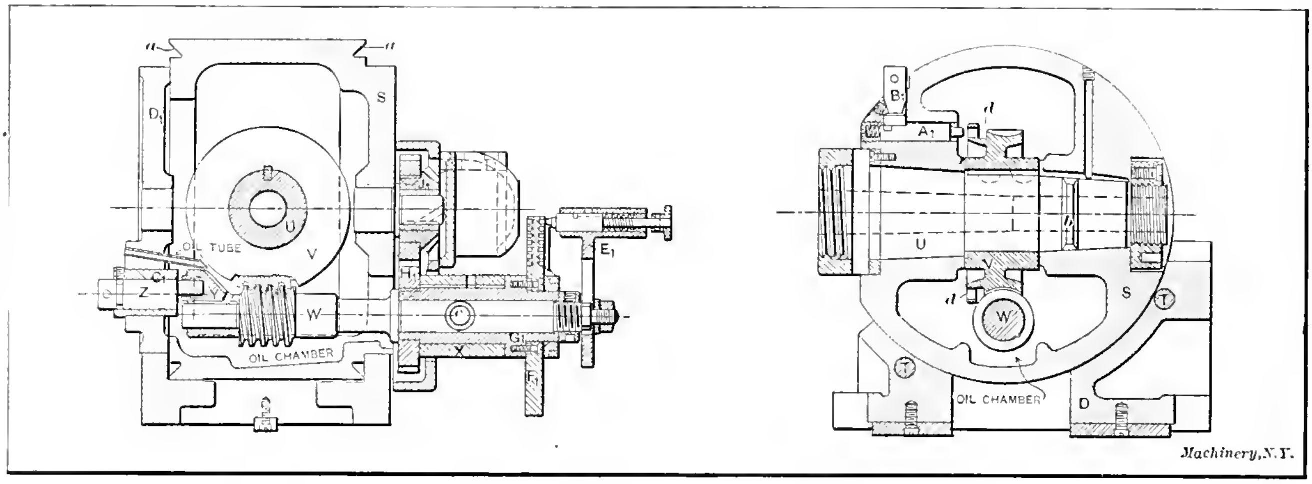

Fig. 6. Mechanism of the Dividing Head showing Direct Indexing Device, Worm Adjustment, etc.

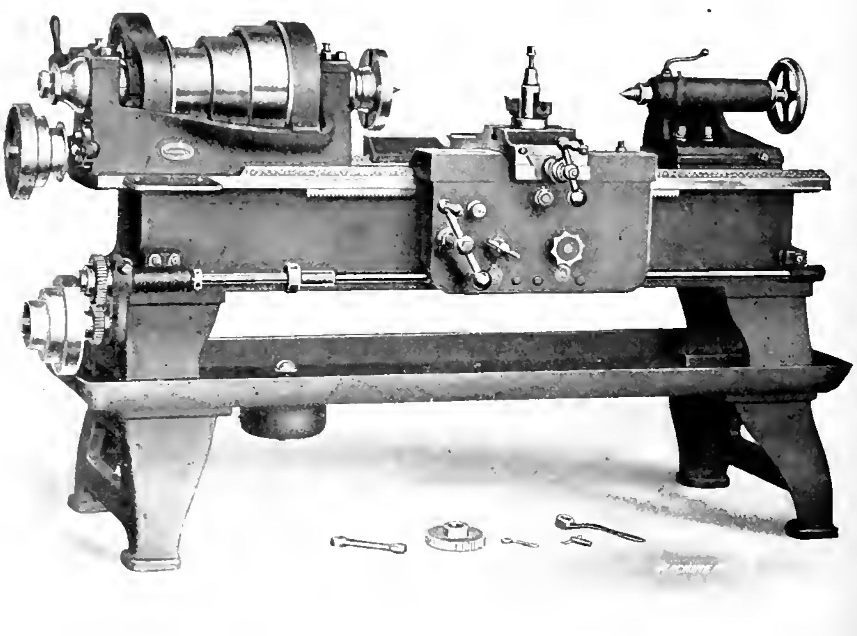
The tailstock of this lathe is of the standard cut-away pattern, held to the bed by two heavy bolts. It can be set over for turning tapers. The tail spindle bearing is $2\frac{3}{8}$ inches diameter by 8 inches long. A special heavy plain rest is furnished on the carriage, having an unusually wide and deep dove-tail slide. The cross-feed screw is provided with a graduated dial. The carriage bears on the V's for its entire length, and is gibbed both inside and outside of the bed.



Special 14-inch Lathe of Unusual Weight, for Automobile and Similar Work

The feed is driven through 3-step cones of unusual diameter and belt capacity. This, in combination with the worm-gearing in the apron, allows ample power for the heaviest cuts. The lower feed cone is mounted on a swiveling arm as shown, so that it may be adjusted to maintain the proper belt tension. An extra feed gear gives six changes in all. The apron is deep and heavy, and is provided with the makers' patented integrally connected bearings for both feeds. As the tool is intended particularly for heavy turning and facing, it is not regularly made with a lead-screw, though this can be furnished at an extra charge if desired by the purchaser.

The lathe is supplied with a steel oil pan as shown, for which an extra charge is made, or it is mounted on regular legs without the oil pan. On the countershaft provided, the loose pulley can be oiled while running, and the hangers have self-oiling boxes. The lathes are made for tools having $\frac{5}{8}$-inch by $1\frac{1}{4}$-inch shanks.

BAKER TWO-CYLINDER AUTOMATIC CYLINDER BORING MACHINE

The tool herewith illustrated and described is for boring automobile and similar cylinders, and was designed and built by Baker Bros., Toledo, Ohio. The machine is of original design throughout, with many unusual features in the mechanism, structure, and materials employed. Among the most noticeable of these innovations may be mentioned the use of chrome vanadium gearing, oil-treated nickel steel shafting, and Hess-Bright ball bearings.

It might be a good plan in describing the machine to state first the particular points aimed at in the design. These points the maker enumerates as follows: General rigidity; powerful, smooth drive; adjustment for wear in spindle bearing, combined with substantial anti-friction thrust; screw feed for table; automatic operation; adjustable center distances for spindle, without sacrifice of rigidity; accuracy of alignment; efficiency of driving mechanism; economy of floor space; and adaptability to motor drive. In describing the machine we will take these points up in the order given.

To secure the desired rigidity, the frame has been made of heavy cored box sections, reinforced by internal ribbing, with broad gibbed surfaces for the table slide and for the heads. The side view in Fig. 2 shows plainly the massiveness of con-

struction. The weight of the complete machine is about 5000 pounds. This in itself gives evidence that weight has not been spared in the design.

The consideration of smoothness and power for the spindle drive is most important, and it is, as well, somewhat difficult of attainment where the spindles have to be set as closely together as in this case. In securing smoothness and power the first point determined on was the use of a single speed drive with a two-speed countershaft, allowing a direct connection through to the spindles. As the machine is expressly intended for manufacturing, it will be set up for one job and run on that for a year or more at a time, so there is no occasion for experimenting with speed changes. It is thus possible to drive the first spindle direct from the driving pulley through a worm and worm gear. The second spindle is driven in the same manner by a shaft parallel with the pulley shaft, driven from it by equal spur gears. The use of double driving shafts also allows the two driving worm gears on the spindles to be placed in different planes, overlapping each other so that larger diameters can be used than would otherwise be possible.

withstand pressure far beyond that ordinarily applied to balls of the size used.

To insure a smooth, uniform table feed, a screw is used for this motion in preference to a rack and pinion. This is clearly shown at A in the sectional drawing, Fig. 3. This screw is normally stationary, being fed by a nut B, revolved by bevel gear C for the power feed. It may be turned at will, however, by the hand-wheel shown to the right of the table, connected with it through helical gears D. These two connections are entirely independent, so that the hand feed may be used in either direction whether the power feed is engaged or not.

Three rates of feed are controlled by handle E. This, through the pinion on the lower end of the shaft on which it is mounted, operates sliding rods F and diving key G, which may be made to engage any one of the three gears H, H_1 and H_2, meshing with the corresponding gears J, J_1 and J_2 on feed driving shaft K. By this means feed shaft L is given three speeds, transmitted through bevel gear C to the revolving feed

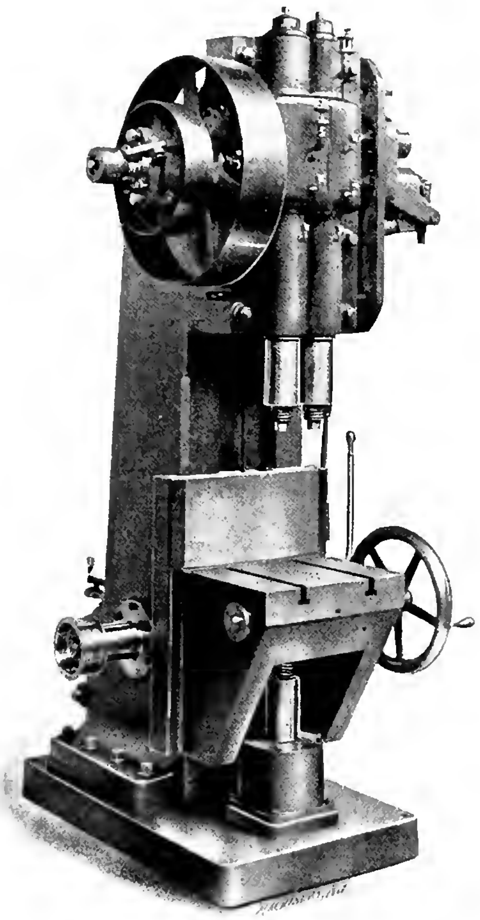


Fig 1. Baker Two-cylinder Automatic Cylinder Boring Machine

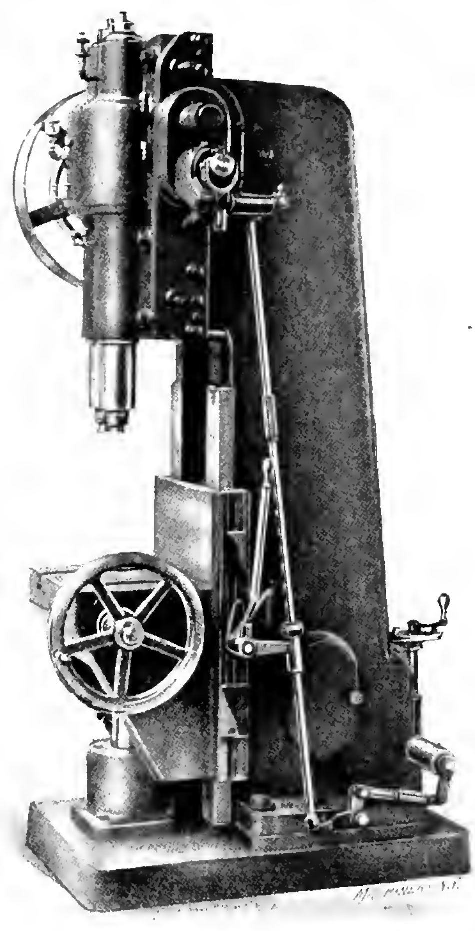

Fig. 2. Side View of Machine, showing Automatic Control for Spindle, Feed and Quick Return

The driving pulley is 24 inches in diameter for a 5-inch belt, and the reduction in the worm gears is eight to one. Particular attention has been given to so proportion the worm gearing as to give an efficient drive. The hardened steel worms have a two-inch lead, and the thrust is taken on ball bearings. The worm gears are of high-grade phosphor-bronze. The size of the worm gears, together with the simplicity of the drive, has given a very smooth, powerful and efficient transmission, which has shown its effect in the fine finish given the cylinders under rapid production.

The spindles have a ball thrust bearing, provided with an adjustment for end play at the upper end. The lower ends are supported in taper bearings, also permitting an adjustment. The spindles are of high carbon, hammered spindle steel, $2\frac{3}{4}$ inches in diameter, and are carefully ground. The ball thrust bearings are made from imported German balls, running in chrome nickel washers made by a special process, which insures great accuracy and gives at the same time ability to

nut as described. Nine feeds in all are provided, a further change of three ratios being given by means not plainly shown in the engraving. These feeds range from 0.03 to 0.20 inch per revolution of the spindle.

Fig. 3, in connection with Fig. 2, also shows some of the details of the automatic operation. In using the machine, the cylinder casting is placed on a fixture clamped to the table. Then the lever shown to the right of the machine in Fig. 2 is depressed. This, through the connections shown with the driving shaft, operates the clutch inside the driving pulley and starts the spindle revolving. At the same time it engages the feed, this being done through the connection of this lever with plunger M in Fig. 3, which enters the hole drilled in feed driving shaft K, and thus controls clutch N. This latter plays between the clutch teeth on worm gear O and those on helical gear T, the former of which gears gives a slow feed, and the latter a quick return, to the table movement.

The table feed having been thus set in motion, when the

proper depth of boring is reached, an adjustable cam on the side of the table drops the starting lever. This, through its connections with the driving pulley clutch, immediately stops the spindles, and at the same time throws in the quick reverse feed, clutch N in Fig. 3 being thrown to the right. This withdraws the work from the cutters. When these are clear, the feed is again automatically disengaged, so that after the cylinder casting has been removed and a new one chucked, the machine is ready for the same cycle over again. Only one movement of one lever is required from the operator, that for starting the machine.

The design of the spindles and heads is such as to admit of varying the center distances without in any way impairing the rigidity. The left-hand head is securely fastened to the frame by ample bolts and taper pins and is lined up with a well-fitted tongue and groove. The right-hand head is secured on the same surface by bolts from the front and back of the machine, and is provided with abutment screws sidewise, so that it is practically solid when set in position. This spindle is adjustable to give center distances ranging from $4\frac{1}{2}$ to $6\frac{1}{2}$ inches, effected by loosening the clamping screws, and then turning the micrometer abutment screws at the extreme top and bottom of the heads. In this way the distance between them is gaged in such a manner as to insure absolute parallelism. The adjustment is then clamped up again as solid as before.

The alignment of the table with the spindles and of the spindles with each other has been very carefully looked out for. Ample gibbed surfaces align the table with the frame. The length of table bearing is 30 inches, and the width $6\frac{1}{2}$ inches. This large ratio of length to width insures very accurate alignment, under free running conditions. The side adjustment is made by a taper gib. The distance from the center of the spindle to the face of the column is made as short as permissible considering the work for which the machine is to be used.

To further insure correct alignment, the heads are carefully roughed out and set aside to season. They are then bored, and afterwards re-planed on an arbor. As they are both clamped to the same surface on the frame, it is a comparatively simple matter to secure accuracy of the highest degree. As was previously explained, the parallelism of the spindles sidewise is maintained by micrometer screws, which permit the finest adjustments possible.

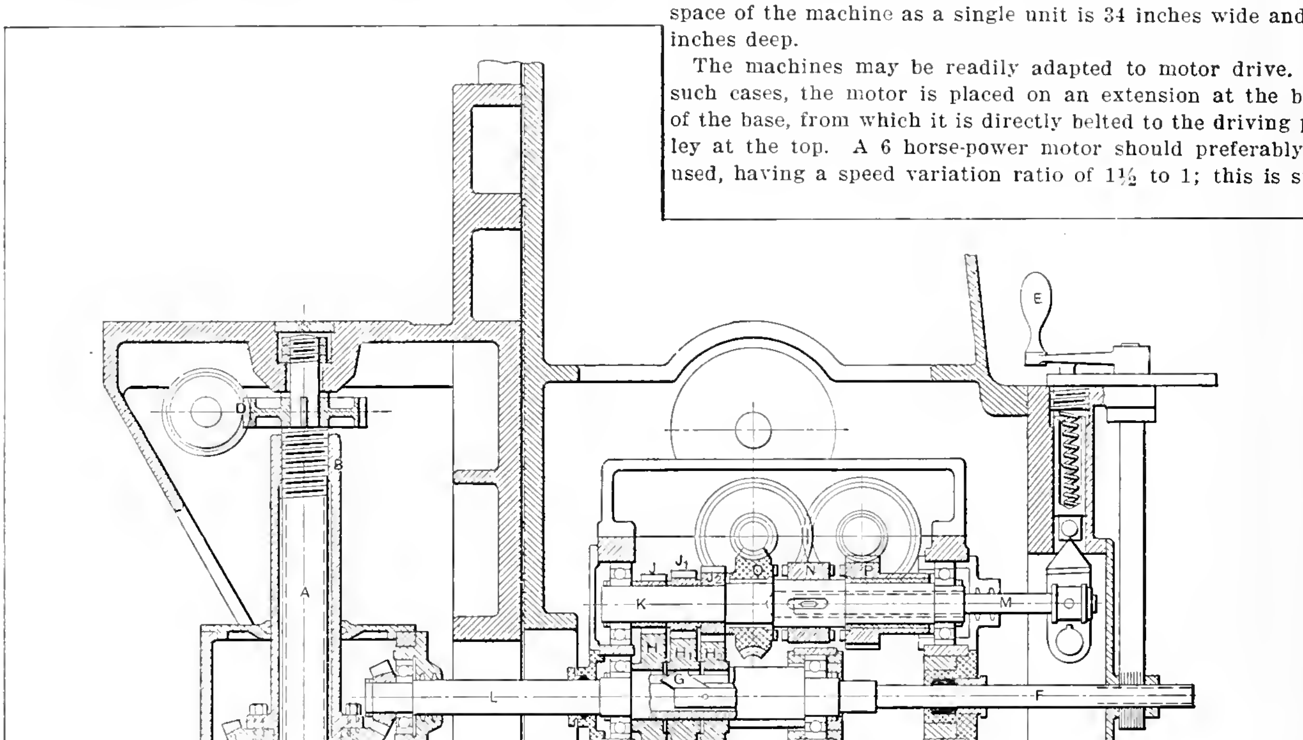

Fig. 3. Vertical Section through Base, showing Feed Change and Quick Return Mechanism

In the matter of efficiency in the mechanism as a whole, extraordinary measures have been resorted to. All the shaft bearings except those of the spindles are, as has been stated, fitted with Hess-Bright ball bearings. The gears are all made of hardened chrome-vanadium steel, and all the shafts are made from oil-treated alloy steel. A ball bearing is also provided to take the thrust of the table screw.

The floor space occupied is very small, being only 32 inches sidewise. That is to say, the machines may be placed in gangs with only this distance between the center lines. When ordered for arrangement in this way, suitable spreaders are provided for connecting the machines together, making a compact unit. This close spacing aids materially in getting from them the maximum possible output, as it reduces the useless moving about required by the operator. The regular floor space of the machine as a single unit is 34 inches wide and 48 inches deep.

The machines may be readily adapted to motor drive. In such cases, the motor is placed on an extension at the back of the base, from which it is directly belted to the driving pulley at the top. A 6 horse-power motor should preferably be used, having a speed variation ratio of $1\frac{1}{2}$ to 1; this is sufficient for the manufacturing work the machine is intended to perform.

This particular No. 3 cylinder boring machine is one of five sizes and types, intended for similar work. It is rated to bore cylinders up to 6 inches in diameter by 14 inches long, in double cylinder castings having from $4\frac{1}{2}$ to $6\frac{1}{2}$ inches between centers. It will also handle satisfactorily, in two operations, quadruple cylinders cast *en bloc*. The table surface is $14\frac{3}{4}$ by $18\frac{1}{2}$ inches, and the vertical feed is 18 inches. The table is counterweighted. The distance from the center of the spindle to the frame is $9\frac{1}{4}$ inches. This has been made as small as possible for reasons of rigidity, but it is great enough to accommodate all present makes of automobile cylinders.

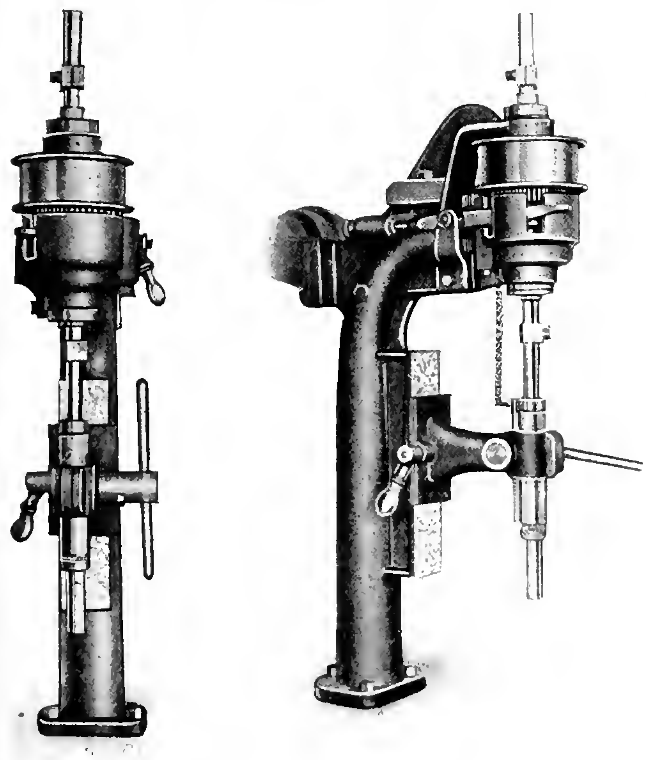
AUTOMATIC TAPPING ATTACHMENT FOR BARR DRILL PRESSES

In Figs. 1, 2 and 3 are shown, respectively, front and side views, and a sectional drawing, of a newly patented device for converting a drill press into a combination drilling and tapping

machine. This device is manufactured by H. G. Barr of Worcester, Mass., and is the result of much study in providing a machine which automatically reverses in both directions for tapping, without requiring any other motion than the regular movement of the lever as in drilling. This result is effected by simple means, which makes possible very rapid and accurate tapping on manufacturing work. It obviates the necessity for reversing "tapping chucks," and has many advantages over such devices, particularly in the fact that the tool is mounted directly on the regular, stiffly supported spindle of the machine.

The device illustrated is known as the "Style A Tapper," and is shown attached to one of the columns of a multiple spindle, style A drilling machine of the maker's line. The attachment itself consists of the post, spindle and pulley complete, and can be applied to any of the style A or B machines, using one or more as required, placing them on the proper spindle to be convenient for jig and manufacturing work.

Referring to Fig. 3, *A* is the driving pulley for the spindle. This revolves loosely in a lined bearing in the overhanging bracket *B*, as shown. It carries on its lower face a gear *C*, which is connected (by intermediate gearing not shown) with a lower gear *D*, which is thus caused to revolve in the direction opposite to *C*. *D* also revolves freely in a lined bearing, supported by the column *E* of the machine. Within gears *D* and *C* the quill *F* is free to revolve; this is provided with clutch pins *G* and *H*, and may be set to engage either the corresponding pins G_1 in gear *C*, or H_1 in gear *D*. Quill *F* is keyed to the spindle of the machine, *J*, which slides freely through it. Lever *K* is provided at one end with a roller entering the groove turned in the collar of the quill, while the other end has a V-point engaging a similar V-point on the spring plunger *M*. This arrangement will be recognized as



Figs. 1 and 2. Spindle of a Multiple Drill Press, equipped with a Barr Automatic Tapping Attachment

a commonly used device, for holding the quill *F* in either the upward or downward position, as it may have been set.

The operation of the attachment will now be intelligible. The spindle *J* of the machine is provided with two adjustable collars *N* and *O*, one below quill *F* and the other above it. With the lever *K* in the position shown, driving pulley *A* is connected with spindle *J* directly through pins G_1 and *G*, and quill *F*, rotating the spindle in the direction to drive the tap into the work. When the tap has entered to the required depth, adjustable collar *O* is set so as to strike and force down quill *F*, pushing pins *G* and G_1 out of engagement. Lever *K* then snaps over to the opposite position under the influence of spring plunger *M*, engaging pins *H* and H_1. The drive is now from driving pulley *A*, through gear *C* and the reversing gears (not shown) to gear *D*, thence through driving pins *H* and H_1 and quill *F*, to the spindle *J*. This reverses the spindle, giving a rapid backing-out movement, which continues until the tap is free of the work, when the natural movement of the hand lever, at the end of the upward stroke, brings collar *N* in contact with the lower end of *F*. By this means reversing lever *K* is snapped back again, re-engaging the spindle with the driving pulley *A* direct, ready for the next downward tapping motion.

Spring *M*, it should be mentioned, may be adjusted by means

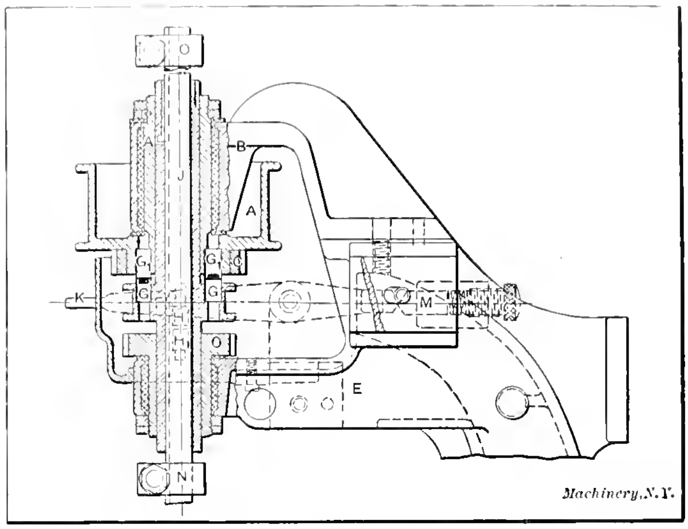


Fig. 3. Automatic Reversing Motion and Adjustable Stops of Barr Automatic Tapping Attachment

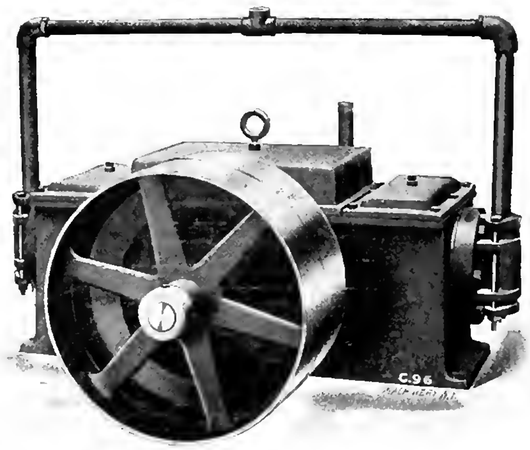
of the screw bushing shown to increase the tension. This may be required to support the "drag" on large taps. It may be as easily reduced, if required, for the more delicate taps. A binder handle is shown at the right of the attachment in the front view. This controls a slide which supports the reverse motion, connecting gears *C* and *D* in Fig. 3. When this slide is pushed back, all the parts are idle except the driving pulley, which may be directly connected with the spindle by pushing reverse lever *K* upward. When so adjusted, the set collars *N* and *O* are loosened on the spindle, and the regular stop attachment to the rack is used for getting the depth. Under these conditions, the spindle can be used for drilling in the same way as the others on the machine, with the added advantage of being quickly convertible into a reversing spindle when required. With this device any drill or "friction slip" chuck can be used for holding the tap. The alignment is as sure as when drilling. The action is rapid and positive; and there is no shock or jar in the mechanism. The style and size of attachment shown here will tap up to 3/8 inch diameter and drill up to 1/2 inch. Another style similar in design will be furnished for tapping up to 5/8 inch and drilling up to 3/4 inch. Other designs are being developed, for special purposes, incorporating the same principles. The style A attachment has been in use long enough to prove its effectiveness for tapping in connection with jig work, or for tapping large quantities of duplicate pieces on the drill press.

COMSTOCK AIR COMPRESSORS

The air compressor shown in the accompanying illustration is manufactured by George S. Comstock, Mechanicsburg, Pa. This air compressor is of the horizontal, center-crank type, and provided with two or more single-acting cylinders. The object in view in designing the machine has been to provide an air compressor which would give reliable service with little attention. The drive may be either through belting or gears, direct clutch or motor drive. The design includes several features not generally found in air compressors of this type. The moving parts are all completely enclosed and protected, and run in oil. The bearing surfaces are exceptionally large and the machines very compact for their capacity, the fly-wheel being placed in the center of the frame, so as not to take up any extra space. The frame is

made of a single casting, containing cylinders, water jackets and crank-case; the pistons are hollow, of coarse-grained gray iron, and are fitted with three rings each. These rings are lap-jointed, and fit tightly in the cylinders, which are reamed to size.

The drive from the crankshaft to the piston is by means of a special patented universal-joint transmission, ensuring an equally distributed pressure. The crankshaft is made of steel in one piece and is of ample dimensions. The valves are vertical, and can easily be taken out for examination or regrinding. The inlet valve is provided with a nickel steel head and carbon steel stem. The discharge valve is of steel



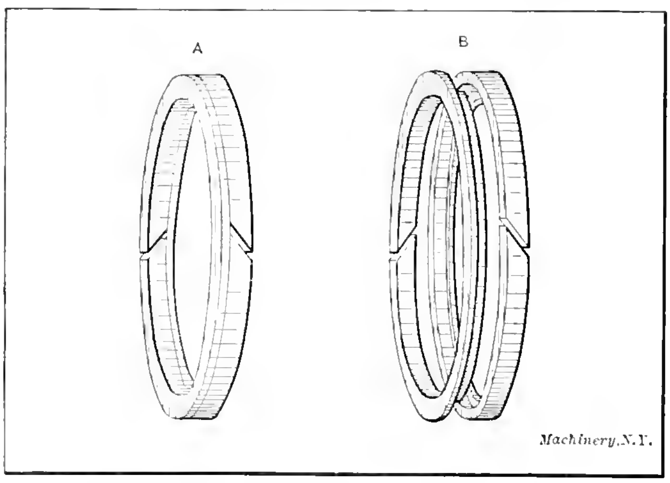
Simple and Compact Air Compressor made by Geo. S. Comstock, Mechanicsburg, Pa.

of a light but strong construction. The cooling is accomplished by large water jackets, and splash lubrication is employed for the moving parts.

The machines are built in eight sizes of a capacity for compressing from 6½ to 140 cubic feet of free air per minute, the horsepower required being from 2½ to 28, and the pressure obtainable 150 pounds for the smallest size and 100 pounds for the larger. The average weight of the air compressors varies from 250 pounds for the smallest to 4,200 for the largest size.

McQUAY-NORRIS "LEAK PROOF" PISTON RINGS

The McQuay-Norris Mfg. Co., 1500 Gaty Ave., E. St. Louis, Ill., has been trying out for several years past a new design of piston head packing ring, for use in gas engines, air compressors, pumps, etc. These experiments have been so satisfactory that the design has been patented, and is now being marketed



A Uniformly Elastic Piston Packing Ring, with Sealed Joints

under the appellation "Leak-Proof" as a trade name. As shown in the engraving, each set is composed of two separate rings, one male and the other female. Each ring carries a flange, outward on the male and inward on the female, as shown at *A* in the engraving. The rings are split diagonally. When the two are placed together in the proper position (that is, with the openings opposite as shown at *B*) each of these openings is overlapped by the other ring, thereby making a close joint and preventing the escape of the steam, gas, water, or other medium under compression in the cylinder.

These rings are made of the best grade of gray iron, giving a high degree of elasticity without the aid of springs or other artificial means. This increases the life of the ring proportionately. Owing to the fact that the points of expansion are opposite in the two rings, a more equal pressure results on the cylinder walls throughout the whole periphery, thus helping to make a tighter joint. In consequence of these conditions, the rings are able to retain their tightness through a very long life of usefulness. The makers have been very successful in replacing other designs of packing with these rings in engines, pumps and compressors.

IMPROVED CHICAGO DUPLEX HAND MILLER

In the August, 1909, issue of MACHINERY a complete description of the design of the new line of Chicago duplex hand milling machines, built by the Chicago Machine Tool Co., of Chicago, Ill., was given, accompanied by several illustrations of the general appearance and details of the machine. A new machine of the same general type, known as the No. 3A,

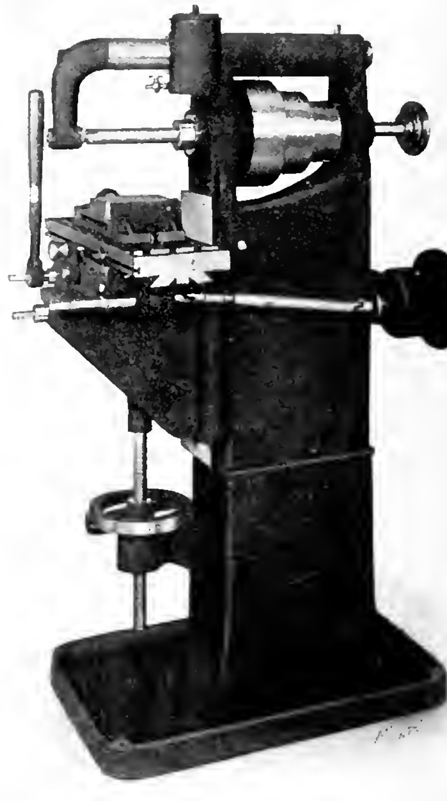


Fig. 1. No. 3A Chicago Duplex Hand Milling Machine

has just been brought out. This machine is shown in the accompanying half-tone, Fig. 1, and embodies some additional improvements. It will be noted that the oil pan regularly furnished on the machines previously illustrated, immediately beneath the knee, has been eliminated in order to facilitate the arrangement shown for the vertical screw adjustment of the knee. The base of the machine has instead been formed into a pan-shape for taking care of the oil or other lubricant used on the milling cutters.

The construction of the vertical screw adjustment for the knee makes it possible to obtain very accurate vertical movements. The elevating screw has four threads per inch, and the large hand-wheel for turning it has 250 divisions, so that the knee may be accurately adjusted up or down 0.001 inch, or even less if necessary. The indicator shown in the front of the hand-wheel is adjustable, so that it can be swung around to any desired position; thus, no matter where the zero point is located at the beginning of the movement, the indicator may be set to it, and it is possible to figure the movement from the zero point without having to add or sub-

tract the various readings, as is usually the case in arrangements of this kind.

In the previous description the design of the table power feed and the quick return of the table were referred to. A good illustration of this design is shown in Fig. 2. As will be remembered, the worm is fastened on the same shaft as the spiral gear which meshes directly with the gear on the universal joint shaft. This whole mechanism is held in a rocker which throws it in and out of mesh with the rack in the table. When the automatic feed is disengaged, the hand lever feed may be operated, and this provides for a quick return of the table when the cut has been taken.

The No. 3A Chicago duplex hand milling machine has an automatic table feed of 20 inches, a transverse feed of $5\frac{1}{2}$ inches, and a vertical screw adjustment of the knee of 10 inches. The machine is provided with micrometer adjustment for the longitudinal and transverse feeds, as well as for the vertical feed as already described.

The universal centers adapted for the No. 3A machine are of an improved construction having a number of features introduced with the aim in view of making them compact, rigid and accurate. As will be seen in Fig. 3, the wormwheel is placed at the front end of the spindle which makes it possible to make it larger in diameter than if it were placed in the interior of the head, where it, at best, could be no larger than the distance between the housings. Other things being equal, a larger diameter of the worm-wheel is conducive to accuracy, and the placing of the index plate and lever directly on the worm-shaft eliminates the inaccuracy which may arise through the introduction of gearing between the

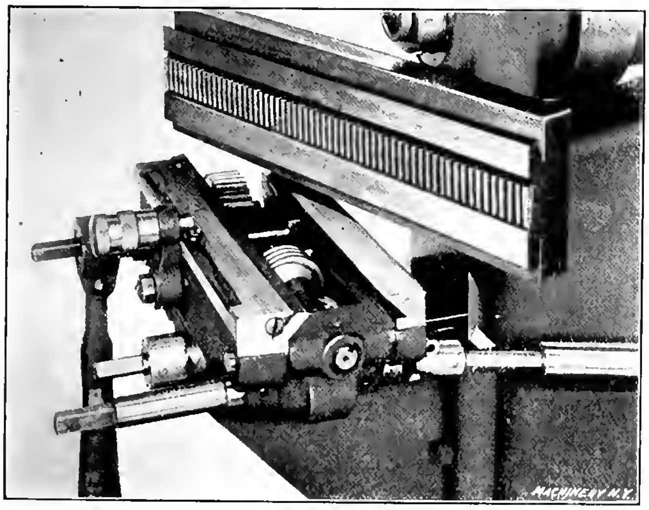

Fig. 2. Details of the Automatic Feed and Quick Hand Return Arrangement

worm-shaft and the index lever, which is necessary when the index plate is placed on a secondary shaft. In order to prevent the spindle from rising too high when turned to a vertical position, the center line of the spindle is placed considerably above the axis of the center block, so that the end

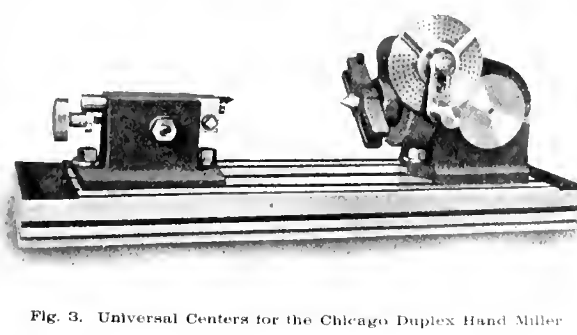

Fig. 3. Universal Centers for the Chicago Duplex Hand Miller

of the spindle, when it swings in an arc around this axis, reaches its highest position before it reaches the vertical direction. The spindle is bored to take a No. 9 Brown & Sharpe taper shank, the same as the main horizontal spindle of the machine. One index plate is furnished, having five circles of holes, the various circles having 33, 39, 42, 46, and 49 holes, respectively, which appears to be sufficient for ordinary work, but additional plates with different numbers of holes can be furnished if required. Hill, Clarke & Co., Inc., of Boston, Chicago, New York, Philadelphia and Cleveland are the selling agents for these machines.

WRIGHT QUICK-ADJUSTING PIPE WRENCH

A quick-adjusting wrench for general use, known as the Wright wrench, was illustrated and described in the May, 1909, issue of MACHINERY. Mr. J. F. Wright, of Canton, Ohio, the inventor of that wrench, has also recently patented a quick-adjusting pipe wrench as illustrated in the accompanying half-tone. This wrench can be adjusted instantly by a slight pressure of the thumb as indicated. To hold the adjustment, there is a toothed rack in the lower edge of the bar or handle, which engages with a toothed pawl in the sleeve. The rack in the bar is inserted so as to be fully protected, the main bar being slotted, and then the rack riveted in place. Should it be necessary to renew it, it can be easily done. The construction of the wrench eliminates any strain being placed on the rack and pawl, as the downward pull of the handle brings an equal strain over the entire length of the sleeve.

Quick-adjusting Pipe Wrench Patented by J. F. Wright, Canton, Ohio

The simple method of adjustment has several advantages. When under pressure or strain there is no rivet that can be pulled out if the wrench is subjected to a side pull, and as pipe wrenches are made to pull but one way, the screw in the sleeve acts as a pivot and the end of the sliding jaw (under the thumb) acts as a check, thereby distributing the strain over the whole length of the sleeve. The spring placed under the end of the sliding jaw as shown in the illustration only serves the purpose of making the adjustment convenient, but this is not depended upon for the working of the wrench, as it will operate either with or without the spring, and the action is entirely positive.

LANDIS AUTOMOBILE CAM GRINDING ATTACHMENTS

The Landis Tool Co., of Waynesboro, Pa., has developed two forms of cam grinding attachments for use on its regular line of universal and plain grinders. The first of these attachments, shown in Figs. 1 and 2, is for detachable cams; the other, shown in Fig. 3, is for those of the integral type, the machine being intended to finish these surfaces complete from the forging, without lathe work or milling.

The first attachment is a self-contained arrangement whose frame, as shown at *A*, is mounted directly on the table of a regular grinding machine. It is connected by a driving arm *B* with the regular driver on the faceplate of the work-spindle, as is clearly shown in both views. It is constructed on the swinging principle, the spindle bearing *C* being suspended from a hinge or pivot directly above it. The work is mounted at *D* on one end of this supplementary spindle, while the master cam is shown at *E*. As this spindle is revolved, the pressure of a spring, not shown, which keeps bearing *C* pressed outward and holds master cam *E* against shoe-plate *F*, will cause the cam outline to be reproduced on the work *D*.

An important feature of the attachment is the fact that it grinds its own master cams, which are copied from full-sized model cams identical with those to be ground. In making the master cam, it is fastened in the place of *D* in Fig. 2, while the model cam is mounted in the place of *E*. The op-

eration is exactly the same as for grinding the work from the master, and the method evidently insures making an exact copy of the model in the finished work. Owing to the fact that the master cam is of enlarged size, the least radius being never less than $1\frac{1}{2}$ inch, the outline is reproduced very accurately on the work, the reduction in the majority of cases being more than 2 to 1.

As in all accurate cam grinding devices, the designer has had to make provision for overcoming the change in the form of the work produced by the decreased diameter of the wheel, as it wears away. Allowance is here made for this by providing a series of shoe-plates *F* as a regular part of the equipment. These plates have a curved working surface corresponding to the diameter of the wheel being used. The number of plates in a set is determined by the size of the machine in which the attachment is to be used; that is, by the difference between the diameter of the grinding wheel at full size and smallest diameter at which it can be used. A plate is furnished for each inch of wheel diameter reduction allowed.

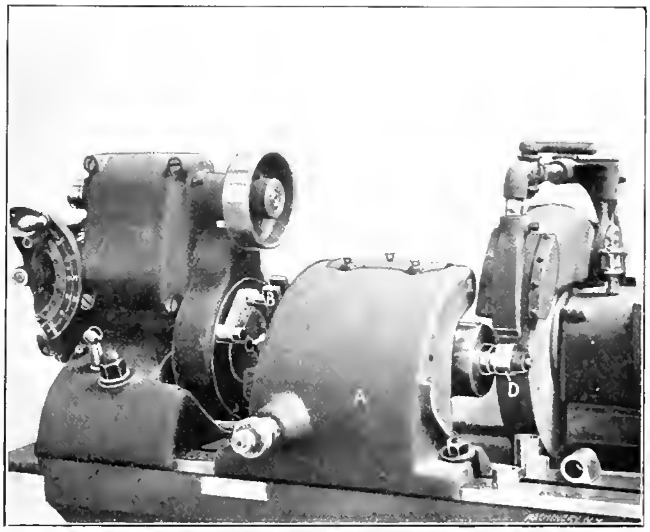

Fig 1. Self-contained Attachment for Grinding Detachable Automobile Cams

In grinding the master cam, a shoe-plate and wheel of equal radii are used, producing, of course, a standard copy of the model cam form. If the cam is placed in its proper position at the other end of the spindle, replacing the model cam and using the same wheel and shoe-plate, an exact copy of the model or work would result. The same thing would follow if any size of wheel and a plate of radius equal to it were used. Without this multiplicity of plates, the tendency would be, as the wheel wears down, for the cams to become slightly full.

In the inch of wheel reduction which each plate covers, this change of form is imperceptible. The master shoe-plates are arranged to distribute or divide this variation evenly. For instance, a shoe-plate of $6\frac{3}{4}$ inches radius is used on wheels from 7 down to $6\frac{1}{2}$ inches radius, or from 14 to 13 inches in diameter. In the same way a $6\frac{1}{4}$-inch radius plate is used on wheels from 13 down to 12 inches diameter, and these changes continue until the wheel is reduced to its minimum size. At no time, it will be seen, does the radius of the shoe differ from that of the wheel by more than $\frac{1}{4}$ inch, and as these extreme variations occur on each side of the middle or exact position, it is clear that the very slight variations in the contour of the cam will be divided equally on each side of the form.

Fig. 3 shows the back view of a standard grinding machine, furnished with an attachment for forming cams made integrally with the shaft. While designed especially for this work, detachable cams can be finished with equal facility, though in such work the master cam would be so made that a full set of either the inlet or exhaust cams could be placed on the arbor and ground together. The action of this machine is entirely different from the one previously described. The master cam and work are both stationary so far as lateral motion is concerned, this being given to the wheel-slide and wheel instead. The master or former cam is shown at *G*. As may be seen, it is of large diameter and stiff design, rigidly supported by bearings bolted to the main column of the bed. It is driven in unison with the work-spindle by a geared connection passing through the casing shown at *H*. The former roll, by whose action on the master cams the wheel-slide is reciprocated, is shown at *J*. This is mounted in bearings attached to the wheel-slide and thus transmits its motion to it, the movement being transmitted in turn from the wheel to the work to give the latter the form desired.

In the same way as in the previous case, the master cam shaft *G* is copied from an actual model cam shaft. In this copying process, the model shaft is supported rigidly between its cam surfaces over its entire length, in bearings provided for the master cam at the back of the machine. This is to overcome any possibility of its yielding or springing during the grinding operation on the master cams. The latter are ground in a solid piece held between the centers, in exactly the same way as the work itself. The cams are more than double the size of the work to be ground, insuring accuracy and freedom of movement in transmitting their motion to the wheel-slide.

Means have to be taken here also to allow for the wear of the wheel. A series of cam rolls *J* is provided, of various diameters, to agree with the diameter of wheel being used. There is one of these rolls for every change of inch in diameter, giving the same results in regard to accuracy as with the other attachment.

A portion of the cylindrical body of the master cam remains between the cam outlines in the form of a collar. When the grinding wheel is traversed along the work in passing from one cam to the next, the roller on the rear of the slide runs on these collars, by which action the grinding wheel is withdrawn clear from the work, and the wheel-slide is held from cross motion. When the wheel has been moved to the next cam to be ground, the roller passes beyond the collar of the master and engages the next corresponding cam surface. It will be seen that the wheel might even be traversed along the work automatically, just the same as in grinding plain work, since the reciprocating or cross motion of the wheel-slide only takes place when the roll is actually on the cam to be ground. The momentary resistance that the roll might suffer in being brought up against the shoulder of the cam is taken care of in either direction by the compression springs shown beneath the wheel-slide, at the left of the spindle on which roll *J* is mounted.

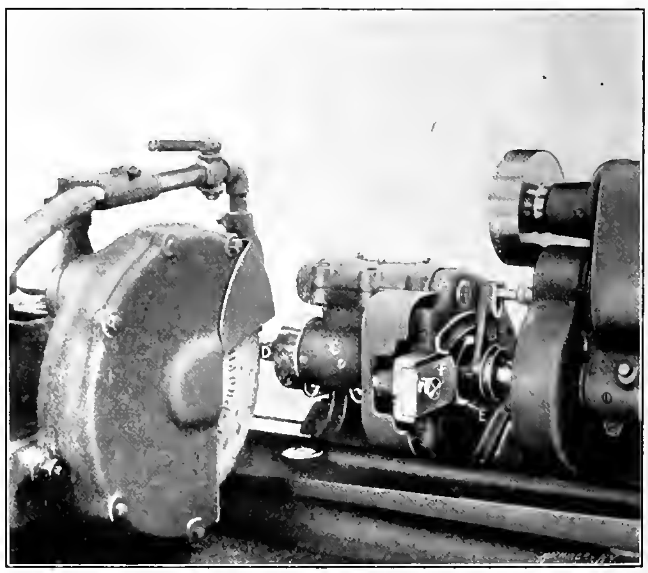

Fig. 2. Rear View of Cam Grinding Attachment, showing Construction

This fixture in no way interferes with plain straight grinding, and the machine can be used for finishing the cylindrical bearings of the shafts with the same facility as when the work is done in a regular plain grinder. To change the machine over to plain work, it is only necessary to slide the grinding wheel back, disengaging it from the master cam. This is effected by a screw operated by handwheel *K*.

Both of these machines and attachments are of rigid construction, especially designed for the rapid production of cam surfaces direct from the forging, without preliminary roughing of any kind. This has become the regular practice and

has resulted in doubling the output over the method previously followed of turning or milling, preparatory to finishing on the grinder. The machine illustrated is one of the maker's regular plain 10- by 30-inch machines.

"CONSOLIDATED" POWER PRESSES FOR AUTOMOBILE MANUFACTURING

The automobile has done a great deal in stimulating the development of the power press, and in widening its applica-

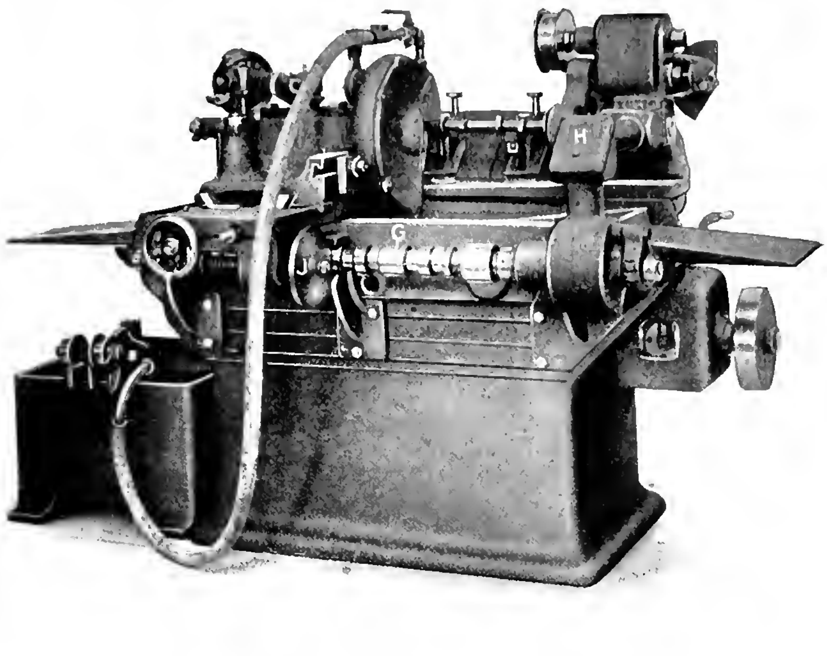

Fig. 3. Plain Grinder provided with Master Cam for Operating Wheel-slide, in Grinding Integral Cam Shafts

tions. The power press, in turn, has been of much assistance in cheapening the automobile, effecting at the same time an

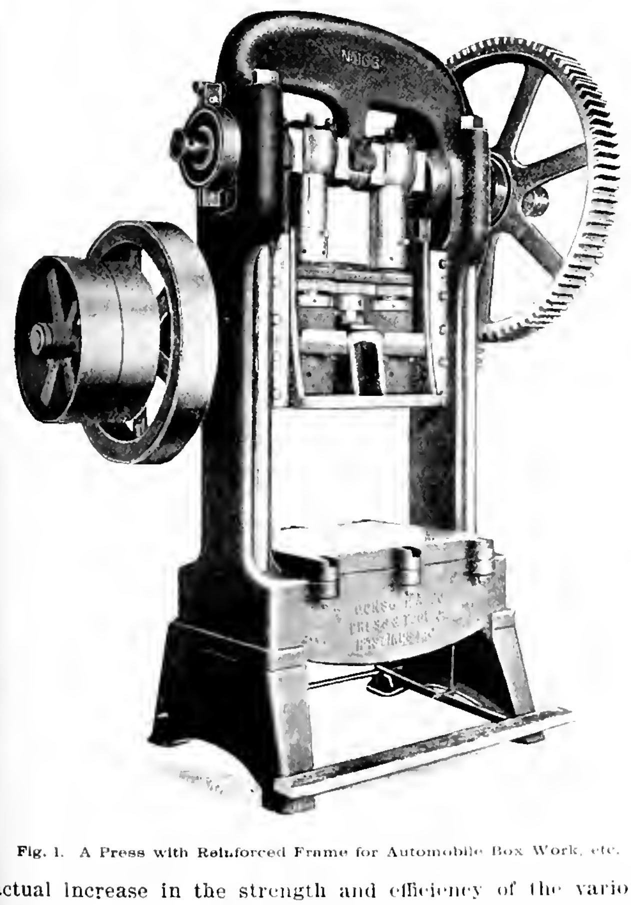

Fig. 1. A Press with Reinforced Frame for Automobile Box Work, etc.

actual increase in the strength and efficiency of the various parts. This has been done by making it possible to replace wooden parts and castings with steel stampings and forgings. The press is now the principal tool used in the making of frames, beds, hoods, radiators, brake drums and bands, rims, axles, etc., and many other parts. In making crankshafts, about all that is needed at the present time is a drop hammer, a trimming press and a grinder. The accompanying illustrations show two forms of press developed by the Consolidated Press & Tool Co., Ford Building, Detroit, Mich., especialy adapted to this important field of automobile manufacture.

The press illustrated in Fig. 1 is especially adapted to making tool boxes and similar parts. On this class of work the strain on the frame, at times, is excessive, and to guard against possible accident each housing is reinforced with two steel rods. These rods are put in hot, and the nuts on the underside of the frame are tightened up and pinned, so that when the rods cool, the strain is equally distributed between the cast-iron frame and the steel rods. It is claimed by the manufacturers that it is practically impossible to break a frame constructed in this manner, and as the life of a press is usually determined by the life of the main frame, the advantage of this type of construction becomes at once apparent.

The distance from the bed to the slide on the press illustrated is 22 inches, which gives ample room for operating the heavy dies used in redrawing, forming and bending the different parts for which it is intended. Some of the other principal dimensions are: distance between uprights, 40 inches; width of bed front to back, 32 inches; height from floor to center of shaft, 94 inches; ratio of gearing, 8 : 1; total weight, 17,000 pounds. This press is built in six sizes and twenty-four different styles, with a varying width between the uprights to suit any class of work.

The press illustrated in Fig. 2 was designed especially for

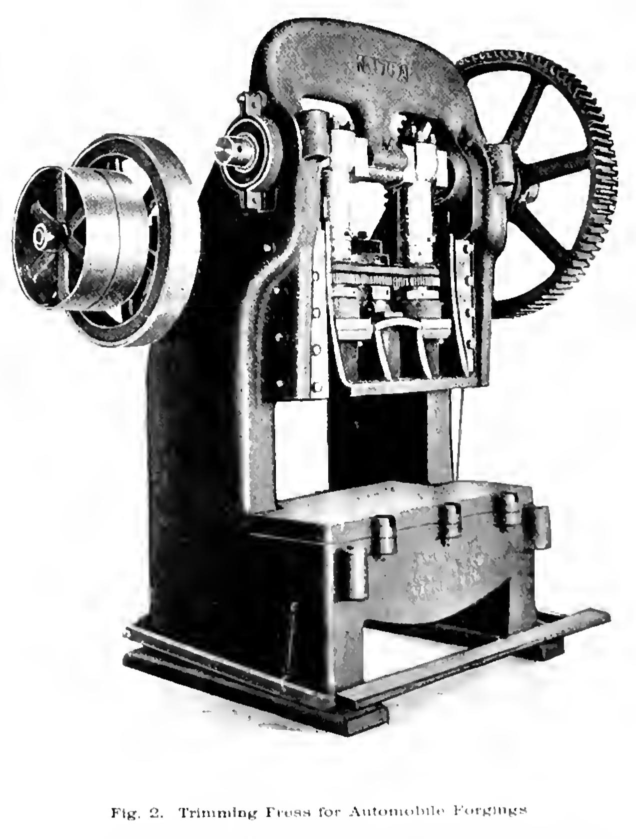

Fig. 2. Trimming Press for Automobile Forgings

trimming the special shapes of forgings used in the automobile industry. While the frame is of the overhanging type, the depth of the throat is not as great as on similar presses intended for working sheets cold, consequently the spring in the frame on heavy work, always so noticeable in machines

of this type when the throat is deep, is entirely overcome. The main frame is cast in one piece instead of in sections, the bed is heavily ribbed underneath, and the crown is exceptionally deep and thick. The section of the housings is made similar to that of a planer housing, instead of following the usual form heretofore used in power-press construction when the frame is cast in one piece. Some of the principal dimensions are: width of bed right and left, 60 inches; distance from bed to slide, 22 inches; ratio of gearing, 8 : 1; total weight, 28,000 pounds. This type of press is built in six sizes classified as to power, and 18 sizes classified by weight, the distance between the uprights being made to suit the work to be performed.

"CISCO" 14-INCH ENGINE LATHE

The accompanying illustration Fig. 1, shows a new 14-inch lathe placed on the market by the Machinery and Equipment Department of the Cincinnati Iron and Steel Co., Cincinnati, Ohio. This lathe is known as the "Cisco" 14-inch quick-change gear engine lathe, and the particular features of the machine are the simplicity of the quick-change gear device, and the exceptionally powerful drive in the apron.

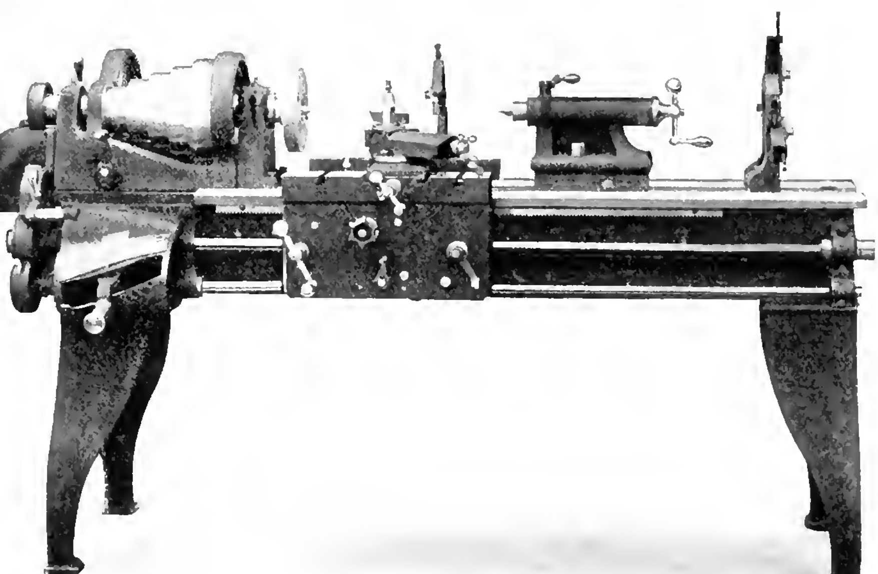

Fig. 1. Fourteen-inch Engine Lathe placed on the Market by The Cincinnati Iron & Steel Co., Cincinnati, Ohio

A view from the end of the headstock is shown in Fig. 2 and a view of the inside of the apron in Fig. 3. This latter illustration indicates the massive construction of this part of the machine. The apron mechanism is worm driven, and provided with a safety device to prevent interference between the lead-screw and the feed-rod drive so that it is impossible to engage the feed rod and lead-screw at the same time. All shafts and studs in the apron are supported at both ends by ample bearings.

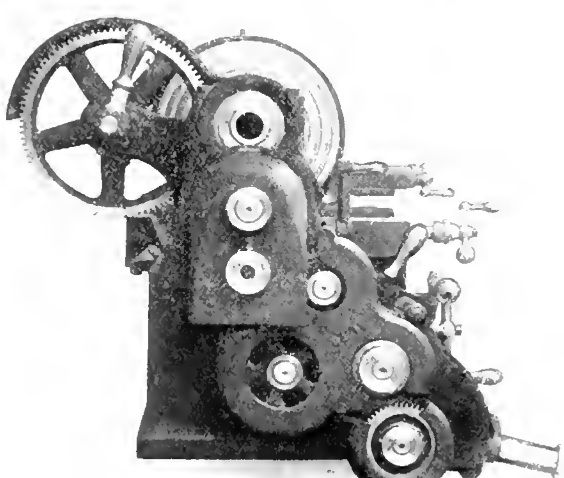

Fig. 2. End View of the Headstock

As will be seen in the illustrations, two levers are used for operating the quick-change gear device by means of which threads from 3 to 32 per inch may be cut. The feed changes possible are 33, varying from 18 to 192 per inch. A positive locking device is provided which makes it impossible to engage two gears at the same time. It will be seen by referring to the illustrations Figs. 1 and 2, that all gears have been very carefully covered in a manner to give the machine a neat and pleasing appearance. Ample oiling facilities and oil pockets have been provided wherever necessary. While the machine is not regularly furnished with the taper attachment, it can be provided with such an attachment at any time, as the carriage has been jig drilled for this purpose, and the application of the taper attachment is a simple matter.

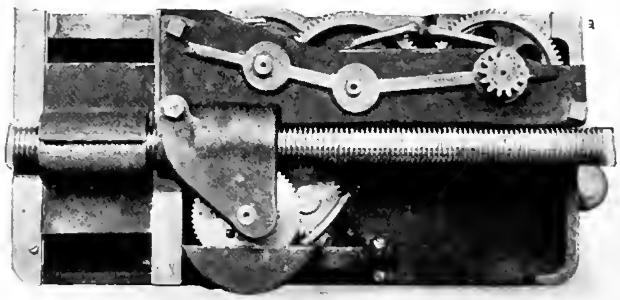

Fig. 3. Construction of the Apron of the "Cisco" Lathe

The headstock is of massive construction. In Fig. 1 the head cone is provided with five steps, but a head cone with four steps can be furnished instead, if required. While the nominal swing of the lathe is 14 inches, the actual swing is 15⅝ inches. A hole is provided through the spindle for stock up to 1 5/16 inch diameter. The bearings are of phosphor-bronze and made amply large, and all the proportions of the machine, including those of the bed and legs, have been made massive and heavy so as to make the machine suitable for the advantageous use of high-speed steel tools. The countershaft provided is equipped with the Nugent friction clutch.

An interesting feature in the lathe is that all studs, screws and nuts have been so selected and their heads milled to such standard dimensions that only two wrenches are required for the entire lathe. This is a great advantage, as considerable time is lost in the ordinary shop in hunting for suitable wrenches for the variety of sizes of nuts and bolt heads frequently found on many machine tools.

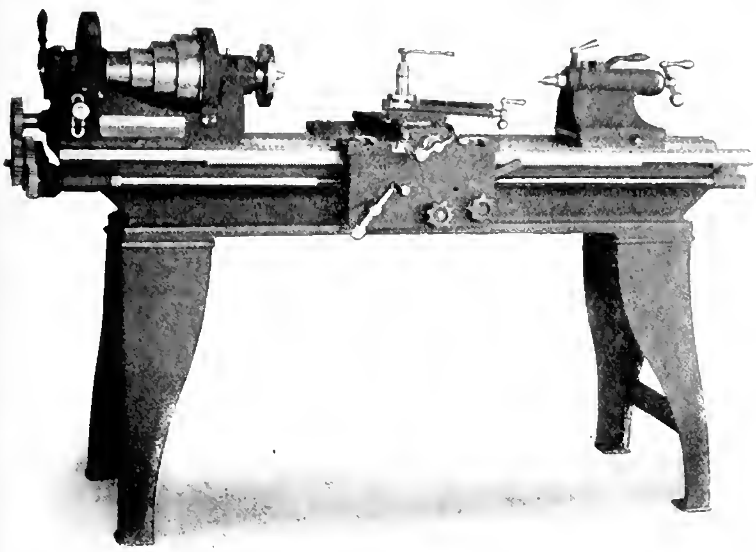
THIRTEEN-INCH "STAR" SCREW CUTTING LATHE

The Seneca Falls Mfg. Co., 330 Water St., Seneca Falls, N. Y., has added a 13-inch lathe to the regular line of machines manufactured. This lathe, shown in the accompanying engraving, is known as the No. 65-E "Star" lathe, and is of the same general design and construction as the 9- and 11-inch sizes built by this company, which were illustrated and described in the September, 1909, issue of MACHINERY.

The actual swing of the lathe is 14⅛ inches over the bed. The length of the bed is 6 feet. The head spindle is made of 60-65-point carbon steel and revolves in large ring-oiling bearings. It is provided with a 1¼-inch hole, and may be fitted with a draw-in chuck with split collets for work from 1/16 to 3/4 inch diameter. The carriage is provide with T-

slots as indicated, and the cross-feed screw is equipped with a micrometer collar to read in thousandths of an inch. All the carriages are arranged for taper attachment, which may be supplied at any time. The plain and compound rests are easily interchangeable, and the same binding device as used on the smaller sizes is employed. The automatic cross and longitudinal feeds are also of the same design as described in the September, 1909, issue. The machine will cut all standard threads from 3 to 72 per inch, including 11½ and 27. When equipped with metric translating gears it will cut international standard metric threads from 0.5 to 8 millimeters lead.

The countershaft is of the same type as supplied with the smaller sizes of "Star" lathes, and all other advantageous features in the smaller sizes are retained. Screws, nuts and small parts liable to become burred or bruised are case-hardened, and ample facilities have been provided to compensate for wear. An additional feature which will be appreciated particularly in shops with limited equipment is the provision of a set of blocking, three inches high, by means of which the head- and tail-stock and the plain, compound and center rests may be raised up to increase the swing of the lathe to 20½ inches.



Thirteen-inch Screw Cutting Lathe, built by the Seneca Falls Mfg. Co., Seneca Falls, N. Y.

CLEVELAND SODA AND POTASH KETTLE

The Cleveland Machine Specialty Co., 202-204 St. Clair Ave., N. E., Cleveland, Ohio, has recently placed on the market a new type of soda and potash kettle for cleaning the parts of disassembled machines. This kettle, which is shown in the accompanying illustration, is heated by gas. The convenience of gas as a fuel will be readily appreciated. The burners are arranged in a fixed position with relation to the kettle, and either natural or artificial gas can be used. The bottoms of the pots are constructed so as to break up the flame in order to distribute the heat rapidly to the solution, thus effecting a greater economy in the consumption of gas necessary to keep the solution boiling. Eye-bolts are attached to the flange of the kettle proper to facilitate handling it when this is necessary.

Cleveland Machine Specialty Co.'s Gas-heated Soda and Potash Kettle

These kettles are made in two sizes, the smallest having a capacity of 10 gallons and the largest 30 gallons. They are meeting with considerable favor among manufacturers of all kinds, according to the makers, which can doubtless be attributed to the convenience of connecting them to the gas supply and also to their economy of operation. Dipping baskets of various sizes are furnished for use in connection with the washing of machine parts.

DIAMOND MACHINE CO.'S POLISHING MACHINE

The Diamond Machine Co. of Providence, R. I., has recently developed a new type of polishing lathe which we illustrate herewith. This machine has been designed to meet the growing demand for a polisher that can be driven by a belt from the floor below, thus doing away with an overhead countershaft and unnecessary belting. The column of this machine is entirely enclosed, as shown, thus giving a rigid construction and at the same time avoiding the danger of interference with the driving belt. The pulleys on the spindle are protected by a cover bolted to the column, which, if desired, can be removed, if for any reason the machine is to be driven from an overhead countershaft. The distance that the polishing wheels project from the column on either side, adapts the machine to a wide range of work. The bearings are long and rigidly supported, as the engraving indicates. A removable cover on the side of the column opposite to that illustrated, provides access to the belt when this is desired, either for inspection or repairs. A removable taper point which may be attached to one end of the spindle is furnished with the machine. The small handle shown projecting from the front of the column, provides convenient means for starting and stopping the spindle. The height of the spindle above the floor is 38 inches, and the total floor space required is 33½ by 54 inches. Polishing wheels up to and including 16 inches in diameter can be easily swung.

Diamond Machine Co.'s New Polishing Lathe which is designed to be driven from the Floor Below

SLOTTING ATTACHMENT FOR MILWAUKEE MILLING MACHINE

The new Milwaukee milling machine, made by the Kearney & Trecker Co., Milwaukee, Wis. (of which the No. 2B plain design was illustrated in the February, 1910, number of MACHINERY), has been provided with an improved form of slotting attachment, herewith illustrated in Figs. 1 and 2. An attachment of this kind may be used to great advantage on the milling machine, particularly in toolroom work, where it will take cuts in boring bars, dies, wrenches, internal gears, key seats, etc., which cannot be done with the milling cutter. The special features of the new design are the simplicity of mechanism, the adjustable stroke, the rectangular ram, the improved tool clamping arrangement, and the adjustable setting of the head to any angle through the whole 360 degrees. The

construction will best be understood from Fig. 2.

The base of the machine K is clamped to the front face of the knee-slide being set down over the dovetail from above, and lined up as shown by the engagement of the top of the recess with the overhanging arm of the machine, which is allowed to project slightly. When thus located, it is clamped in place by gibs in a way similar to that by which the knee is gibbed to the same surface. This arrangement makes the

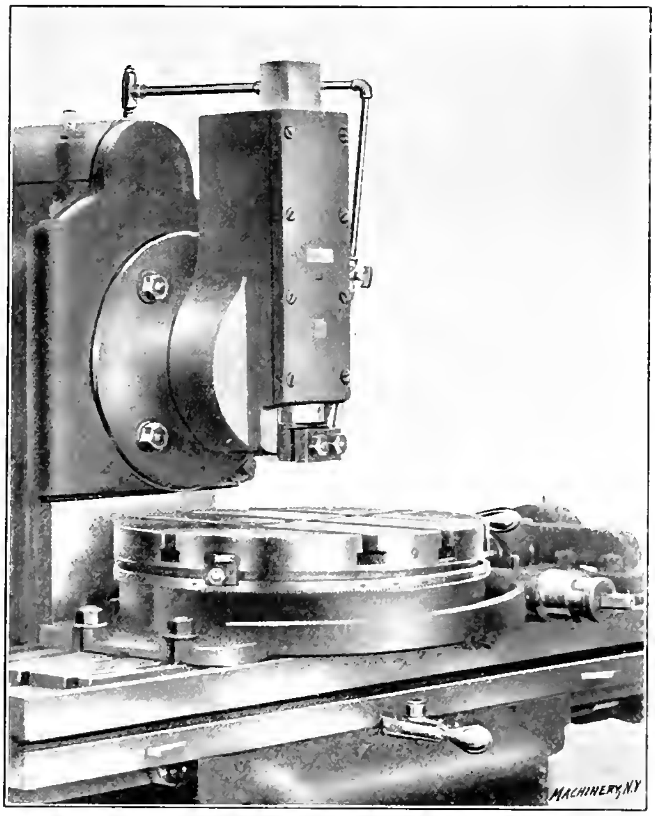


Fig. 1. Slotting Attachment with Adjustable Stroke and Quick Return, for Milwaukee Millers

base of the attachment practically solid with the base of the machine, and thus gives it great rigidity. The extension of the dovetailed knee bearing, on which the attachment is fastened, was designed for the specific purpose of firmly holding this and other similar appliances.

Collar J is fitted directly to the main spindle of the machine. It carries a pivot on which is supported bronze block H, fitting a groove cut in the face of the driving plug E. Plug E and the spindle of the machine are eccentric by a considerable amount, as shown, so that E receives from the spindle a quick return movement of about two to one, in accordance with the principle of the well-known Whitworth

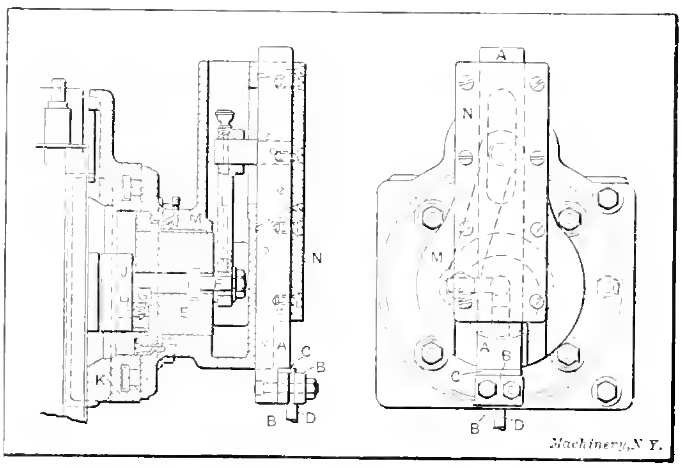

Fig. 2. Section and Face View of Slotting Attachment, showing Construction

quick-return mechanism. The front face of E is slotted for the crank pin F. This is adjusted to or from the center to give a less or greater stroke, being reached with the wrench through an opening in the right side of the attachment. It operates the ram A through the connecting-rod L as shown. The ram A is a rectangular steel bar. This form gives a long bearing in proportion to the width, insuring stiffness and a better alignment. The lower end of the bar is provided with V-blocks BB, and has a hardened piece C to back up the tool.

A convenient improvement in the machine is the provision made for swinging the entire head around a full circle on base K. This adjustment is read from angular graduations, making it possible to set the ram accurately to any position. In the vertical position it may be used in connection with the rotary table for any work requiring slotting and indexing, such as internal gears. When swiveled to the horizontal position, it may be used in connection with the indexing head for similar work, when the rotary table is not available. It is also then useful for work held in the chuck, such as hex or socket wrenches, dies, etc.

The machine is made in three sizes, giving 10½, 11 and 11¾ inches respectively from the center of the tool to the face of the column. The tools used can be of any size from ¼ to ¾ inch diameter, and of any shape, rough or finished. The adjustment of the stroke for all sizes is from 0 to 4 inches. The net weight of the device is 195, 220, and 262 pounds, respectively, for the three sizes.

S. M. HILDRETH CO.'S COLLAPSIBLE STEEL HORSE

A patented collapsible steel horse or trestle has been placed on the market by the S. M. Hildreth Co., 2 Rector St., New York. This horse, which is illustrated herewith, will be found very convenient in a machine shop or, in fact, anywhere that a device of this kind is used. It is light in weight but very strong and rigid, being constructed of steel angles throughout. The steel construction precludes any chance of breakage, even under heavy weights, and insures a long life. The collapsible feature of this trestle, makes it very convenient for handling and transporting, and the very

A Collapsible Steel Trestle, or Horse, Folded and Ready for Use

small amount of space which it occupies when not in use is undoubtedly its most valuable feature. The upper engraving shows how compact the trestle is when folded ready for storing. Anyone who has had experience with trestles of the rigid type, will readily appreciate the compactness of this new design. Obviously, these trestles may, if desired, be checked out from the tool or stock-room the same as with other tools. These horses are manufactured in various sizes to adapt them for any purpose required. The manufacturers also intend to bring out a type which may be raised or lowered to various heights.

ROCKFORD HAND MILLER AND ATTACHMENTS

The Rockford hand milling machine, herewith illustrated and described, is made by the National Machine Tool Works, of Rockford, Ill. The machine itself is of interest in a number of ways, particularly in the combination lever and screw feed provided. Its interest and usefulness are increased, however, by the line of attachments furnished. Two of these, the slotting and vertical milling attachments, are here illustrated.

In Fig. 1 the machine itself is shown; it is of the familiar column and knee type, set on a substantial base with a tool cupboard. Adjustable micrometer stops are provided for the vertical movement of the knee on the column. This movement is effected by a lever, keyed to a rack and pinion for quick operation. The longitudinal motion of the work-table is also provided with stops, which bring up solidly against a post attached to the saddle. The combination screw and lever feed for the table is plainly shown in the engraving. It consists of a worm-gear keyed to the shaft on which the hand lever is mounted, meshing with the feed-screw of the table. Means are provided for clamping this worm-wheel fast, in which case the feed-screw may be run out and in over it the same as through the usual stationary feed nuts. When it is desired to handle the table with the lever, the worm-wheel is unclamped. Under those conditions it operates as a gear, meshing with the double thread screw as though the latter were a rack, thus making provision for quick operation of the longitudinal feed.

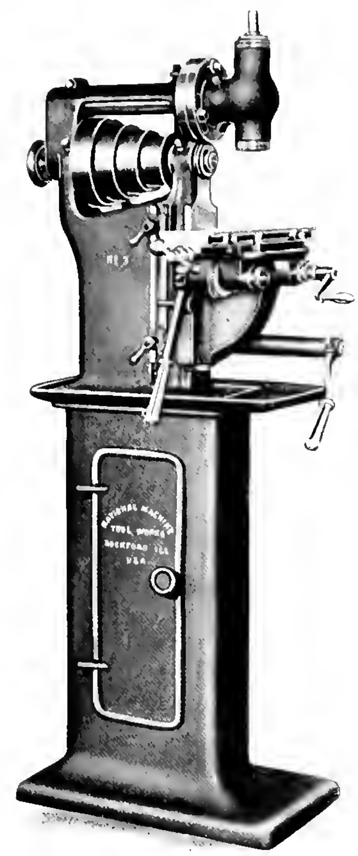

Fig. 1. Hand Miller with Combination Screw and Lever Feed; Vertical Attachment shown in Place.

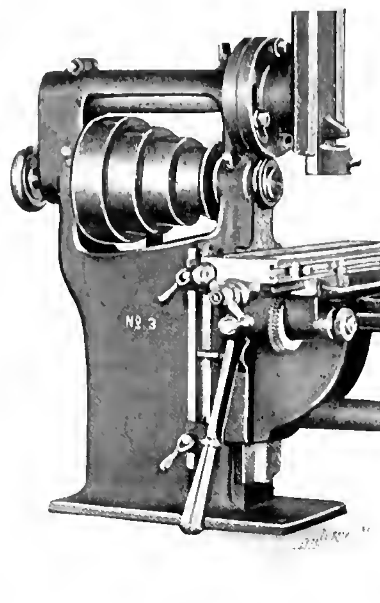

Fig. 2. Stiffening Flange for Overhanging Arm, Clamped to Attachment Flange on Column

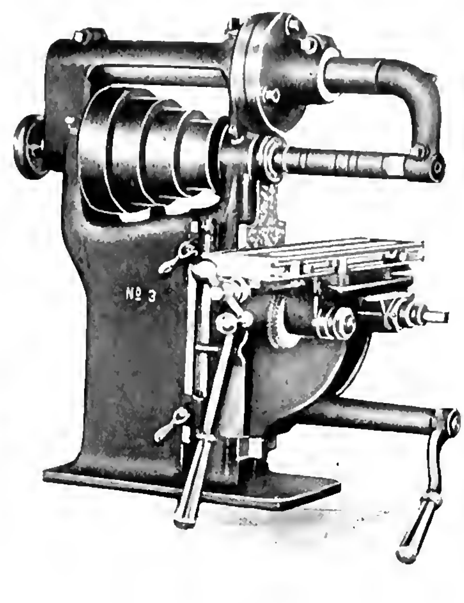

Fig. 3 Rockford Hand Miller, fitted with Slotting Attachment

The spindle of the machine is provided with a draw-in tube for collets of any size up to ¾-inch hole. A collet is also furnished bored to the No. 7 Brown & Sharpe taper, for holding end mills, drill chucks, etc. The overhanging arm, as shown in Fig. 2, has a stiffened flange or plate mounted on it, and screwed fast to a corresponding flange cast solid with the machine. This extends out 3½ inches on the overhanging arm, and serves to support it more thoroughly.

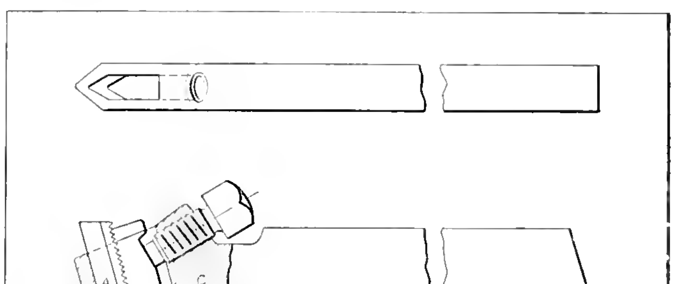
While this flange on the column serves, when clamped to the plate, to stiffen the the outboard arbor support, it was not primarily designed for this purpose. As shown in Figs. 1 and 3, its regular function is to serve as a base for the vertical and slotting attachments. The vertical attachment is shown mounted in Fig. 1. The spindle of this is driven by bevel gears from a horizontal shaft, extending to the back of the machine through a sleeve in the seat for the overhanging arm. Here it is connected with spur gears for the rear end of the spindle. This sleeve is made so that it can be slipped out from the back end in an instant. It is held in place by the rear clamping screw, which tightens the overhanging arm.

The advantage of this construction is that a very rigid support for the vertical spindle is furnished, and at the same time it is set high enough so as not to materially lessen the vertical capacity of the machine. The flange of the base is graduated in degrees, so that the head may be set to any position desired for angular cuts, by loosening the three clamping screws and adjusting as required. The same draw-in collets and taper socket are furnished as for the main spindle of the machine. The spindle thus holds end mills, drill chucks, etc. It is possible on some work, indeed, to use both the horizontal and vertical spindles simultaneously. The attachment has been found well adapted to jig work, as both the cross and longitudinal feeds of the table are accurately graduated to thousandths of an inch.

The slotting or shaping attachment shown in Fig. 3 has been found useful for cutting keyways, planing out dies, etc. It is clamped to the column in the same way as the vertical milling attachment in Fig. 1. It has a 2-inch stroke, and takes tools with ½-inch round shanks. These may be set with the cutting edge on any side, and the whole attachment may be swiveled round to any angle. The device should be especially useful for die sinking and similar work, as it permits cutting to a line scribed on the top of the work where it is always in sight, and so runs no risk of being under cut and destroyed. The same connection with the rear end of the main spindle of the machine is made as in Fig. 1.

"READY" STRAIGHT THREADING TOOL

The accompanying illustration shows an improved threading tool, which is being placed on the market by the Ready Tool Co., of New Haven, Conn. As may be seen, it is of the inserted blade type, and is very simple in construction, there



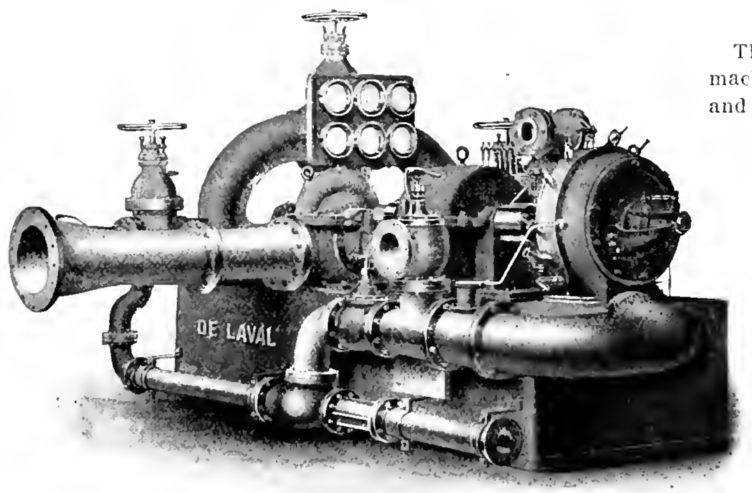
Thread Tool Holder with Improved T-Head Clamping Block

being but three parts to it besides the blade. The holder is straight and flush on both sides with no projections, presenting a very neat appearance. The blade *A* is adjustable, being provided with ratchet teeth on its rear face which engage corresponding teeth in the face of clamping block *B*, which thus serves to lock it under the pressure of the screw *C*. The clamping block is held in position by its T-head (not clearly shown in the engraving, which keeps it from dropping

through the slot, and thus in turn supports the blade against the pressure of the cut. The screw holds the V of the blade wedged in the V-slot broached out in the holder to receive it, thus binding the blade and holder firmly together. The tool will also be furnished with the offset form of shank if required.

SELF-CONTAINED TURBINE PUMPING ENGINE

The improvements made in centrifugal pumps and steam turbines during recent years have made possible a very efficient combination of both, which compares favorably as to size, cost, simplicity and steam consumption with reciprocating pumps. This combination also has an advantage over the reciprocating unit in cases where a pump is required to work against different pressures, which requirement is easily met with good steam economy by a turbine-driven multi-stage centrifugal pump, properly arranged for series and parallel



DeLaval Self-contained Pumping Engine

operation. A pump of this type is shown in the accompanying half-tone illustration. It consists of two 10-inch De Laval double suction centrifugal pumps, driven by a De Laval steam turbine, and arranged so that the pumps can be operated either in parallel or series, thus covering a range of operation from a normal delivery of 7,550 gallons per minute against a 50-foot head, to 2100 gallons per minute against a 175-foot head. The pumps are operated in parallel up to a head of 80 feet, and for higher heads in series.

As will be seen from the illustration the pump, turbine, condenser, and accessories are mounted compactly on a box-shaped bed-plate of moderate size. The condenser is of the ejector type, receiving the injection water under considerable head from the first pump, so that a good vacuum is possible with simple and inexpensive apparatus. If it is desired to shut off the condenser at any time the unit can be operated non-condensing by closing the water check valve in the exhaust pipe, so that the steam escapes through the exhaust relief valve.

The exhaust pipe contains a speed limiting device which prevents the turbine from running away in case of failure of the main governing valve. This emergency speed-limiting device consists of a butterfly valve in the exhaust pipe normally held open by a spring, but controlled by a piston. If the turbine exceeds a certain speed, a governor on one of the gear shafts will open a valve admitting air behind the piston, which will then turn the butterfly valve to a position athwart the exhaust steam pipe. As soon as the speed is checked, the air will leak from the cylinder into the exhaust pipe, so that the valve will resume its normal position.

As will be seen, all gages have been brought together upon a gage board attached to the piping connecting the two pumps. The six gages show the steam pressure on the turbine throttle, the steam pressure above the nozzle, the water pressure in the pipe lines, the suction lift, the water pressure in the injection pipe to the condenser, and the vacuum.

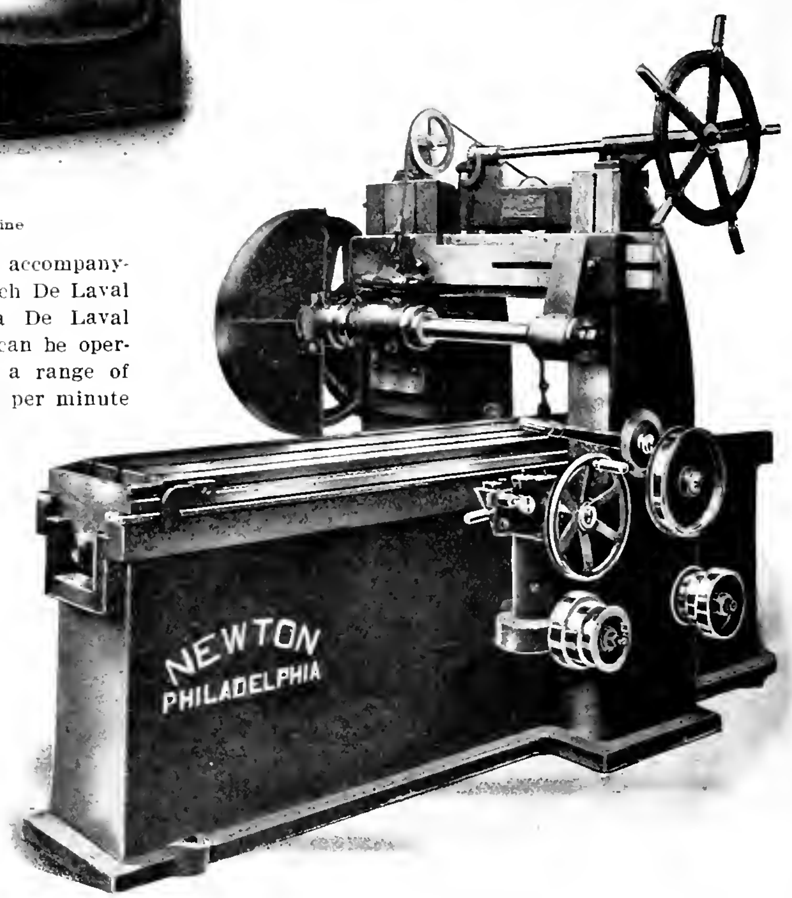
The lubrication is furnished from a central multiple oiler mounted on the gear case of the turbine, the oil from this lubricator being used for the high-speed bearings, gears, and governor pins. All oil from these points is carried to a common reservoir in the bed-plate and from there pumped to a filter from which it flows back to the central multiple oiler.

The unit, which is built by the De Laval Steam Turbine Co., Trenton, N. J., is very compact and is self-contained so that it is only necessary to connect it with the steam and water piping and place it on a suitable foundation, which latter need not be very heavy, due to the fact that there is practically no vibration.

NO. 1 NEWTON HORIZONTAL MILLING MACHINE

The accompanying engraving shows a horizontal milling machine, made by the Newton Machine Tool Works Inc., 24th and Vine Sts., Philadelphia, Pa. This design is provided with an improved spindle bearing which gives the cutters an axial adjustment, which can be accurately gaged by a screw control. The bearing is mounted for this purpose, as shown, in an auxiliary slide.

The machine is strongly built, and is intended for the rapid milling of small duplicate parts. The spindle, saddle, and cross-rail form an integral casting, giving the machine advantages in this respect



A Horizontal Milling Machine for Manufacturing Operations

over the column type with which it is offered in competition. Provision is made for supporting the outer end of the arbor by a saddle fitting the cross-rail, insuring accurate alignment at all times. The outboard support has a bearing with parallel internal and taper external surfaces, with adjusting nuts to compensate for wear.

There are six changes of belt feed for the table, with automatic release, hand adjustment and power quick return; the latter is controlled by the friction disks and operating lever shown at the front side of the machine. The spindle is 3½ inches in diameter, with a maximum capacity for cutters up

to 7 inches in diameter. The work table is 14 inches wide, with an extra inch between the uprights. The maximum distance from the center of the spindle to the top of the table is 15 inches. The table is long enough to take cuts 48 inches long, and is entirely surrounded by an oil tank.

The builders have found a wide demand for this machine on work which had previously been done on the standard column and knee type miller.

GARVIN VERTICAL MILLING ATTACHMENT

The accompanying halftone and line engravings illustrate a vertical milling attachment, made by the Garvin Machine Co., New York City. It is shown in Fig. 1 applied to the maker's No. 2 universal milling machine. This attachment is unusual,

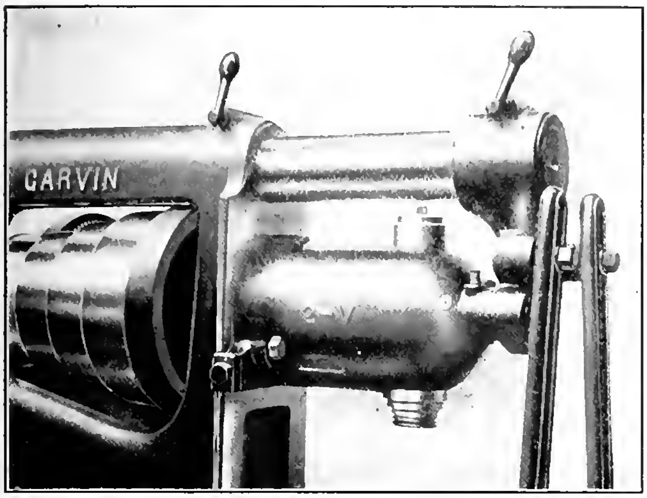


Fig. 1. Rugged Attachment for Vertical Milling Exclusively

in that no provision is made for swiveling the vertical spindle about the horizontal axis of the machine. This adjustment was dispensed with because it is seldom required. Its abandonment has resulted in giving this attachment much greater rigidity and capacity, as it makes possible a substantial decrease in the number of joints and connections necessary.

Referring to the reference letters in Fig. 2, in connection with Fig. 1, it will be seen that the casing of the attachment and the support on the face of the milling machine column, are made in one piece, shown at *A*. This casting is clamped to the column by the three bolts *B*, and is supported at its outer end by a pivot closely fitting the regular outboard support of the machine. While this, as explained, does not regularly provide

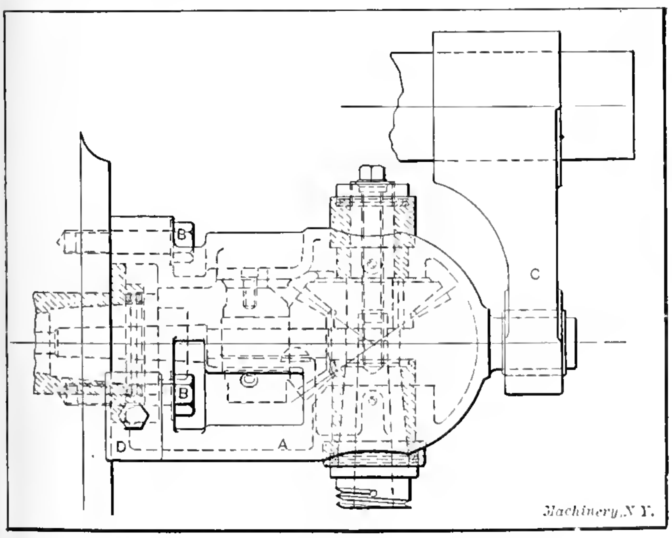

Fig. 2. Section of Garvin Vertical Milling Attachment

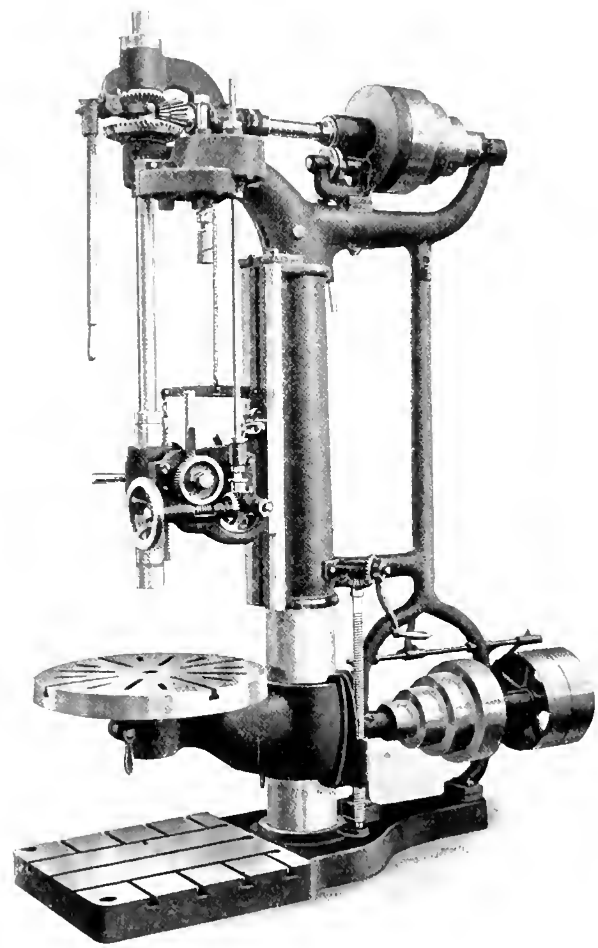
for swiveling the spindle away from the vertical, provision is nevertheless made for tipping the spindle very slightly in other direction, to prevent dragging of the cutting edges on the back side of the cutter. Bolts *B* are a little loose in their holes, permitting the spindle to be rocked slightly to the right or left. This rocking adjustment is controlled by clamps *D*, which engage the V's on either side of the front face of the column, and swing the attachment slightly one way or the other, depending on which side is screwed down. It should be noted that the body *A* of the device is made cylindrical, with spherical end, so as to give the operator an unobstructed view of his work.

This attachment is driven by miter gears, having a coarse pitch and strong teeth. The spindle is ground, having a No. 10 Brown & Sharpe taper hole for the arbor or cutter shank; it is provided with a draw-in rod for holding the cutters in place. The lower bearing is taper, running in a solid self-oiling bronze box. The upper bearing is straight, running in an adjustable bronze box, provided with a take-up nut for end motion. The nose of the spindle is threaded to the standard $2\frac{1}{2}$ inch diameter, four pitch, left-hand V-thread. The attachment is made in two sizes, and may be applied to many sizes or styles of the makers' milling machines.

MECHANIC'S MACHINE CO.'S NO. 32 UPRIGHT DRILL

The accompanying illustration shows a new No. 32 upright drill, made by the Mechanic's Machine Co., of Rockford, Ill. The tool, as may be seen, is of the sliding head design, and is



An Upright Drill with a Simple Design of Tapping Attachment and Geared Feed

notable for the simplicity of the tapping attachment and the provision of geared feed changes. A back-gear device of the internal type is also furnished.

Referring to the engraving, the construction of the tapping attachment will be plainly understood. Its construction is the most direct possible, as only two gears are used in addition to the ordinary crown gear and pinion; these two are simply an additional crown gear and pinion for the reverse movement, the ratio of which is such as to give the desired return. The reverse crown gear is made from steel, and is provided with a large hub, bored out to sufficient size to furnish a bearing for the clutch sleeve in it. This gives a chance to use a very long and durable clutch sleeve, and one which will not be cramped under any conditions. This sleeve is

made from steel, but is surfaced on the outside with hard bronze to give a good bearing in the steel gear.

The enclosed gear feed mechanism gives the eight changes, varying from 0.005 to 0.062 inch per revolution of the spindle.

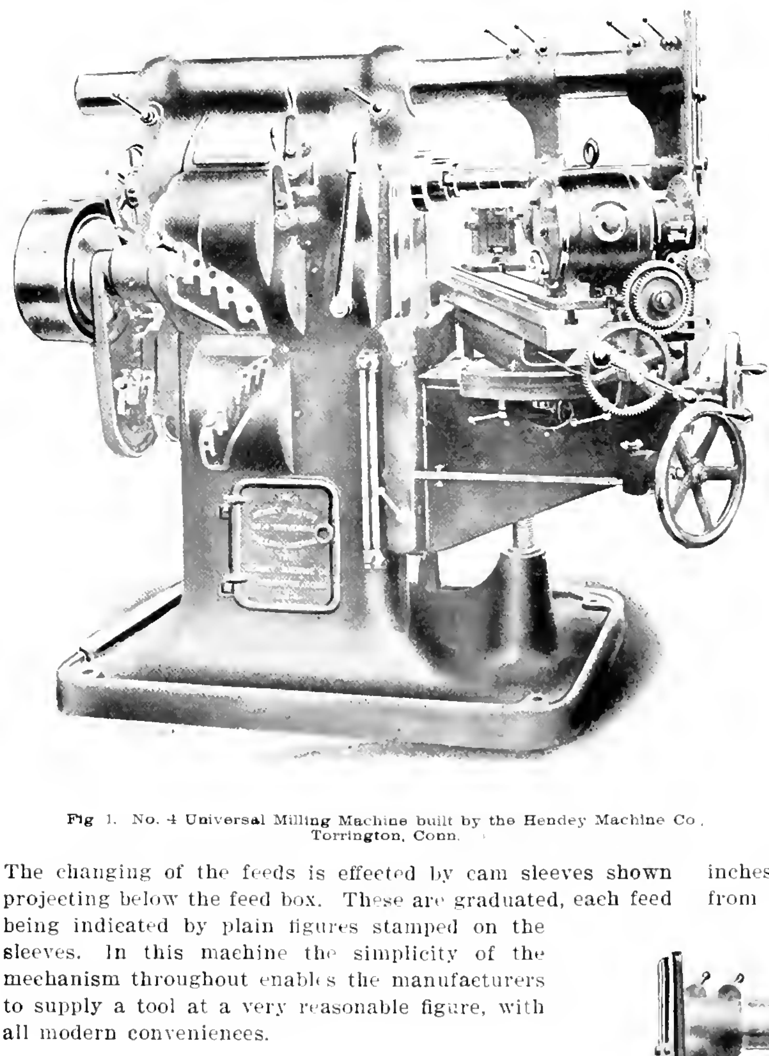


Fig. 1. No. 4 Universal Milling Machine built by the Hendey Machine Co., Torrington, Conn.

The changing of the feeds is effected by cam sleeves shown projecting below the feed box. These are graduated, each feed being indicated by plain figures stamped on the sleeves. In this machine the simplicity of the mechanism throughout enables the manufacturers to supply a tool at a very reasonable figure, with all modern conveniences.

HENDEY NO. 4 UNIVERSAL MILLING MACHINE

A universal milling machine, known as the No. 4 G.-S. type has recently been brought out by the Hendey Machine Co., Torrington, Conn. The right and left sides of the machine are shown in the accompanying illustrations. In designing this machine the same general construction has been followed as is employed in the No. 4 plain gear-driven milling machine built by the same company, which was mentioned in a note in the July, 1909, issue of MACHINERY. The object aimed at in designing this machine has been to provide ample power and a wide range of spindle speeds and feeds, and at the same time produce a machine of simple construction. There are but few and easily understood movements required for the various feed changes, the gearing for which is arranged according to the same system as has been applied so successfully on the Hendey-Norton lathes. The number of spindle speeds obtainable are 15, and the range of spindle speeds obtainable through the back-gears is from 12 to 106 revolutions per minute, while the range obtainable through the geared cone is from 134 to 350 revolutions per minute. The feeds are positive and obtained through chain and sprockets. There are 21 feed changes, ranging from ¼ to 25 inches of table travel per minute. The feeds are all automatic and can be operated simultaneously, and reversed while the machine is in motion. The longitudinal travel of the table is 35 inches, the transverse travel 12 inches, and the vertical travel 20 inches. All feeds are provided with safety trips. The total dimensions of the table are 60½ by 15 inches, the working surface being 55½ by 15 inches. The table is provided with three ¾-inch T-slots.

The dividing head is of very heavy construction. The frame furnishes annular bearings for side plates which, in turn, serve as trunnions for carrying the center block of the head; the spindle is provided with taper journals on both ends. The nose of the spindle is made with a clutch driving collar, and furnished with a draw-in bolt. The swing of the index centers is 15 inches, the maximum distance between the centers being 31 inches. The front plate on the index head, intended for direct indexing, has three rows of holes, with 24, 30 and 36 holes, respectively. The plunger pin for these holes is carried on an eccentric shaft graduated to indicate the row of holes engaged with. Only one side plate for the wormwheel indexing is required, this plate being reversible and having nine circles of holes on each side, running from 15 to 49 holes per row, the intermediate numbers being according to the usual system. The indexing crank rotates on its pin when marking spacings, and is provided with a snap catch which holds it free from the plate when indexing. The worm in the index head runs in an oil bath, and an adjustable stop is provided to regulate the proper engagement between the worm and wormwheel.

The general dimensions of the machine are as follows: The taper hole in the end of the spindle is a No. 12 Brown & Sharpe taper; the straight hole through the spindle is 1⅜ inch, and the diameter of the nose of the spindle 3½ inches, with three triple left-hand threads per inch. The width of the driving belt is 5 inches, the diameter of the driving pulley 16 inches, and its speed 350 revolutions per minute. The distance from the center of the spindle to the overhanging arm is 8⅜ inches, and the distance from the end of the spindle to the center in the arbor support is 28 inches. The floor space required is 108 by 117 inches and the net weight is 6900 pounds.

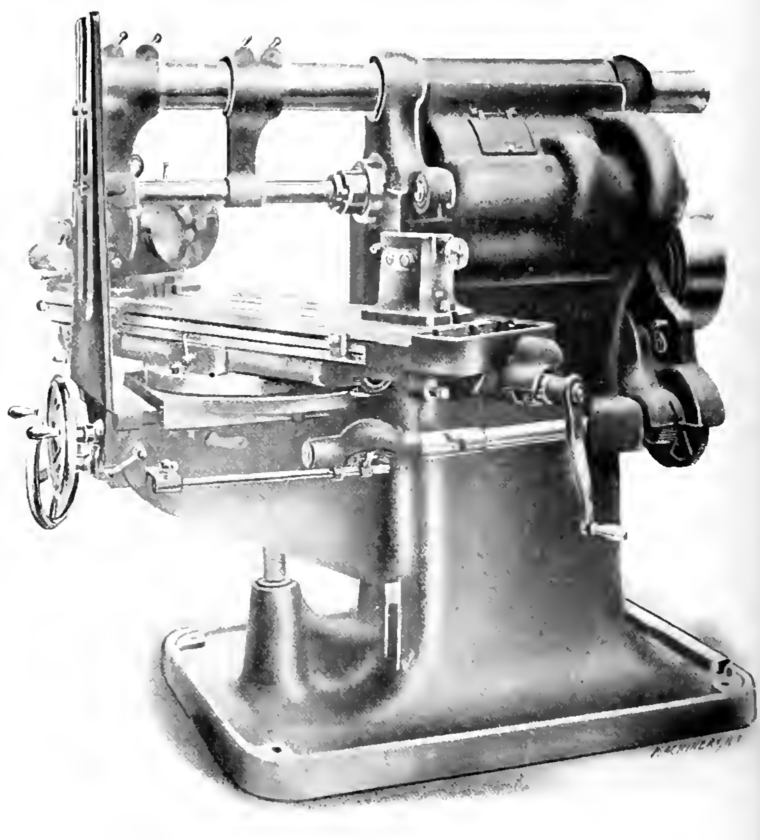

Fig. 2. View of Universal Milling Machine showing General Arrangement of Feed Mechanism

IMPROVEMENTS IN THE WOODS UNIVERSAL TOOL AND CUTTER GRINDER

In the March, 1908, number of MACHINERY, we illustrated and described a very complete tool and cutter grinder made by the Woods Engineering Co., Alliance, Ohio. This machine has since been improved in a number of particulars, resulting in the new design herewith described and illustrated.

Fig. 1. Improved Design of Woods Universal Tool and Cutter Grinder

The principal change consists in providing for the angular adjustment between the wheel and work, by swiveling the wheel-head instead of the work-table. This results in a marked increase of rigidity, as the column can now be made solid instead of having the split sleeve construction previously required. Less floor space is needed as well, the work-table being always in the same position. For the same reason it is now at all times directly under the countershaft, to which it can always be belted for driving the work in cylindrical grinding.

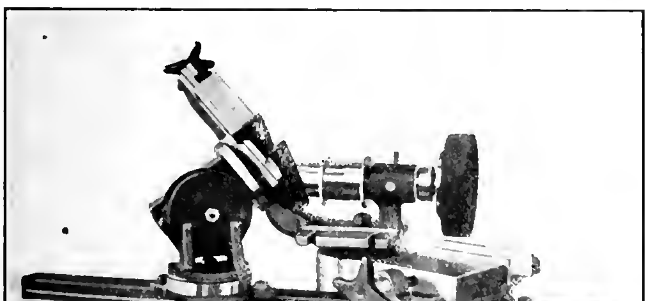

Fig. 2. Three-swivel Mounting for Vise, permitting Universal Adjustment

Another improvement relates to the vise, which is now made to fit on the headstock. This is shown most plainly in Fig. 2, where it will be seen that the new arrangement gives the vise three swivels, making it strictly universal and capable of holding work in any conceivable position. The vise also fits the base of the headstock, bringing it close to the table for surface work. The other attachments have been simplified and at the same time improved so as to give them a wider range of action and more varied uses.

As seen in Fig. 1, handwheels have been supplied for all the movements. They are placed so that the operator can control them all without shifting from his natural position. All the working parts are easily accessible for cleaning, and adjustments are provided throughout for wear, allowing the original accuracy of the machine to be preserved for a long period of time. In other points the good features of the original design have been preserved.

The longitudinal travel of the machine is 22 inches, and the cross-feed is 7½ inches. The vertical adjustment is 9 inches. It will take 22 inches between centers and swings 9 inches over the table. A full outfit of wrenches, dogs, tool-rests and attachments is provided, together with wheels suitable for the work of the machine. The weight without countershaft is about 700 pounds.

GENERAL ELECTRIC ALTERNATING CURRENT GRINDING AND BUFFING EQUIPMENT

The General Electric Co., Schenectady, New York, has brought out improved types of alternating-current buffing and grinding equipments designed for use in wood-working shops, machine and repair shops, foundries, etc., where alternating current is available.

The grinding equipment, as shown in Fig. 1, consists of an alternating-current motor with substantial supports, fitted with tool-rests and water attachments. These latter accessories are rigidly clamped to the bearing brackets, and can be easily removed if required. Each end of the extended shaft is provided with two steel flanges, two leather washers and one nut for clamping the emery wheels securely in position. The motor is absolutely enclosed, so as to be thoroughly dust-proof, and the shafts, bearings and attachments have been designed with a view of making the device able to withstand hard and constant usage.

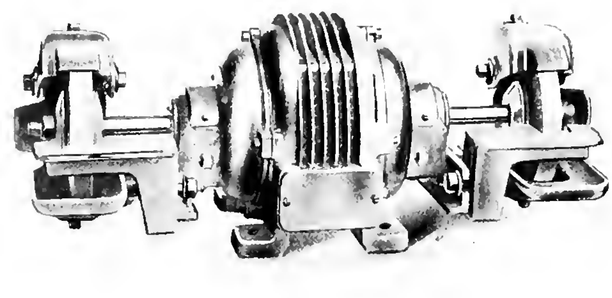

Fig. 1. Motor-driven Grinding Equipment built by the General Electric Co, Schenectady, N. Y.

The self-contained buffing equipment shown in Fig. 2 provides a very efficient polishing device, similar in construction to the grinding outfit, with the exception that the tool-rests and water attachments are omitted. The shaft is also made longer, and each end is tapered and threaded for receiving the buffs. The bearing brackets are circular and so designed that they may be turned through 90 degrees to admit of side wall installation.

The motors can be furnished for operation on either single-, two-, or three-phase circuits of 110 or 220 volts. The single-phase motors are of ¾, 1, 2 and 3 horsepower capacities, and the polyphase motors of ¾, 1, 2, 3, 5 and 7½ horsepower capacities.

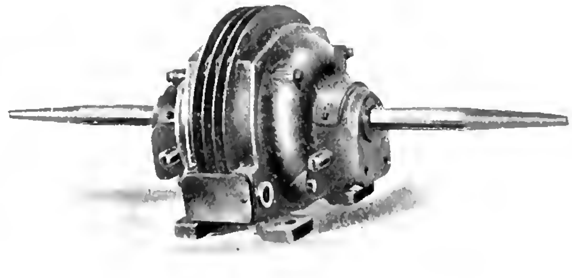

Fig. 2. Buffing Equipment of the same General Design as the Grinding Equipment in Fig. 1

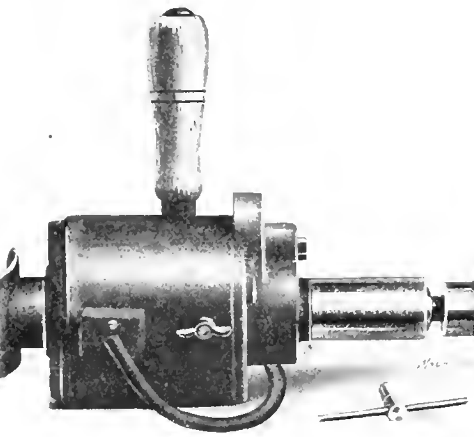
WILLEY PORTABLE ELECTRIC BREAST DRILL

The portable breast drill shown in the accompanying engraving, made by the Willey Machine Co. of Jeffersonville, Ind., is of the same general type, but of an improved design,

as compared with the drill made by the same company and illustrated and described in the November, 1908, issue of MACHINERY. Instead of having the power transmitted by only two gears as in the previous design, four gears are used, this construction being more advantageous. The gears are all cut from a solid steel bar. A system of air ducts in the frame provide for ventilation and cool running of the motor.



Improved Portable Electric Breast Drill built by the Willey Machine Co., Jeffersonville, Ind.

The tool is made in three sizes, having a maximum capacity for drilling 3/8, 1/2 and 3/4-inch holes in steel. The motors, as mentioned in the previous description referred to, are wound for either direct or alternating current and for any voltage up to 250.

* * *

NEW MACHINERY AND TOOLS NOTES

MACHINIST'S HAND-SCREW OR CLAMP: Tower & Lyon Co., 95 Chambers St., New York City. This is a clamp designed on the familiar lines of the wood-worker's hand-screw, but made of sheet steel pressed to shape, with steel screws. The construction is stiff and durable.

CORUNDUM OILSTONES: American Emery Wheel Works, Providence, R. I. This line of oilstones is made in five different sizes (4, 5, 6, 7 and 8 inches long, respectively), and in three grades, coarse, medium and fine. The stones are impregnated with vaseline, so that they are practically self-lubricating.

"CORUBIN," A NEW ABRASIVE: Goldschmidt Thermit Co., 90 West St., New York City. This is a material which has been extensively used abroad as an abrasive, but has only recently been introduced in this country. It is a by-product formed in the manufacture of chromium by the thermit process. It is supplied in three grades, coarse, medium and fine.

DUPLEX MILLING MACHINE FOR PISTON RINGS: Ackley & Abbey Machine Co., Battle Creek, Mich. This tool is designed for milling lap joints in piston rings used for automobile and other engines. Both sides of the ring are cut and jointed in one operation. Pneumatic devices are provided for clamping the work, making the operation of the tool exceedingly rapid. It will cut and joint 4-inch rings, 5/16 inch wide, at the rate of 400 per hour.

"COLUMBIA" VERNIER CALIPER WITH DEPTH GAGE ATTACHMENT: E. G. Smith Co., Columbia, Pa. A recent addition to this line of calipers provides jaws for inside measuring, agreeing with the setting of the regular jaws, and provides also a depth gage connected with the sliding jaw and read to the same graduations. Outside, inside and depth measurements can thus be taken simultaneously at the same reading. This tool is furnished with a number of different styles of graduations.

SPECIAL MILLING MACHINE FOR ANGLE SLOTS IN PISTON RINGS: Ackley & Abbey Machine Co., Battle Creek, Mich. This special miller is provided with a work-table, set at an angle of 45 degrees, and provided with an air clamp for rapidly grasping or releasing the work. Rings up to 8 inches in diameter may be cut. These are located by suitable plugs on the angular table. The machine is operated by two hand levers, which make possible rapid manipulation and consequent high output.

INTERCHANGEABLE BLADE SCREW-DRIVER: Tower & Lyon Co., 95 Chambers St., New York City. This screw-driver has a wooden handle, reinforced with a steel shank, and provided with a spring pin for retaining the various screw-driver blades furnished with the set. These are of two kinds, round and square, and of two diameters for each style. Various lengths are furnished from 1 to 36 inches, for work under a wider variety of conditions. The square shanks of the blades adapt them to be used in bit braces also.

ARBOR PRESS: Cleveland Machine Specialty Co., Cleveland, O. This arbor press is of improved design, particularly in the matter of the shape of the main casting, which is of box section, giving great strength for the weight. The No. 3 machine has a capacity for arbors up to 1 1/2 inch diameter and work up to 12 inches diameter by 12 inches high. It will exert the pressure of three tons with ordinary effort, and has a net weight of 108 pounds. It can be mounted on the lathe or bench, or can be provided with a special pedestal.

OIL AND GAS FURNACES: Strong, Carlisle & Hammond Co., Cleveland, O. These furnaces are furnished in a wide variety of styles, adapted for all metal working purposes, both for regular and special work. They are made to be fired with either natural gas or oil. Two convenient designs for general use are a heating, annealing and tempering furnace with a pre-heating oven; and an oil tempering furnace with an oil burner. These furnaces are especially noteworthy for their very convenient arrangement and attention to detail in design.

DRAW-IN CHUCK ATTACHMENT FOR LATHES: Cleveland Chuck Co., Cleveland, O. This is a draw-in attachment of the adjustable jaw type, adapted to be applied to existing screw machine and turret lathes, or to engine and speed lathes provided with hollow spindles. The working parts are hardened and ground. The device will be furnished with either three or four jaws, or with stepped or special jaws for special work. Its wide adjustability gives it a great advantage over the usual construction of spring collets of one size each and limited adjustment.

BALL TURNING DEVICE FOR LIBBY TURRET LATHE: International Machine Tool Co., Indianapolis, Ind. This device is adapted to be used in place of the regular cross-slide tool-post on the Libby turret lathe, and is connected with the regular power cross-feed without alterations. The tool-post is mounted on a swivel table, which may be rotated by hand or power to turn balls from 2 to 12 inches in diameter. Stops are provided for locating so that the axis of the swivel motion will coincide with the center line of the spindle. The tool-post is of the turret type and can be locked in two positions, one for roughing and one for finishing.

IMPROVED HANDLE FOR HACK-SAW FRAMES: Simonds Mfg. Co., Fitchburg, Mass. This firm's line of straight cut hack-saw frames for blades from 8 to 12 inches inclusive, is now furnished with a gutta percha handle in shape resembling a regular saw handle, reaching from the frame proper down to the saw itself. The sides are checkered to make the grasp surer. Brass screws are used to connect the handle and the frame. The metal parts are polished with nickel, and the blades may be used in any one of four directions. This improved handle gives a firm steady grasp, and results in corresponding efficiency in the use of the tool.

MOTOR-DRIVEN MANUAL TRAINING LATHE: F. E. Reed Co., Worcester, Mass. This lathe is driven by a one-half horsepower motor, mounted in a cabinet leg beneath the bed. It is so supported that the tension of the belt can be easily adjusted. The headstock is mounted on an overhang of the bed, permitting a direct cone pulley drive from the armature spindle. A faceplate is provided at the back end of the lathe spindle for turning large diameters. A shelf beneath the bed and one at the back, furnished with the lathe, afford place for work and tools. The lathe swings 12 inches and, with a 4 foot bed, will take 24 inches between centers.

DUENKEL RECIPROCATING METER: Mechanical Instrument Co., 120 Liberty St., New York City. This instrument positively measures the number of linear feet traversed by any reciprocating machine member, and can thus be used to check the working life of such parts as piston rings, rods, packings, pump valves, elevator cables, etc. In its application to pumps, it would evidently be useful, in addition, in giving an indication of the number of gallons of water delivered. The recording dial is driven by reversing and clutch mechanism, which operates the hand continuously in one direction, both on the forward and on the back stroke of the reciprocating parts.

MOTOR-DRIVEN DIE SLOTTER: Garvin Machine Co., Spring and Varick Sts., New York City. The slotter has a motor bolted to the side of the column and directly belted to the regular driving pulley, so that practically no change is required in the machine itself. Cross, longitudinal and vertical adjustments of the table are provided and a rotary table is furnished as well, adapting the machine especially to working out the shapes found in die cutting. The head may be adjusted to the proper angle for the draft or clearance. The stroke is 2 1/2 inches, and the machine runs from 29 to 87 strokes per minute. The weight of the machine is 1,480 pounds.

"SHARPEN EZY" COLD CHISEL: H. D. Smith & Co., Plantsville, Conn. This chisel is drop forged to special shape. The body of the tool is fluted, allowing a comfortable grip and preventing the tool from slipping in the hand. The head, of course, is solid. The blade is shaped so as to be easily sharpened and is tempered for its full length instead of only for about one-half inch from the point as with the ordinary hand-made tool. It does not then have to be redressed from time

to time, and as it can be used clear up to the body, its life is a long one. Each tool is tried under a sledge hammer test before marketing. It comes in four sizes with blades from 3/8 to 3/4 inch wide.

Punching and Shearing Machines: Carpenter-Kerlin Gear & Machine Co., 77 White St., New York City. This line of machinery is built in different forms—either as a shear for angles, squares and rounds alone, or combined with a plate shear or with a punch. It is built in several sizes, the largest of which will punch a 2-inch hole in a 1 9/16-inch plate, shear rounds up to 3 inches diameter, angles up to 7 by 3/4 inch, and other sections in proportion. High grade material is used, steel castings being employed throughout with shafts of tempered steel, running in phosphor-bronze or cast iron bearings, depending on the service. A motor drive may be easily applied to this machine.

Knight Beam Compass: Sherwoode Tool & Instrument Co., Westtown, Pa. This compass is intended both for the drafting-room, and for shop use in laying out work. Adjustment of the sliding head is made by graduations which permit it to be quickly set to approximately the position desired. The fine adjustment is then made by turning the pivot point, which is set eccentrically with its shank for the purpose. The sliding holder is clamped by a nut which permits vertical as well as horizontal adjustment. It will hold either a pencil or drawing-pen as desired, or a scriber for metal work. Beams up to six feet in length will be furnished, reinforced with wood to give the proper stiffness.

Lane's Ratchet Screw-driver and Wrench: J. C. McCarty & Co., 21 Murray St., New York City. This wrench is provided with a variety of screw-driver blades and sockets, which may be quickly changed by unscrewing a knurled nut. The ratchet mechanism is automatic in action and may be instantly changed from right to left or *vice versa* by the movement of a convenient lever. The knurled clamping nut may be employed for rapidly twirling off the nut or screw after it has been loosened, thus saving considerable time. The tool is 7 inches long over all, and drop-forged from the steel that is best suited to the work each part has to do. This wrench should be very useful in working in confined places, in assembling automobile work, and for similar applications.

Pipe Attachment for Automobile Wrench: Charles E. Hall Co., Buffalo, N. Y. This firm is the maker of a steel wrench particularly suited to the automobilist's use. For the Nos. 18 and 20 of this line, which are respectively 9½ and 11½ inches over all, an attachment has been provided which immediately converts the tools into a pipe wrench. This attachment consists of a separate jaw with the usual ratchet teeth cut in it, which may be slipped in place in the wrench and quickly locked by a spring clip. In addition to the convenience afforded by this attachment, the handle of the wrench is so shaped as to be serviceable in removing pneumatic tires from wheel-rims, and is available as well for general leverage in the many emergencies occurring in connection with automobile work.

Reversing Tapping Chuck: Pawtucket Tool Co., Pawtucket, R. I. In the department of New Machinery and Tools in the December, 1909, number of Machinery, was published a note descriptive of a new tapping chuck made by the above firm. This was of the pull-off type, on which the tap is released when the proper depth of thread has been cut. The new design is provided with self-contained reversing gears and automatic clutch mechanism, which stops the tap at the bottom of the hole and reverses it by the operation of the regular feed lever of the drill press. It is, therefore, adapted particularly to presses not provided with a special reversing attachment. It is of very compact and of rugged design, with a friction device graduated to suit the size of tap used, making it very simple to set.

Motor Drive for No. 00 Screw Machine: Garvin Machine Co., Spring and Varick Sts., New York City. In this application to a small screw machine, the motor is mounted on a base attached to the legs of the machine on the back side, and connected with the spindle by a pair of round belts, one of which is crossed. A hand-operated lever is provided for shifting the belts on and off of the grooved driving pulley on the spindle, for reversing. The driving pulley is made of larger diameter than the loose pulleys, so that the belt not in use is released from tension. This machine has a capacity for stock up to ¼ inch diameter. It may be used for anything from this down to the very finest of rod work. The machine is very quickly handled, making high production possible. It weighs about 500 pounds, including the motor.

"Utility" Machine Vise: Jackson Vise & Tool Co., 85 Beekman St., New York City. This is a strongly constructed tool, covering a large range of work both as to size and shape, without the use of attachments. This is made possible by the fact that the fixed jaw is four-sided, and may be swiveled to bring any one of its four sides in line with the movable jaw. All the sides of this jaw are machined. One has a steel face, while another is shaped to answer the purpose of an angle-plate. A third side has a V-groove extending its full depth, admitting rounds, squares, etc., to be held vertically. A similar horizontal groove is provided on the fourth side. The vise gives an opening of 6½ inches high and 8½ inches extreme distance between the jaws. By the use of supplementary jaws, a still wider adjustment is provided for.

Carr Combination Tool-holders: Henry G. Thompson & Son Co., New Haven, Conn. In the November, 1907 and 1908 issues of Machinery, we described various members of the line of Carr combination tool-holders. The manufacture of these has now been undertaken by the firm above mentioned, and the line has been materially added to. It consists at present of a tool-holder body adapted to be clamped onto the tool-rest by the use of the regular tool-post of the lathe. This is done in a way, however, that holds it much more solidly than any tool held in the tool-post. In this holder may be clamped any one of a series of tools, comprising turning tools, boring tools of various sizes, threading tools, etc. One form of the holder permits rocking the blade so as to give an adjustment for the height of the center. This is particularly adapted to the use of cutting-off tools. Blades clamped in these holders are held with unusual firmness, having a support directly down onto the tool-rest of the lathe.

Combined Vertical Milling and Drilling Machine: W. B. Knight Machinery Co., St. Louis, Mo. This machine resembles a drill press somewhat in its general lines, but is built with an exceedingly stiff column and with adjustable work tables which adapt it to milling operations. In place of the usual rotary work-table and swinging arm, a knee is provided with a milling machine saddle and table, giving adjustments in two directions. This knee is supported on a pivot, so that it may be tilted to any angle, and it may also be swung about the column of the machine, making it universal. The vertical adjustment for the mill, 12 inches, is obtained from the sliding spindle head. The feed of the spindle in the head is 4½ inches. Positive geared changes are provided for the speed and feed. The latter has 10 rates varying from 0.008 to 0.76 inch per revolution, and may be applied to either the longitudinal or the cross-feed of the work-table. A swiveled vise is provided with a graduated base. The machine weighs about 2,000 pounds.

Cincinnati Special Forge Planer: Cincinnati Planer Co., Cincinnati, O. This tool is intended for severe duty, especially where the sideheads are called upon to do a large share of the work. For this reason the faces of the housings have been made very wide (18 inches on the 56-inch machine) and the heads have been gibbed to them in such a way as to give them great rigidity. Owing to the weight of these heads, they have been furnished with a power rapid traverse under immediate control of the operator. Besides this special attention to the sideheads, another important feature has been incorporated in the design—namely, the use of double driving and reverse belts, with a separate driving shaft for the latter, so as to eliminate cross belts entirely. The forward and reverse shafts on top of the housings are connected positively by gearing in the proper ratio. The narrow straight belts used with this arrangement, while transmitting great power, can still be shifted quickly and easily, giving instant and accurate control to the reversing motion.

Blevney Tube Polishing Machine: John C. Blevney, 216 High St., Newark, N. J. This machine employs the same principles of construction as the one illustrated in the department of New Machinery and Tools of the May, 1909, issue of Machinery. The polishing member is a belt of emery cloth, supported and driven by a leather belt whose surface is formed into ridges which keep the emery cloth spread out flat, and at the same time give it a ribbed surface which greatly increases its cutting capacity. This particular design of machine is provided with a special table carrying rubber-covered roller shafts for supporting the tubes as they pass through the machine. The tubes are carried through by the friction between them and the surface of the abrasive belt. As they pass at a slight angle the tubes are revolving automatically, so that their whole surface is ground; the table is also automatically shifted during the grinding to distribute the wear over the full area of the belt. For tubing of rectangular section the work is carried through on a feed belt.

Fuel Oil Burning Process: Gilbert & Barker Mfg. Co., Springfield, Mass. This firm has developed a system of fuel oil which has proved to be economical, convenient, efficient and safe to a high degree. The supply tank or tanks are located underground outside the building. The oil is drawn from them and forced into the nozzle by means of a power pump connected with a release valve which maintains a pressure of five pounds in the system. A series of baffle plates in the vent pipe of the storage tank prevent the entrance of fire through this opening. The air is furnished by a positive rotary blower at a working pressure of about two pounds. The air and oil are combined at the nozzle in portions regulated by suitable valves. The fuel is sprayed in the form of a fine mist, which is as easily regulated and burns as freely as a gaseous fuel. As an ingenious safety provision, the fuel pump is belted to the blower, so that if the latter should fail from the breaking of a belt, burning out of a motor or otherwise, the supply of oil would also cease at once. This system is adapted to anything from large forges, to small bench furnaces for light hardening, tempering, etc.

TOOL OUTFIT FOR MACHINING FLY-WHEELS ON THE BORING MILL: Colburn Machine Tool Co., Franklin, Pa. This firm is furnishing an outfit of tools for gas engine fly-wheels which has proved very successful. The boring mill used is provided with two regular tool-heads and a central boring spindle. The latter is revolved independently of the table, so as to give the proper cutting speed to the tools which finish the bore at the same time that the rim is being machined. In the first operation a tool in one of the heads turns the outside diameter of the rim. Simultaneously a box tool held in the other head faces both edges of the rim, the wheel being mounted in a special fixture which holds it firmly, but allows these cuts to be taken simultaneously. At the same time also, the central boring spindle is roughing out the bore with an inserted blade boring-bar. By the time the operations on the rim are finished a roughing and finishing boring cut has been taken in the hub and the reaming is in progress. For the reaming, the floating holder described in the New Tools Department of the December, 1909, issue of MACHINERY is used. The final operation consists in facing the hub with an inserted blade holder, steadied by a pilot in the bore, and chamfering all four edges of the rim inside and out. With this outfit of tools the following rate of production has been found practicable: 22-inch wheels, 15 minutes complete; 26-inch wheels, 18 minutes; 30-inch wheels, 20 minutes; 36-inch wheels, 23 minutes; 42-inch wheels, 25 minutes apiece.

* * *

UNITED STATES TRADE REPORTS BOBS UP AGAIN

The following interesting correspondence, which speaks for itself, may be read with profit by manufacturers unacquainted with the game. It has been played for several years with profit, and although exposed many times it seems to flourish still:

Industrial Press,
New York, N. Y.

MOLINE, ILL., 2/12/'10.

Gentlemen:—We enclose herewith letter which we recently received from a Cincinnati concern. . . . We received exactly the same letter from them about a year and one-half ago and are enclosing herewith copy of our reply to them at that time, and also to the last letter received from them. These parties were shown up in the trade publication a few years ago but are evidently getting busy again and believe that it would be well to warn the trade against them. The point of the matter is the fact that we are the sole and only and exclusive builders of screw driving machines in this or any other country, to the best of our knowledge and belief. The writer is easy and falls for a good many advertising schemes, but this one is too raw. Very possibly, however, others new in the business would be taken in by such a scheme and we believe that it would be well to post the trade through your publication.

Very truly yours,
REYNOLDS MACHINE CO.

CINCINNATI, 1/20/'10.

Reynolds Machine Co., Rock Island, Ills.

Gentlemen: The enclosed article is an editorial prepared on the subject of Screw Driving Machines, which we intend to publish in our columns.

Our policy of furnishing reports on any commercial matter about which our readers may request information brings numerous inquiries on all subjects pertaining to trade. This editorial gives facts that are needed and will be appreciated by a large number. As we have highly indorsed your machine, we ask that you add to or alter same as you may think best and return as soon as possible. If you have any cuts that will illustrate the subject, kindly loan them to us and we will return them promptly.

As this is an editorial of course there is no charge for publication and in addition if you can use any extra copies of the issue in which it will appear, we will be pleased to make you the following special reduced rates as we are desirous that you should get as much benefit out of it as possible.

The price of the United States Trade Reports is 15c. per copy, but we can supply you with 100 at 12c. per copy, 250 at 10c. per copy, 500 at 9c. per copy, 1,000 or over at 8c. per copy, shipped to you or if you will send us a list of the names of those whom you wish to reach, we will mail marked copies to such without any extra charge to you for the postage, wrapping, addressing or marking.

Although the publication does not depend on an order for copies, such an order will be appreciated by us.

Awaiting an early reply with corrected copy, we remain

Yours truly,
UNITED STATES TRADE REPORTS.

Following is the article headed "Disinterested Advice" that was to be published in the U. S. Trade Reports—if "approved":

DISINTERESTED ADVICE

It is often a very difficult matter for the average person to determine the "best" in this or that line and especially so where every producer heralds his own particular product as the acme of perfection. The many points to be taken into consideration in determining the superiority must all be given careful thought, and even if one had the time and energy to devote to a careful research, there are still many obstacles to overcome.

It is perhaps a realization of these facts combined with the knowledge that this paper has better facilities for such examinations and researches than any individual that induces the numerous inquiries we receive in which we are asked the merits or advantages of this or that commodity where they have not the means of ascertaining for themselves.

One of the chief facters, however, in arriving at a satisfactory solution of this question must always be the reliability of the firm you contemplate dealings with. Knowing the firm you deal with so as to be able to place perfect reliance in their integrity is by far the best test.

On the subject of Screw Driving Machines and where can be obtained the best make we beg to draw attention to the valuable products of the Reynolds Machine Co. of Rock Island, Ills.

We are convinced that this machine is superior to all others that has come under our observation because the manufacturers use every endeavor to make their products perfect.

This company enjoys an enviable reputation for the high standard of excellence and their products are used in preference to all others wherever they have been introduced. They are of the highest commercial standing and any representations they may make can always be relied upon.

Those interested may esteem this our reply and a communication addressed to them direct will elicit information and details which would be out of place in an editorial like this.

January 25, 1910.

U. S. Trade Reports,
414 Home Street,
Cincinnati, Ohio.

Gentlemen: Replying to yours of the 20th inst., in regard to proposed editorial for your publication, we call your attention to our letter of June 20th, '8, in reply to a similar communication.

We expressed our opinion of you and yours at that time and have had no reason since to change it.

Very truly yours,
REYNOLDS MACHINE CO.

U. S. Trade Reports,
Cincinnati, O.

June 20, 1908.

Gentlemen: We are in receipt of your favor of the 17th inst. on the subject of editorial you propose to publish in regard to our Screw Driving Machine.

Beg leave to advise you that while we are new in manufacturing, we have been in the mechanical line long enough to know your reputation in the mechanical world.

We would think it would be necessary or at least advisable for you to make greater change in your proposed editorials than to merely change the name of the machine recommended and its manufacturers.

While we of course have not committed your letter to memory, it has a very familiar sound and believe it is exactly the same as you are in the habit of sending out to manufacturers in all lines.

You might at least pay us the compliment of making some little change in the wording in your proposed editorial.

Beg leave to advise you in conclusion that your proposed editorial if published would be of no earthly benefit to us and on the contrary we believe if published by you would be good grounds for damage suit against you. You will therefore oblige us by taking no further steps in the matter.

Yours truly,
REYNOLDS MACHINE CO.

* * *

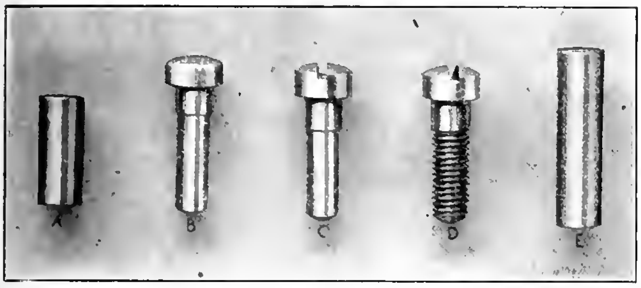
According to the *Industritidningen Norden*, rotary files are used to a great extent in a prominent German machine shop. The files are placed in special machines similar to small grinding machines. They are made of a diameter of from 3/8 to 1 inch and are rotated at a velocity of 2,000 revolutions per minute for working iron and steel, and at a velocity of from 2,500 to 3,000 revolutions per minute for brass and softer metals. The files are used for a number of different purposes, such as the removal of burrs, the rough finishing of holes and hollow portions in castings, etc. It is stated that in many cases from 20 to 50 per cent of the time can be saved in this manner, as compared with other methods of performing the same work.

NEW METHODS OF MANUFACTURING MACHINE SCREWS

The International Machine & Screw Co., Springfield, Mass., has recently brought out machine and wood screws made by an entirely new process, invented and patented by Mr. George T. Warwick. In this process there is no waste of material, the product is stronger than that made by ordinary methods, is very uniform and of high finish, and long screws are made as rapidly as short ones.

The machines for making this product are entirely automatic. Two methods are in use. One method is by a single machine that makes the screw complete; this is known as the combination machine. This machine takes wire of the size of the screw head from the reel (the stock being coiled, instead of in straight bars) straightens it, cuts off the blank to the required length, swages and elongates the screw body, heads, slots, threads and delivers a finished screw with no waste of stock and with great speed.

By the other method a unit of three machines is required to make the complete screw. The first machine in the set is the blanking machine. This machine takes the wire of the size of the screw head from the reel, straightens it, and cuts



Progressive Stages of the Manufacture of Screws by a New Method

it to the required length by shearing. Then the piece is taken by a gripping chuck and passed to elongating dies where it is reduced to the proper sizes for the shank and thread parts, and thence to dies that finish the head and point and deliver it to a receiving box. The appearance of the blank is as shown at *B* in the half-tone.

The second machine in the set is the slotting machine. The blanks are put in a hopper from where they are fed automatically to the dies that press the slots in the heads; the slotted blanks are then fed to a receiving box, their appearance being as shown at *C*.

The third machine in the set is the threading machine. The slotted blanks are put in the hopper from which they are fed automatically to the dies that roll the threads on them. In the threading process a slight burr is raised at the point where the thread begins; this burr is removed while in the threading machine by a revolving tool. This completes the screw, as shown at *D*. Fillister head screws are shown in the illustration, but all other regular and special shapes are as readily made. By the processes mentioned it takes but slightly more than one-half the stock to make a screw than is used by ordinary methods. This saving of stock varies in the different sizes and lengths, the longer screws saving more stock in proportion than the shorter ones. As an example, the stock used by the new process is shown at *A*, while that used by ordinary methods is shown at *E*. In a recent test for speed and stock on a 3/16 by 5/8-inch size screw, the International Machine & Screw Co.'s combination machine made 100 screws in a little less than three minutes. For a given number of screws made by regular methods, the stock weighed 20 ounces; for the same number and size of screws made on the International Machine & Screw Co.'s automatic machine the stock weighed 11½ ounces.

Tests for strength made at Columbia University on these screws show an average of 17 per cent greater tensile strength of thread and 5 per cent greater bending strength for the new process.

The machines themselves will not for the present be sold or leased, but the company will build them for its own needs, and will place upon the market a complete line of screws and like products.

ENGINES AT THE MOTOR BOAT SHOW

The exhibition of gasoline engines recently held at Madison Square Garden, New York, in connection with the sixth annual National Motor Boat Show, was impressive, partly because of the improvements embodied in many of the designs and also because of the size and power of many of the units exhibited. A large number of engines of both the two- and four-cycle types were shown, the power of which ranged from 1 to 250 horsepower. The engines intended for driving the high-speed motor boats, which have recently become so popular, formed one of the most interesting features of the exhibition. These were of both the two- and four-cycle types and were equipped with four, six or even eight cylinders. There was also an unusually large exhibit of two-cycle engines having one or two cylinders.

These motors were, of course, practically all of the marine type, having been designed to develop a maximum of power in a minimum of space. The weight per horsepower of many of the motors shown, particularly those of the high-speed type, has been reduced considerably by the use of aluminum in the construction of such parts as beds, crank-cases, cylinder heads, exhaust manifolds and other parts not directly subject to wear. The weight has been further reduced on some of the highly developed motors of the racing type, by the use of copper water-jackets. A careful inspection of the engines of all classes, showed that much attention has been given by the manufacturers to the matter of lubrication and ignition. A great many of the motors shown were equipped with mechanical oiling devices, and the engines of the multi-cylinder high-speed type were in many instances fitted with gear-driven magnetos, supplemented by batteries on the larger engines, for starting.

One of the high-speed engines which attracted considerable attention was exhibited by the Jencick Motor Co., Port Chester, N. Y. This engine, which develops a maximum of 250 horsepower, has eight gun metal cylinders which are cast separately. These are furnished with cooling water by four pumps, each pump supplying a set of two cylinders. The ignition system is of the double, high-tension type, a Bosch magneto being used. An automobile type of steering wheel is attached to the rear of the engine and on this are mounted the controlling levers. This motor is to be installed in a 40-foot flyer.

Another interesting motor of the eight-cylinder type was shown in the exhibit of the Dean Mfg. Co., Newport, Ky. It was this particular engine that drove *Brer Fox II.* on her record-breaking trip from Cincinnati to New Orleans, a distance of 1554 miles, at an average speed of 29.08 miles per hour, thus establishing a world's endurance record. The motors now being built by this firm are equipped with a new arrangement to which much of their power and reliability is attributed by the makers. This is known as an "accelerator" and is, in reality, a fourth port through which a small amount of pure air is admitted to the cylinder, in advance of the gas mixture for the purpose of expelling the burnt gases.

An interesting line of high-speed motors of the two-cycle type was shown by the B. F. Brown Gas Engine Co., Syracuse, N. Y. The bases of these engines are of aluminum and those intended for racing have, in addition, aluminum cylinder heads, inlet and exhaust manifolds, etc. These manifolds are water-cooled, the water being pumped through the exhaust manifolds into the cylinder jackets. The motors built by this firm are of the three-port type, the ports being proportioned for a maximum of efficiency at high speeds. The Bosch magneto is used in connection with the ignition system. The largest engine in this exhibit had six cylinders and developed approximately 80 horsepower on the brake, while the smallest with one cylinder, known as the "Brownie," was rated at a single horsepower.

The largest motor in the show in point of size was a mammoth 100 horsepower, four-cylinder, kerosene oil motor, the product of Mietz & Weiss of New York. This engine embodies many novel and interesting features. It is air starting and reversing, by the movement of a single lever, which also controls both the air and fuel supply to the cylinders. The engine operates on the two cycle principle, and the cylinders

are of the three-port type. The fuel is forced directly into the cylinders on the compression stroke, by means of a pump which is actuated by the governor. The compressor which supplies the air for starting, is self-contained and is driven by an eccentric which also drives the circulating pump. Lubrication is supplied to thirty-two different places by a mechanical lubricator. The hot-tube system of ignition is employed.

The Thrall Motor Co., Detroit, Mich., showed a number of heavy-duty two-cycle engines and also an interesting design of light high-speed motor. The last type referred to has, in addition to the regular third port, a fourth port in each cylinder which might be properly called an auxiliary third port. This auxiliary set of ports is used for high speeds in order to get a sufficient supply of gas into the compression base. Each set of third or intake ports is connected to a carburetor by separate manifolds so that the carburetors may be used independently. For speeds below 800 or 900 revolutions per minute, one carburetor only is used, but for higher speeds both carburetors are brought into action, thus giving a double amount of gas and increasing the power. These high-speed motors, which have bases and other parts of aluminum, give one horsepower for each ten pounds of weight. The forced-feed system of lubrication is used, the crank-case compression being utilized for this purpose. The oil for the cylinders is fed from an oil cup above the carburetor through the intake manifold.

The Standard Motor Construction Co., of Jersey City, exhibited a complete line of high-power motors, among which was a 100-horsepower engine of the type and size used by the Russian government in its submarine boats. This engine has six cylinders and is air starting and reversing. A six-cylinder, 60-horsepower motor of the auto-marine type, which is also self-starting and reversing, attracted considerable attention. In addition, there was a line of heavy-duty motors exhibited, ranging from 12 to 60 horsepower. The engines of the heavy-duty type are all equipped with automatic governing devices which are contained in the fly-wheel.

In the motor exhibit of the Fay & Bowen Engine Co., of Geneva, N. Y., there was a 30-horsepower combination kerosene and gasoline engine which the makers claim has proved very successful. This type of motor is intended for use in countries where gasoline is either difficult to obtain or too expensive. When the motor is first started, a small amount of gasoline is used; this is fed into the crank-case through a mixing device which, when the engine is using kerosene, becomes an inlet for pure air. The kerosene is vaporized before passing into the crank-case, where it is mixed with the air, by being forced into a chamber surrounding the exhaust.

The Charles L. Seabury Gas Engine & Power Co., New York, had in addition to a large boat exhibit, a complete line of four-cycle motors of various sizes. A six-cylinder engine in this exhibit, of the air starting and reversing type, contained many interesting features in its design. The cylinders are cast separately and are cooled by a circulating pump of the gear-driven type, which operates in either direction. The intake and exhaust valves, which are actuated by two camshafts, are located on the same side of the cylinder. When the engine is to be run in a reverse direction, the position of the cams with relation to the crank is changed by means of a spiral gear. The air used for starting is admitted to the cylinders on the explosion stroke by a special camshaft. Two magnetos are used in the ignition system, one for each direction of rotation.

In addition to the motor exhibits which have been briefly referred to in the foregoing, there were, of course, many others worthy of note, and also an interesting line of motor accessories. The entire exhibit showed in a striking way the wonderful progress that has been made in the development of the gasoline engine, and those who have been regular attendants at this annual exhibition could not have failed to observe the progress which has been made by the manufacturers in bringing the internal combustion engine up to its present state of simplicity, reliability and efficiency.

* * *

During 1909 the new main line railroad track built in the United States amounted to 3,748 miles.

AMERICAN EXPOSITION IN BERLIN ABANDONED

The American exposition of American products, which was to be held in Berlin, Germany, June 1 to August 31, has been abandoned because of the fierce opposition of German officials and manufacturers to the project. A storm of protest was raised because of the exclusiveness of the exposition, it being the original plan to show only American machinery and products. A compromise was proposed under which the exposition would include both German and American machinery and products, but the plan was rejected as was also the plan to postpone it until the summer of 1911. The real animus seems to have been dislike of Americans and American goods. The incident at one time threatened to develop international complications, and as it was it caused some painful embarassment to the diplomatic representatives of the two countries.

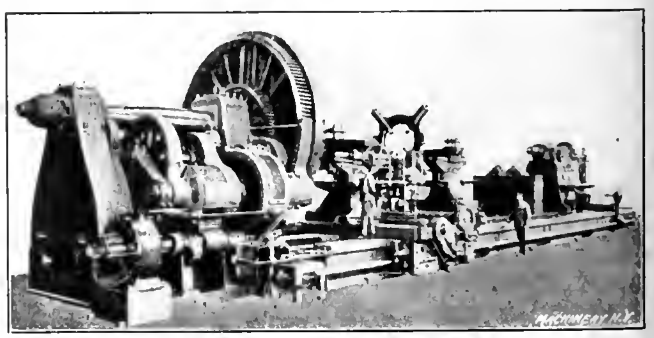
The project originated with some Berlin capitalists owning a fine exhibition hall in Berlin, who cast about for a paying exhibition enterprise for the summer of 1910, and the proposed American show was the outcome. The following bearing on German hostility is quoted from a resumé of the affair printed in the New York *Times*:

By far the most significant aspect of the whole incident is the light it has thrown on the latent hostility to American industrial competition with which the entire German business world is honeycombed. The blunt, brutal truth is that the German manufacturers' dread of their American competitors borders on jealous hatred. While clamoring for the widest possible privileges for themselves in the American market, German manufacturers resist by every means at their command the extension of fresh privileges to American manufacturers in the German market. Every sale of an American typewriter, cash register, shoe machine, or harvesting machine in Germany is regarded as an act of war by the average Teuton manufacturer. He bars the doors of his factories to American visitors and regards our consular officials as spies. It was in this spirit of blind unreasoning hostility that influential German Chambers of Commerce petitioned their government to boycott the proposed American exhibition, and it was to mollify the influential industrial community that Secretary Delbrück made his celebrated break. When the history of this latest German-American incident comes to be written, one statement will require to be underlined, namely, that the entire exhibition scheme and the resultant squabble were exclusively made in Germany. America throughout has played the role of the innocent bystander.

* * *

LARGE GERMAN LATHE

The accompanying illustration shows a large lathe built by the German Niles Works at Oberschöneweide. It is the largest lathe of this type ever built in Germany, and so far as we know, it is the largest lathe of its kind built anywhere. The maximum distance between the centers is 52½ feet, and the maximum diameter of work that can be turned in the lathe is 17 feet 2 inches. The total length of the machine is about 85 feet, and its weight is 385 tons. The



Large Lathe built by the German Niles Works, Oberschöneweide

lathe was built for the dock-yards at Kiel, and will be used especially for the turning of the rotating parts for steam turbines. The maximum speed of the faceplate is 30 revolutions per minute, which means a maximum speed at the periphery of the faceplate of 1,600 feet per minute. The machine is driven by an 80 horsepower motor, and by means of the variable speed in the motor and the gearing, 60 speeds are obtainable.

COMPLETE DIMENSIONS OF ACME STANDARD THREAD PARTS

Most hand books and catalogues give rather meager, and sometimes misleading, information in regard to the Acme standard thread. The writer has compiled the accompanying table giving not only the dimensions for the screw parts, which nearly all tables refer to, but also the data required

Table of Acme Thread Parts.

Dimension Required	Class of Thread	Symbol on Drawing	Formula	Example: Nominal Diam., 2 inches, 4 Threads per inch
Outside Diameter	Tap	A	Nominal size* + 0.020 inch	2.000 + 0.020 = 2.020
	Nut	B	Nominal size + 0.020 inch	2.000 + 0.020 = 2.020
	Screw and Die Tap	C	Nominal size	2.000
	Die	D	Nominal size	2.000
Root Diameter	Tap	E	$\text{Nominal size} - \left(\frac{1}{\text{No. of thds per inch}} + 0.020\right)$	$2.000 - (\frac{1}{4} + 0.020) = 1.730$
	Nut	F	$\text{Nominal size} - \left(\frac{1}{\text{No. of threads per inch}}\right)$	2.000 − 0.250 = 1.750
	Screw and Die Tap	G	$\text{Nominal size} - \left(\frac{1}{\text{No. of thds per inch}} + 0.020\right)$	$2.000 - (\frac{1}{4} + 0.020) = 1.730$
	Die	H	$\text{Nominal size} - \left(\frac{1}{\text{No. of thds per inch}} + 0.020\right)$	$2.000 - (\frac{1}{4} + 0.020) = 1.730$
Width of Flat on Top of Thread	Tap	J	$\frac{0.3707}{\text{No. of threads per inch}} - 0.0052$	$\frac{0.3707}{4} - 0.0052 = 0.0875$
	Nut	K	$\frac{0.3707}{\text{No. of threads per inch}}$	$\frac{0.3707}{4} = 0.0927$
	Screw and Die Tap	L	$\frac{0.3707}{\text{No. of threads per inch}}$	$\frac{0.3707}{4} = 0.0927$
	Die	M	$\frac{0.3707}{\text{No. of threads per inch}} - 0.0052$	$\frac{0.3707}{4} - 0.0052 = 0.0875$
Width of Flat at Bottom of Thread	Tap	N	$\frac{0.3707}{\text{No. of threads per inch}} - 0.0052$	$\frac{0.3707}{4} - 0.0052 = 0.0875$
	Nut	P	$\frac{0.3707}{\text{No. of threads per inch}} - 0.0052$	$\frac{0.3707}{4} - 0.0052 = 0.0875$
	Screw and Die Tap	R	$\frac{0.3707}{\text{No. of threads per inch}} - 0.0052$	$\frac{0.3707}{4} - 0.0052 = 0.0875$
	Die	S	$\frac{0.3707}{\text{No. of threads per inch}}$	$\frac{0.3707}{4} = 0.0927$

*Nominal size is the actual outside diameter of the Acme thread screw

in connection with taps, die taps, and dies. This table will perhaps clear up a great deal of misunderstanding and misinterpretation of existing tables. In order to make the formulas clear, an example has been given, in which the nominal diameter of the screw thread is two inches, there being four single threads per inch. A.

* * *

PERSONALS

Herbert M. Wilcox, chemical engineer, experienced in various industries, has joined the staff of Walter B. Snow, publicity engineer, Boston, Mass.

J. J. Voelcker, an occasional contributor to MACHINERY, has taken the position of machine shop foreman with the H. Mueller Mfg. Co., Decatur, Ill.

Benjamin Baker, formerly of the *Boston Transcript*, and late editor of *The Navy*, has joined the staff of Walter B. Snow, publicity engineer, Boston, Mass.

Henry Smith, who has represented the *Iron Age* and associated publications for the past thirty-seven years, twenty-seven of which have been spent in Cincinnati, has resigned.

Andrew Rogers, until recently foreman of Foundry No. 1, Eddystone plant, Baldwin Locomotive Works, has taken charge of the foundry of the Lima Locomotive and Machine Co., Lima, Ohio.

George Ahrens, of Spokane, Wash., who has been president of the Moline Tool Co., Moline, Ill., for several years, but not actively connected with the business, assumed charge of the sales department of the company March 1.

H. E. Strohm, formerly of the Lodge & Shipley Machine Tool Co.'s sales department, has taken a position as salesman with the W. R. Colcord Machinery Co., St. Louis, Mo., and will cover the Illinois territory lying south of Quincy.

Frank E. Bocorselski, superintendent of the Baush Machine Tool Co., Springfield, Mass., for the past ten years, has resigned to take the position of assistant supervisor of plants with the American Locomotive Co., at Richmond, Va.

Harry Hoover, a well-known foundry foreman, has taken a position with the S. Obermayer Co., Cincinnati, Ohio, manufacturer of foundry supplies and equipment. He will look after the company's interests in Buffalo and Dunkirk, N. Y.

W. A. Sabin, inspector at the United States Armory, Springfield, Mass., has been promoted to the position of foreman of the Ordnance Department at Manila. Mr. Sabin is now on his way to the Philippines.

George U. Poole, manager of the Boston branch of the Dodge Mfg. Co., Mishawaka, Ind., lectured before the mechanical and electrical association of the University of Maine, February 26th, on the manufacturing of pulleys and castings and methods of power transmission.

Douglas T. Hamilton, die-sinker, toolmaker, designer of automatic screw machines, tools, etc., and author of "Formulas for Machine Screw Button or Split Dies," "Knurls and Knurling Operations," "Circular Form and Cut-Off Tools," etc., has joined the editorial staff of MACHINERY.

C. W. Werst, a member of long standing in the American Society of Mechanical Engineers, and for eleven years with the Baldwin Locomotive Works, Philadelphia (where he was one of the general foremen) has assumed the position of assistant superintendent and general foreman of the Lima Locomotive and Machine Co., Lima, Ohio.

* * *

OBITUARIES

Robert J. Hancock died at his home in Springfield, Mass., February 26, aged 70 years. Mr. Hancock had recently resigned the position of superintendent of the Blair Mfg. Co., makers of lawn mowers.

Jonathan Bailey died in Providence, R. I., March 4, aged 74 years. Mr. Bailey was for several years superintendent of the Providence Tool Co., and was at one time foreman of the Brown & Sharpe Mfg. Co.

Thomas H. Dodge died at his home in Worcester, Mass., February 12, aged 87 years. Mr. Dodge was a noted inventor and patent lawyer. The cylinder printing press is probably the most notable of his inventions.

Andrew Gale, president of the Belcher & Taylor Agricultural Co., died February 8 while presiding at a meeting of the company's directors, aged 74 years. Mr. Gale was the inventor and patentee of many agricultural appliances.

George W. Sunderland, head instructor of machine work, McKinley Manual Training School, Washington, D. C., died March 9. Mr. Sunderland contributed the article on the McKinley Manual Training School, in the January, 1910, number of MACHINERY.

Thomas C. Page, of Chicopee Falls, Mass., died in New York, February 5, following an operation, aged 61 years. Mr. Page was prominent in manufacturing circles, having been at the head of the Lamb Knitting Co. for several years. In the bicycle days he was manager of one of the large plants of the American Bicycle Co. In recent years he was assistant treasurer of the Stevens Arms & Tool Co. and of the Stevens-Duryea Co., and also a director in several companies.

CHARLES F. AARON

Charles F. Aaron, general manager of the New York Leather Belting Company and one of the best known belting manufacturers in the United States, died at his home in Plainfield, N. J., on March 4, aged forty-three years, following an operation for hernia.

Mr. Aaron had for many years been closely identified with the largest machinery and supply manufacturing interests of the United States. He was, from its organization, prominently identified with the American Supply and Machinery Manufacturers' Association, whose membership represents more than half a billion dollars' worth of American factories. He was president of this association from May, 1908, to May, 1909, and prior to that time had for several years been the vice-president and chairman of its executive committee. He is best known for his work in this association and outside of it in connection with his efforts for higher standards of production among American manufacturers.

It was largely his inspiration and suggestion that prompted the American Supply and Machinery Manufacturers' Association in convention at Pittsburg last May to adopt what was known as its Declaration of Principles. This document, which was unanimously adopted, put all members of that association on record as pledging themselves and their factories to higher qualities in the goods they produced and it condemned the practice of substituting inferior goods as first qualities. The document referred to caused much discussion and favorable comment in the daily and trade press of this country as well as abroad as being an advance step among American manufacturers for higher qualities and fitting condemnation of the manufacturer of low-grade American products.

Mr. Aaron is perhaps even better known in connection with a campaign he was making up to the time of his death for raising to a higher plane the standards of manufacture of leather belting. He was promoting a plan for general adoption by belting manufacturers of standardizing the specifications upon which all leather belting of first quality should be built. His plan entailed the national adoption by all manu-

Charles F. Aaron

facturers, dealers and consumers, of rigid belting specifications, a national stamp or trade mark which should go upon all such goods by whomever manufactured, and a severe penalty to the manufacturer who put out supposedly first quality goods bearing this stamp which did not fulfill specifications. Several of the largest of the Supply Dealers' Associations now have his plan under advisement of committees, who will report upon it in connection with like reforms in other lines at conventions to be held this spring.

He was a man who had brought himself to the front among American manufacturers by sheer hard work. He started at the very bottom of the ladder, spending several years in the leather belting factory of his father, mastering every technical detail as to the methods of manufacturing followed by his company. Following his apprenticeship in the factory he made suggestions for the improvement of qualities in the belting put out by his concern. The result was that his company was able to put out goods of superior quality that have won a fine reputation.

Mr. Aaron also is author of the first book ever published in this country describing the whole system of manufacturing leather belting from the time the hide is taken from the steer until it is ready for installation on pulleys. This book is used in several colleges as an authority on the most improved method of manufacturing leather belting. He traveled most of the time in later years and was known to almost every mill supply dealer in the United States as well as by the operative heads of almost every manufacturing plant of size in the United States. He was prominently connected with the Masonic order, was a Knight Templar, and a Shriner, belonging to Kismet Temple A. A. O. N. M. S., and a member of the Elks. He was also a member of the Machinery Club, and the Crescent Athletic Club of Brooklyn. He leaves a wife and three children.

* * *

COMING EVENTS

April 5-7.—Joint convention of the Southern Supply and Machinery Dealers' Association, and American Supply and Machinery Manufacturers' Association, Jacksonville, Fla., Seminole Hotel, headquarters. Alvin M. Smith, secretary and treasurer of the Southern Supply and Machinery Dealers' Association, Richmond, Va.

April 13-14.—Annual convention of the National Metal Trades Association at the Hotel Astor, New York. Robert Wuest, commissioner, 605 New England Building, Cleveland, Ohio.

April 27-28.—Annual meeting of the National Association of Cotton Manufacturers in the Mechanics' Fair Building on Huntington Ave., Boston, Mass. An exhibition of textile machinery will be held in the same building by the Textile Exhibitors Association. C. J. H. Woodbury, secretary and treasurer, 45 Milk St., Boston, Mass.

May 4-5.—Annual meeting of the Iron and Steel Institute at the institution of Civil Engineers, London. G. C. Lloyd, secretary, 28 Victoria St., London.

May 10-13.—Seventeenth annual convention of the Air Brake Association, Indianapolis, Ind., Dennisson Hotel, headquarters. An interesting program has been prepared on air brake construction, air pumping, piping inspection and cleaning, triple valves and brake cylinders, recommended practice, etc. F. M. Nellis, secretary, 53 State St., Boston, Mass.

May 11-13.—Joint convention of the American Supply and Machinery Manufacturers' Association and the National Supply and Machinery Dealers' Association at Atlantic City, N. J. F. D. Mitchell, 309 Broadway, New York, secretary-treasurer, American Supply and Machinery Manufacturers' Association.

May 16-18.—Fifteenth annual convention of the National Association of Manufacturers, Waldorf-Astoria Hotel, New York. George S. Budinot, secretary, 170 Broadway, New York.

May 24-25.—Spring convention of the National Machine Tool Builders' Association at Rochester, N. Y., Hotel Seneca, headquarters. Charles E. Hildreth, secretary, Worcester, Mass.

May 31-June 3.—Spring meeting of the American Society of Mechanical Engineers, Atlantic City, N. J.

June 6-10.—Convention and exhibition of the Foundry and Manufacturers' Supply Association, Detroit, Mich. C. E. Hoyt, secretary, Lewis Institute, Chicago, Ill. Cadillac Hotel, Detroit headquarters of the association convention week.

June 7-9.—Convention of the American Foundrymen's Association and American Brass Founders' Association, Detroit, Mich. Headquarters, Hotel Ponchartrain. Richard Moldenke, secretary, American Foundrymen's Association, Watchung, N. J. W. M. Corse, secretary, American Brass Founders' Association.

June 13-16.—National Gas and Gasoline Engine Trades Association convention at Cincinnati, Ohio, Hotel Sinton, headquarters. Albert Stritmatter, secretary.

June 15-17.—Annual convention Master Car Builders' Association, Atlantic City, N. J. J. W. Taylor, secretary, Old Colony Building, Chicago, Ill.

June 20-22.—Annual convention of the American Railway Master Mechanics' Association, Atlantic City, N. J. J. W. Taylor, secretary, Old Colony Building, Chicago, Ill.

June 20-July 6.—Detroit Industrial Exposition, Detroit, Mich., under the auspices of the Detroit Board of Commerce to accelerate the city's industry and commerce. The exposition grounds will be on the Detroit River where a large exposition building will be erected and used in conjunction with the Wayne Pavilion. W. G. Rose, manager, Detroit Board of Commerce, Detroit, Mich.

July 26-29.—Joint meeting of the American Society of Mechanical Engineers and the British Institute of Mechanical Engineers in Birmingham and London, England.

SOCIETIES AND COLLEGES

Columbia University, New York, has announced that beginning with next September it will conduct an important extension of its work. The new undertaking is an outgrowth of the success of the summer session of the university which has been established for ten years and which in 1909 attracted more than two thousand students from all parts of the United States. It is now proposed to extend the operation of the principles of the summer session so as to provide class and laboratory work in the evening at the university and both in the evening and during the day in other parts of the city as well as in north New Jersey and Westchester County for the benefit of those who are not able to avail themselves of the course of instruction at the university.

National Gas and Gasoline Engine Trades Association.—The first meeting of the National Gas and Gasoline Engine Trades Association was held in Chicago, December 8, 1908. The constitution adopted at that time stated that the purpose of the organization was as follows: "The object of the association shall be to protect, promote, further and advance the interest of the trade; also for the purpose of holding national conventions once a year of interest to the parties. The purpose of such conventions shall be for the promotion of education and sociability among the members of the association." Since the initial meeting there have been held three conventions and at the Chicago convention in December, 1909, there were over 200 present. The next meeting will be in Cincinnati, June 13, 14, 15, and 16. Indications point to a very large attendance. Provisions are made at all meetings for the exhibition of gas engines and accessories. No charge is made for space. The entertainment feature, while of high class, has been entirely subordinated and there are few bodies in which the entire conventions maintain so high a degree of interest in the technical features of the programs offered. The dues for membership are $5 per year and an initial fee of $10 has been suspended, as it was found that the dues provided sufficient funds to maintain an ample surplus in the treasury. The officers of the association are as follows: M. A. Loeb, Cincinnati, Ohio, president; C. O. Hamilton, Elyria, Ohio, vice-president; Otto M. Knoblock, South Bend, Ind., treasurer; Albert Stritmatter, Cincinnati, Ohio, secretary.

NEW BOOKS AND PAMPHLETS

Northwestern University Bulletin. Annual catalogue 1909-1910. 371 pages, 6 x 9 inches. Published by the Northwestern University, Evanston and Chicago, Ill.

The Vermont Bulletin. Catalogue 1909-1910. 173 pages, 5¼ x 7½ inches. Published by the University of Vermont and State Agricultural College, Burlington, Vermont.

A Study of Base and Bearing Plates for Columns and Beams. By N. Clifford Ricker. Bulletin No. 35. 36 pages, 6 x 9 inches. Published by the University of Illinois, Engineering Experiment Station, Urbana, Ill.

The Thermal Conductivity of Fire-Clay at High Temperatures. By J. K. Clement and W. L. Egy. Bulletin No. 36. 32 pages, 6 x 9 inches. Published by the University of Illinois, Engineering Experiment Station, Urbana, Ill.

Twenty-third Annual Report of the Commissioner of Labor for the Year 1908: Workmen's Insurance and Benefit Funds in the United States. 810 pages, 6 x 9 inches. Published by the Department of Commerce and Labor, Washington, D. C.

Ballistic Electro Dynamometer Method of Measuring Hysteresis Loss in Iron. By Martin E. Rice and Burton McCollum. 23 pages, 6 x 9 inches. Published by the University of Kansas, Engineering Experiment Station, Lawrence, Kansas.

Proceedings of the Nineteenth Annual Convention of the American Railway Bridge Building Association Held in Jacksonville, Fla., October 19-21, 1909. 340 pages, 6 x 9 inches. Published by the association, C. A. Lichty, secretary, Chicago & Northwestern Ry., Chicago, Ill.

American Water Works Association Proceedings, 1909. 796 pages, 6 x 9 inches. Numerous illustrations and folding plates. Published by the Secretary, 14 George St., Charlestown, S. C.

This volume contains the papers presented before the twenty-ninth annual convention of the association, held at Milwaukee, Wis., June 7-12, 1909. About forty papers were presented, all of which are included.

The Second Law of Thermodynamics. Its Basis in Intuition and Common Sense. By W. S. Franklin. 18 pages, 6 x 9 inches. Reprinted from the *Popular Science Monthly*, March, 1910.

This interesting and popularly written treatise on the second law of thermodynamics is intended to form a part of a book on "Elementary Theory of Heat" now in preparation. The author, who is a professor at the Lehigh University, possesses an unusual ability of making scientific matters clear and simple to the lay mind, and he frequently uses illustrations from everyday life to make scientific truths plain.

Record of Transportation Lines Owned and Operated by and Associated in Interest With the Pennsylvania Railroad for Year Ending December 31, 1909. 40 pages, 9 x 12 inches, and folding map. Published by the Pennsylvania Railroad Co., Philadelphia, Pa.

The Pennsylvania Railroad system has 11,234.36 miles of lines of which 6,294.32 lie east of Pittsburg and Erie, Pa., and 4,940.04 lie west of Pittsburg. These lines run through fourteen states in which live more than 45,000,000 people. The book gives statistics of all the constituent lines of the system.

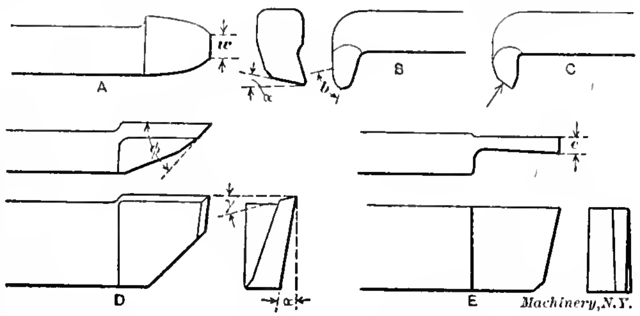
Exporters' Encyclopedia. Sixth (1910) edition. 776 pages, 5½ x 8¼ inches. Published by the Exporters' Encyclopedia Co., New York. Price $5.

Supplement to MACHINERY, May, 1910

Operations for the Article in this number entitled "Machine Shop Practice—Tool Grinding"—II

SHOP OPERATION SHEET NO. 133

Franklin D. Jones MACHINERY, May, 1910



Grinding Lathe Tools—I

NOTE.—A number of lathe tools of different types are illustrated on this and the two following sheets. As these tools are intended for different purposes, the shapes vary widely and there are certain points in connection with the grinding of each, which should be observed.

1. At A is shown a plan view of a tool that, because of its broad flat nose, is used for finishing cuts when a wide feed may be taken. When such a tool is used, the cut taken is very light and the feed is slightly less than the width w. This tool is, however, only adapted to rigid work, for if a broad-nosed tool is used on slender and flexible pieces, chattering will occur, which will cause the finished surface to be rough. Consequently, for slender work the width of the cutting edge and the feed must be reduced, the reduction depending upon the rigidity of the work. As a finishing tool cuts only on the point, it should be ground without side slope. The angle of back slope should be about 12 or 15 degrees.

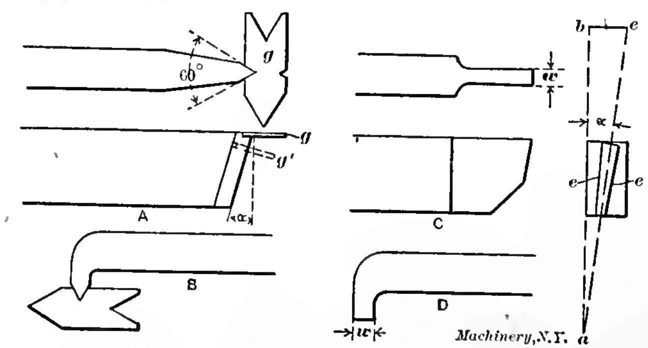
2. The top view of a well-shaped boring tool is shown at B, and at C the same tool is shown improperly ground. When the cutting edge is beveled off as at C, the pressure of the cut acts in the direction of the arrow and tends to deflect the tool from the work. For the same reason, a broad-nosed boring tool is not adapted to finishing cuts, as the spring of the tool at right angles to its shank causes chattering, except when the shank is unusually rigid or the tool is being used in a heavy boring-bar. The clearance angle a of a boring tool should be great enough so that the cutting point of the tool can be set to the same height or slightly below the center of the work. A boring tool that is used for roughing cuts should have more side slope than back slope, as the cutting is done along the edge b.

3. Three views of a right side-tool are shown at D. This type of tool is used for facing the ends of work, beveling corners, etc. It should have a clearance angle a of 10 or 12 degrees, and a side slope γ of 12 or 14 degrees. The end of the tool should be ground to an angle ϕ of about 45 degrees so that it will clear the lathe center when facing. The end should also slope backward to an angle of 4 or 5 degrees.

4. A parting or cutting off tool is shown at E. This tool is also used for cutting grooves, etc. The cutting edge e has a slight amount of clearance, both backward and downward. This tool is usually ground on the top without slope.

SHOP OPERATION SHEET NO. 134

Franklin D. Jones MACHINERY, May, 1910



Grinding Lathe Tools—II

1. A tool used for cutting V-threads is shown at A. The top of the tool is ground without slope and the end is given an included angle of 60 degrees, as shown in the plan view. This angle may be tested by holding a thread gage g against the tool. The gage should be held parallel with the top, and not inclined as illustrated by the dotted lines at g^1. If the tool is ground to a gage held as at g^1, the angle between the cutting edges at the top will be less than 60 degrees. A tool of this type should have a clearance angle a of about 15 degrees. When grinding a thread tool it should be pressed lightly against the stone to avoid "burning" or drawing the temper of the cutting edge. A grindstone is preferable to an emery wheel for grinding a thread tool as a finer edge may be obtained. The stone should, of course, have a copious supply of water.

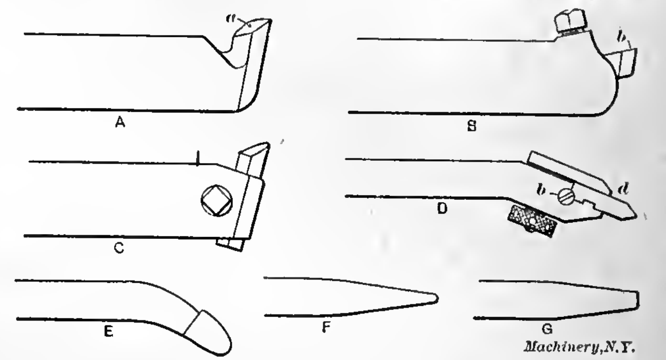
2. The thread tool, a plan view of which is shown at B, is for inside work, that is for cutting a V-thread in a hole. The cutting point of this tool is shaped like the point of the outside thread tool. When the gage is held against the point, as shown, it should be practically parallel with the shank of the tool. If the tool were ground so that the gage was at a considerable angle with the tool shank, the latter might strike against the end of the hole, when properly set, before the tool could traverse the full length of the part to be threaded.

3. A square thread tool is shown at C. This tool is similar to a parting tool, except that the cutting end is at an angle with the shank. This angle a depends on the diameter of the screw and the pitch of the thread; it may be determined graphically by laying off a line a—b equal to the circumference of the screw to be cut, and a line b—c at right angles to the first and equal to the lead of the thread. The angle a, between the lines a—b and a—c will be required angle. The tool illustrated is for cutting a right-hand thread. If it were intended for a left-hand thread, the cutting end would, of course, incline to the left. The sides e of the tool should be ground with a clearance of 4 or 5 degrees, and the width w be made equal to one-half of the pitch of the thread.

4. A tool for cutting an inside square thread is shown at D. The cutting end is shaped practically the same as the tool at C. If a tap is to follow the threading tool, the width w may be made 0.002 or 0.003-inch less than the width of the tap teeth.

SHOP OPERATION SHEET NO. 135

Franklin D. Jones MACHINERY, May, 1910



Grinding Lathe Tools—III

1. The tool shown at A is known as a diamond point; this type is much used for outside turning, particularly on comparatively light work. It should be given a clearance of 8 or 10 degrees. The slope of the lip surface a and its direction will depend upon the work for which the tool is intended. If it is to be used for roughing cuts, a back slope of 8 degrees and a side slope of 14 degrees will be about right for general work. If for finishing cuts, there should be little or no side slope, and a back slope of 12 or 14 degrees.

2. A tool-holder with an inserted cutter is shown at B. As the cutter b is held in a fixed position by the set-screw shown, it can be sharpened by simply grinding the end, except when it is desired to give the cutter a different slope from that due to its angular position.

3. Another type of inserted-cutter turning tool is shown at C. With a holder of this type, it is the clearance of the tool that is fixed, and the sharpening is done by grinding the top of the tool to the proper slope.

4. A plan view of a thread tool of the holder type is shown at D. The angle of the blade d is accurately ground by the manufacturers, so that the tool is sharpened by simply grinding it flat on top. As the top is ground away, the tool is raised by turning the screw b, which can also be used for setting the tool to the proper height.

5. A bent round nose turning tool is shown at E. This tool, as far as clearance and slope is concerned, is ground practically the same as the diamond point referred to in paragraph 1. By having the ends of the various-shaped tools used for turning or planing, bent either to the right or left, they are adapted to work for which they could not otherwise be used.

6. The plan view of a tool for turning brass is shown at F. Brass tools, which are intended for general work, are drawn out quite thin, and they are given a comparatively narrow point, which is flattened or rounded. The top of a brass tool is usually ground flat or without slope, as otherwise it tends to gouge into the work, if the latter be at all flexible. The clearance should be from 12 to 14 degrees.

7. A brass tool suitable for finishing cuts on comparatively large and rigid work, such as brass pump linings, etc., is shown at F. The cutting edge is made wide and the tool is used with a coarse feed.

LOADS FOR ECCENTRICALLY LOADED RIVET GROUPS—I

Contributed by Harry Gwinner

Directions for Using Tables.

The following tables facilitate the finding of the number of rivets to support eccentric loads.

All the tables are calculated for a vertical spacing of rivets of three inches; size of rivets, 3/4-inch; and maximum stress per square inch, 10,000 pounds.

To use the tables, decide on the number of vertical rows of rivets, and the distance between the outside rows, if more than one row is used. Then, in the table for the number of rows adopted, find the number of rivets required for the given load.

Example:— Find number of rivets required for supporting a load of 5000 pounds applied 18 inches from the center of the rivet group. Three vertical rows of rivets will be used; distance between outside rows, 6 inches. (See illustration below).

In Table III, giving the number of rivets for three vertical rows, find the distance (18 inches) between the load and center of rivet group; then in the section headed "18 inches" and in the column headed "6 inches" (horizontal distance between the outside rivet rows), find the figure nearest to the given load. This figure is 5.6, which, being in thousands of pounds, is equivalent to a load of 5600 pounds. Now follow the horizontal line from 5.6 to the left where the number of rivets for the given case is found to be 9.

LAYING OUT STEERING GEARS FOR AUTOMOBILES

By JOHN L. BARRA*

IN designing automobiles, the steering gear probably receives less consideration than any other equally important part of the entire car. As it is one of the most important parts of the automobile, it should, however, be theoretically investigated in order to secure the best possible results. Before entering upon this investigation, it should be thoroughly understood that the meaning of the expression "steering gear" here is not the worm and wheel with their attachments, but the parts to which the first-mentioned is connected by means of a system of levers, that is the so-called "knuckles," which are rigidly fastened to the front wheels, and the link which joins these knuckles. This link will be called the connecting-rod.

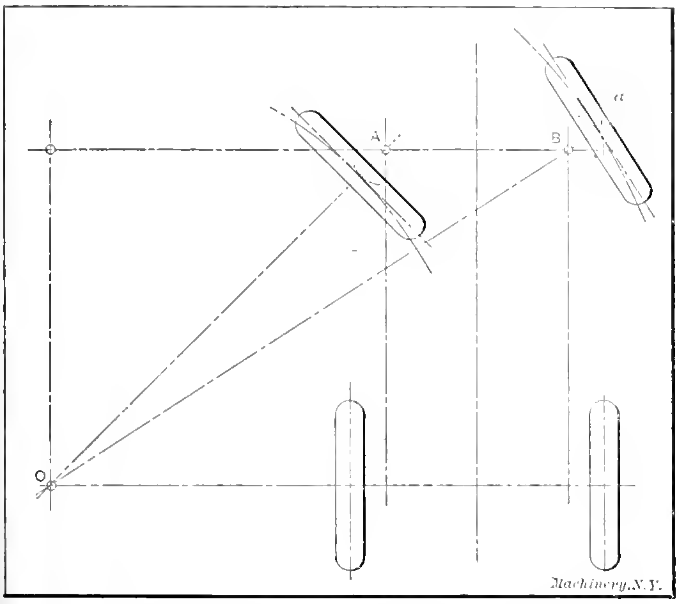

Fig. 1. Diagram showing Action of Car Wheels when turning a Curve

This system of levers and knuckles, when not properly designed, will result in a stiff-steering car, and will also cause undue and excessive wear on the front tires. This comes about in the following manner:

By referring to Fig. 1, it is seen that the center of the curve or circle through which the automobile is turning is at a point O on the center line of the rear axle produced. The location of point O depends on the radius of the curve. In reality there are two concentric circles, one of radius OA, and the other of radius OB. At any point of the curve through which the car is turning, as at a, the outer wheel must be perpendicular to its radius OB to insure perfect rolling action of the wheel over the road; the inner wheel must also be perpendicular to its radius OA at the corresponding point in its path. If the wheels are not perpendicular to their corresponding radii, never-ending trouble will result. It is easily understood how sliding of either the inner or outer tire will occur with an incorrectly designed system of levers, and it is still easier to compare a sliding tire on a sandy road to one rubbing against an emery wheel.

Referring to Fig. 3, let the arms or links bc and de be called the right and left steering knuckles, respectively, and the cross-link ce, the connecting-rod. The knuckles can be made of any length desirable, usually from 5 to 8 inches between centers. Some designers contend that the point f at which the center lines of the knuckles produced intersect the center line of the car should be at the center of the rear axle. On the contrary, so simple a rule cannot be formulated.

* Address: 1619 Race St., Denver, Colo.

Fig. 2 shows the layout for the derivation of the formulas to be used. Throughout the rest of this discussion we shall observe the following notation:

W = wheel base,

T = distance between centers of swivel joints about which the front wheels turn,

m = the angle of the inner wheel,

n = the angle of the outer wheel.

P (Fig. 3) = the angle made by bc and de with the center line of the front axle.

The following relation exists between the angles m and n (see Fig. 2):

$$\cot m = \frac{AC}{CO}; \quad \cot n = \frac{BC}{CO} \qquad (1)$$

But $BC = AC + AB$, and $AB = T$. Hence $BC = AC + T$. Substituting this value of BC in equation (1) we have:

$$\cot n = \frac{AC + T}{CO} = \frac{AC}{CO} + \frac{T}{CO}.$$

Since $CO = W$, the wheel base, we have:

$$\cot n = \frac{AC}{W} + \frac{T}{W} \text{ and } \frac{AC}{W} = \cot n - \frac{T}{W}$$

But

$$\frac{AC}{W} = \cot m$$

Therefore,

$$\cot m = \cot n - \frac{T}{W} \text{ and } \cot n = \cot m + \frac{T}{W} \qquad (2)$$

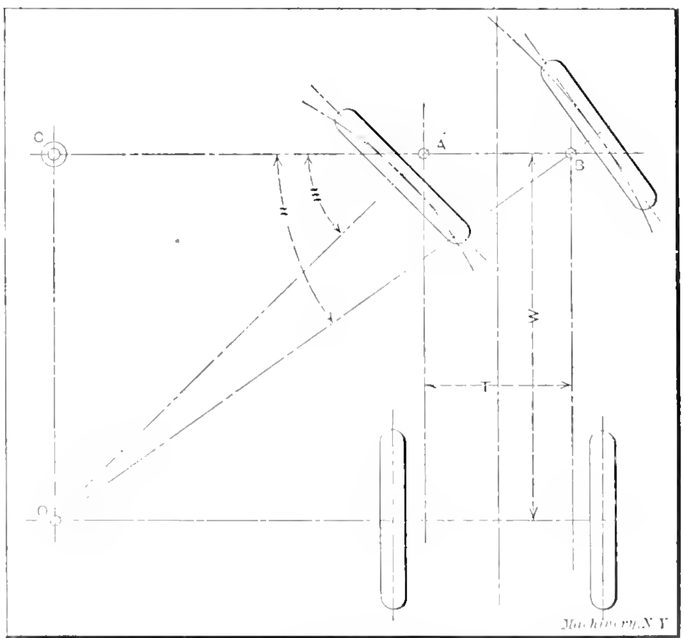

Fig. 2. Diagram giving Notation used in Formulas

From Fig. 3 we find,

$$\cot P = \frac{\frac{T}{2}}{h} = \frac{T}{2h} \qquad (3)$$

Now assume a value for h about 90 per cent of W and by equation (3) obtain the angle P. Having found P, lay out, full size, the points A and B, as indicated in Fig. 4, representing the centers of the swivel joints about which the front wheels swing, and also the angle P of the steering knuckles. Then with any convenient radius, describe two arcs from A

and B as centers and divide the left-hand arc of what will be called the inner wheel, into about nine 5-degree spaces, representing the conditions found in actual service. The length of the connecting-rod or cross-link will be DE.

With a beam compass set to the length DE and with a, b, c, etc., as successive centers, mark the points 1, 2, 3, etc., on the arc through E. Connect the points 1, 2, 3, etc., with the center B and using a protractor, scale the angles $EB1$, $EB2$, $EB3$, etc., and tabulate them under the heading "Angle of Outer Wheel by Trial" in the table, Fig. 6.

It is now necessary to see how nearly correct these trial angles are. The theoretical values of the correct angles of

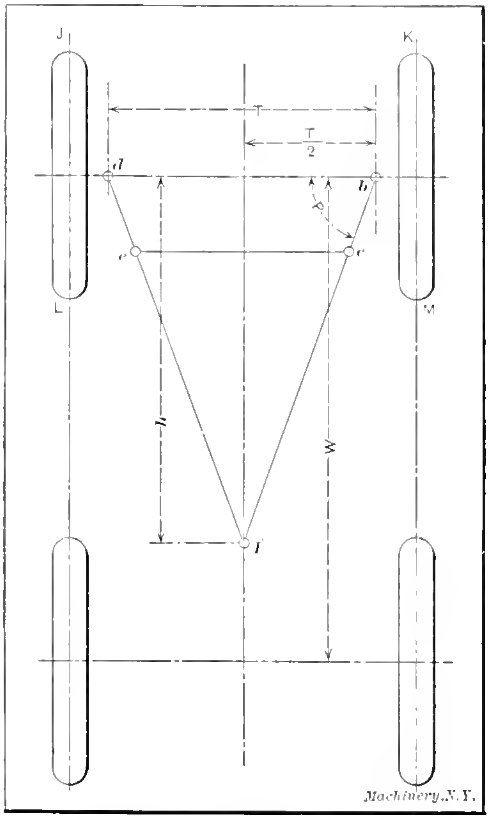

Fig. 3. Diagram for the Deduction of Formulas for Steering Gear

the outer wheel are obtained by equation (2). The values of the cotangents of m the angle of the inner wheel are obtained from a table of natural cotangents. These values are tabulated in Column 2 of Fig. 6. The value of $\frac{T}{W}$ (using

1	2	3	4	5	6

40	1.1918	$\frac{T}{W}$	....	....	....
45	1.0000	$\frac{T}{W}$	....	....	....

Fig. 6. Table for comparing Tentative with Theoretically Correct Results

numerical values for T and W) is to be added to the cotangents of m as per equation (2). This sum is then tabulated under the heading cot $m + \frac{T}{W}$.

The angles having the value in Column 4 for cotangents are now found in a table of natural functions, and placed in Column 5.

On comparing the angles by trial with the theoretical (Column 5) angles, they will not be found to agree to any considerable extent. If the difference between the trial and the theoretical angles is very large, say from 3 to 5 degrees, it will be necessary to assume a new position of f and make a new calculation for the angle P and a new full-size lay-out. This calculation and construction is to be repeated until angles of the outer wheel are found which show a difference of not more than 2½ or 3 degrees with the theoretical angles.

When a set of angles has thus been found agreeing closely with the theoretical values, a curve can be plotted on

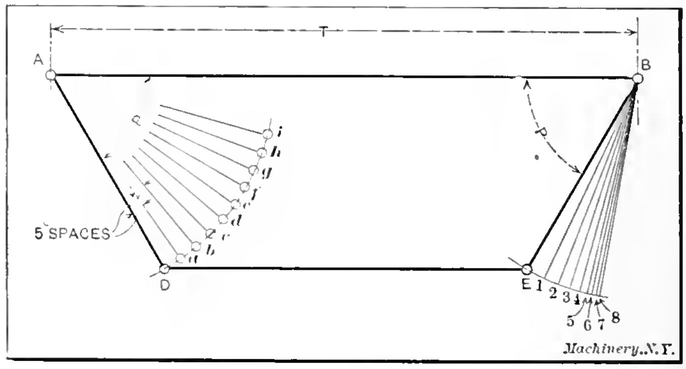

Fig. 4. Tentative Lay-out of Steering Gear Links

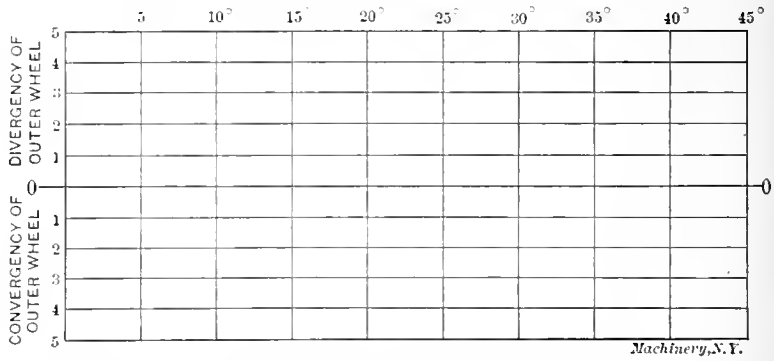

Fig. 5. Drawing-paper ruled for Laying Out Curve showing graphically Comparison between Tentative and Theoretical Angles

the curve sheet Fig. 5. The curve which would give a perfect rolling to both tires is the straight line 0-0, since this line is one of no difference between the trial and theoretical angles. It is impossible ever to attain this degree of perfection in actual practice. The best that can be asked for is that the angle difference does not exceed 2½ or 3 degrees anywhere between the 0 and the 45-degree point.

The horizontal spacing shows the different angles of the inner wheel, and the vertical spacing the difference between the trial and the theoretical angles. These differences for every 5 degrees are to be plotted above the base line 0-0 if the trial angles are less than the corresponding theoretical angles, and below if they are greater. If the trial angles are greater than the calculated angles, it is at once known that JK, Fig. 3, is less than the distance LM and the front wheels are convergent; on the other hand, if the trial angles are less than the calculated angles, the distance JK is greater than the distance LM, and the front wheels are divergent. In either case there will not be a perfect rolling action which will result in the car steering stiffly and cause excessive wearing of the tires.

The joints c and e should lie on the lines bf and df, respectively, and may be either ahead of the front axle or behind it.

The safest place for the knuckles and connecting-rod is just back of the front axle if it is possible to place them there. When they are placed back of the axle they are protected by the axle against accidents due to hitting rocks and stumps.

Having obtained a value of P which gives good results for the angles of the outer wheel, it now remains to design the steering knuckles and connecting rods by the methods laid down in mechanics, bearing in mind the fact that the parts are subject to quite severe shocks due to rocks and irregularities in the road, making it necessary to use a large factor of safety.

FORGING IN OLD FRANCE

By JOSEPH G. HORNER*

A smith's shop previous to 1771, taken from a French encyclopedia of that date, is shown by Plate I. It is termed the workshop of a master smith. At *d* bellows, and the rod by which they are operated, are shown. At *e* a blacksmith is urging the fire with bellows and heating the iron at the forge. The hood and chimney of the forge at *f* will be noticed. At *g* a man is occupied in filing a piece of work in the vise. Another vise is seen at *h*, both being tail vises fastened to the bench *i* exactly as they would appear to-day.

The anvils are not of exactly the same patterns as ours, and they rest on wooden blocks. There is a water bosh in front of the double forge. There is plenty of ventilation to the shop, as there are no glass windows, but hinged shutters hooked up to the ceiling which can be let down. The iron storage is seen outside. It is illustrated separately in Plate II. The bars are tied up in bundles *b* and laid against the wall, and a large pair of scales suspended from a wooden tripod has bars in one pan being weighted by the two workmen. One man is passing bars into the shop, which are being taken charge of by another workman within.

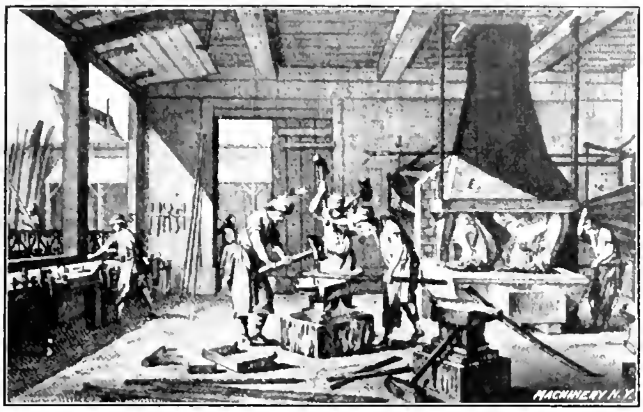

Plate I. A French Blacksmith Shop about 1770

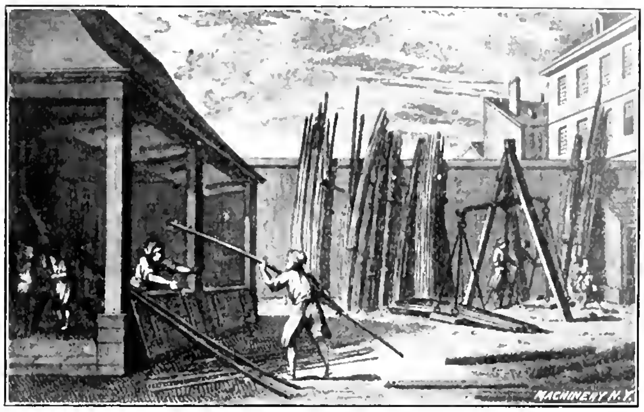

Plate II Stock Storage and Scales for Weighing the Material

Plate III shows trusses or bundles of iron bars tied up by iron rods *A*. Figs. 3, 4 and 5 show round, flat and square bars as used by the blacksmith of that time, and Figs. 6 and 7 show forged bars. In Plate IV are shown a packet of sheet iron and a coil of iron wire. A curious bar gage is seen in Fig. 10, similar to a modern wire gage with notches terminating in round holes down both sides of the gage. Another gage, Fig. 11, is formed by bending a bar in S fashion, which is suggestive of a spring. Illustrations are given in this plate of forgings termed anchors, apparently used for building purposes; Fig. 12 is a "straight" anchor, Fig. 13 a "finished" anchor. Fig. 14 is a drawing strap, *C* being the anchor. Fig. 15 is a forging with a forked end.

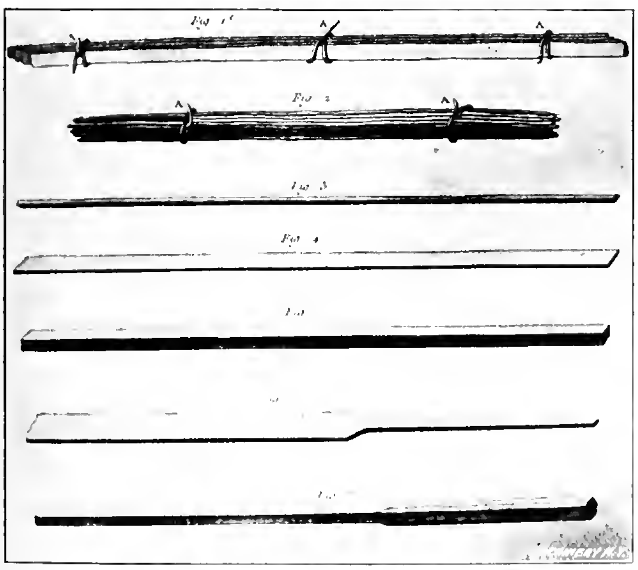

Plate III. Rough Stock and Forged Bars used in Blacksmithing 150 years ago

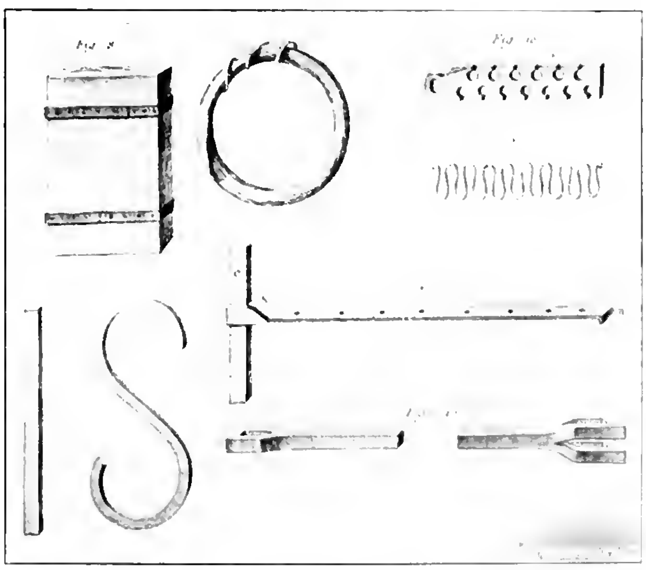

Plate IV Materials and Tools used in Early Blacksmithing

In Plate V another smith's shop is shown with several workmen engaged on various operations. At *a* a man is urging the forge bellows; at *b* another is manipulating a forging on an anvil, turning, and turning it about on the four faces; the one at *c* is placing a piece on for welding, on which the men at *d* and *e* are hammering. The man at *f* is cutting a file.

In Plate VI, Fig. 1 is the "mass" from which the body of the anvil is to be made, seen again at *A* in Fig. 2. Into a square hole in it a bar *B* is fitted, to be manipulated by the cylinder of wood *C*, shown again separately in Fig. 4, and bonded at *A* with iron hoops. Holes at *B* receive the handle bar, Fig. 5, by which it is turned about. Fig. 6 shows at *A* the piece to be welded, *B* being its porter bar. In Fig. 7 the top *B* is seen welded on the body *A*. Fig. 8 shows a beak *A* prepared for welding with a porter bar *B*, and Fig. 9 is the same in place. In Fig. 10 both beaks are welded on. Figs. 11 and 12 show the steel face and the body of the anvil separately, and Fig. 14 is the finished article.

In Plate VII the making of a stake is shown, beginning with Fig. 1. In Fig. 2 the collar *B* is fitted, shown separately in Fig. 3, and welded in Fig. 5; the end *B* is then upset. In Fig. 6 one of the horns in Fig. 7 has been welded on. Fig. 8 is the steel face with its porter. In Fig. 9 the stake is complete. Figs. 10 to 17 represent the stakes in the making of a hammer, Figs. 11 and 14 being the steel jaws hatched up for welding. The next group of Figs., 18 to 20, illustrate the making of a billhook. Figs. 21 to 32 are other examples of forging.

Die forging was practiced in the eighteenth century in a small way, and the practice was the forerunner of the die forging applied to the manufacture of pistols in America, and of locks in the Black Country. Several dies are illustrated in Plate VIII for the work of making sliding bolts for doors and other purposes, which figured more largely then than they do in these days of cheap locks. The stamps were laid upon

the anvil and held securely. Fig. 1 is a die for imparting a truly cylindrical form to round rods for window bolts, A being the stamps, and B the horns or ears. One of molded section is seen in Fig. 2, and the same is clamped to the anvil in Fig. 3. It is secured with a bridle and key. The bridle holds in the ears B of Fig. 2 and is shown separately in Fig. 4, and its key in Fig. 5. Figs. 6, 7 and 8 are other forms of dies; Fig. 6 is for a collar; Fig. 7 combines two recesses, one for plain bar, the other as in Fig. 8 for a molding. Fig. 9 is another kind of stamp for forging the portion A in Fig. 10. Figs. 12 and 13 are two stages of nail making for window bolts, Fig. 12 showing the nail blank ready for stamping, and

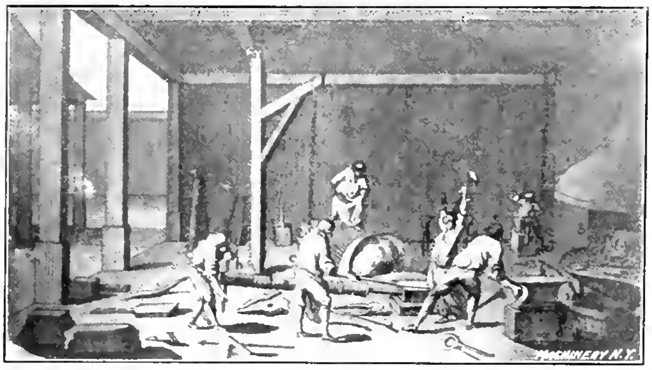

Plate V. Another Early Blacksmith Shop

Fig. 13 being the same taken out finished from the stamp in Fig. 14. Fig. 15 is a key for turning the nuts of bolts, A being the fork and B the handle. Fig. 16 is a tool for stamping nuts, and Fig. 17 is the same reversed showing the end by which the stamping is done. Half a dozen nuts are shown being stamped from a piece of flat bar in Fig. 18. Figs. 19, 20 and 21 are top stamps with handles. They are of the same type as those used in any smithy to-day.

Figs. 22 to 26 show separate stages in a piece of work. Fig. 22 is the first heat taken on the bar A, in which rings 23 or 24 are welded round a plain bar. In Fig. 25 a groove has been fullered round at A, and in Fig. 26 the molded sections at A have been finished in a third heat. In Fig. 27 a piece A for the ward of a key is welded on a shank, the piece being seen at Fig. 28. At a second heat the ward is flattened as in Fig. 29 at A. In Fig. 31 a wrist or boss A has been welded to the rod B. The wrist is seen in Fig. 30, and horns A are

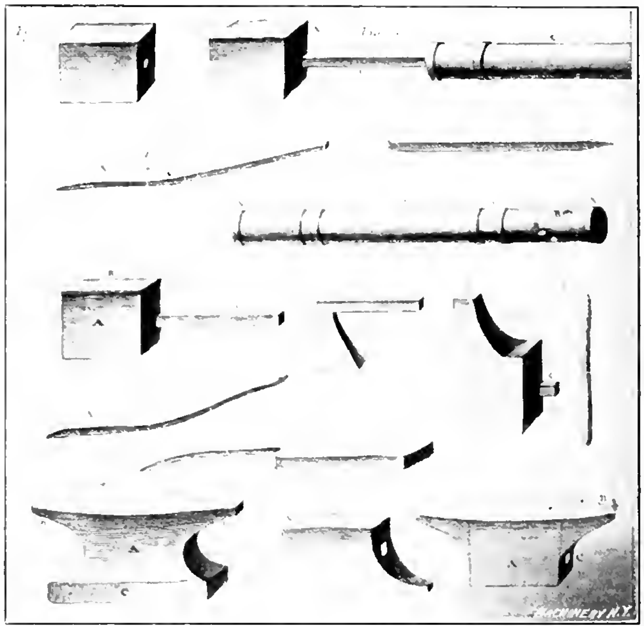

Plate VI. Successive Stages in the Forging of an Anvil

shown to enable it to hold during the welding. In Fig. 32 a piece of drawing down is shown, the drawn-down portion being afterwards bent to form the elbow A in Fig. 33.

How microscopic are the differences between the tools shown in Plate IX and those of a modern smithy! There is

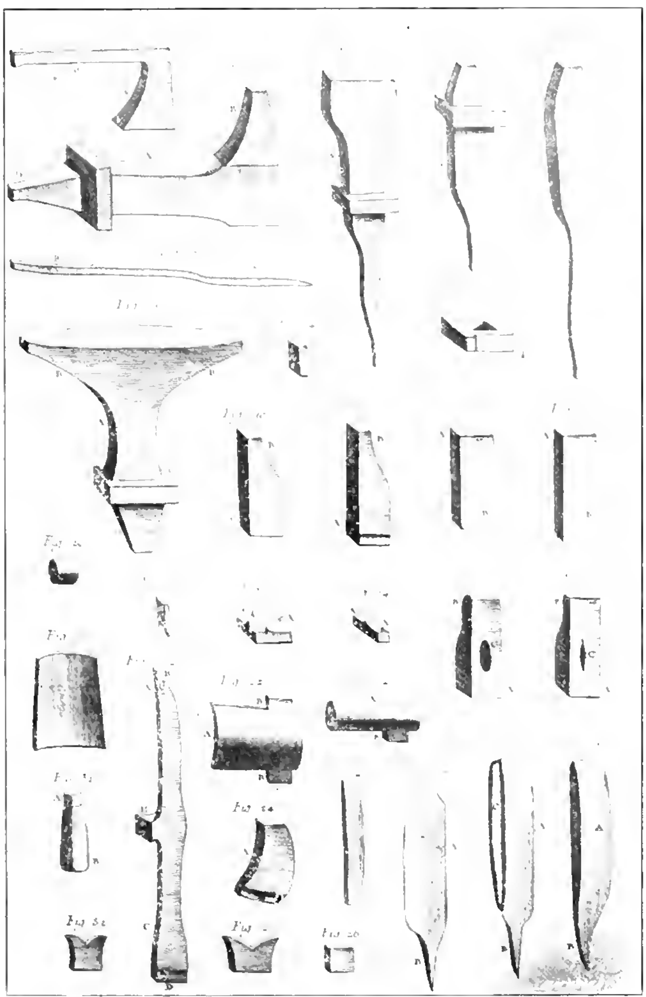

Plate VII. Examples of Forging Methods in Early Days

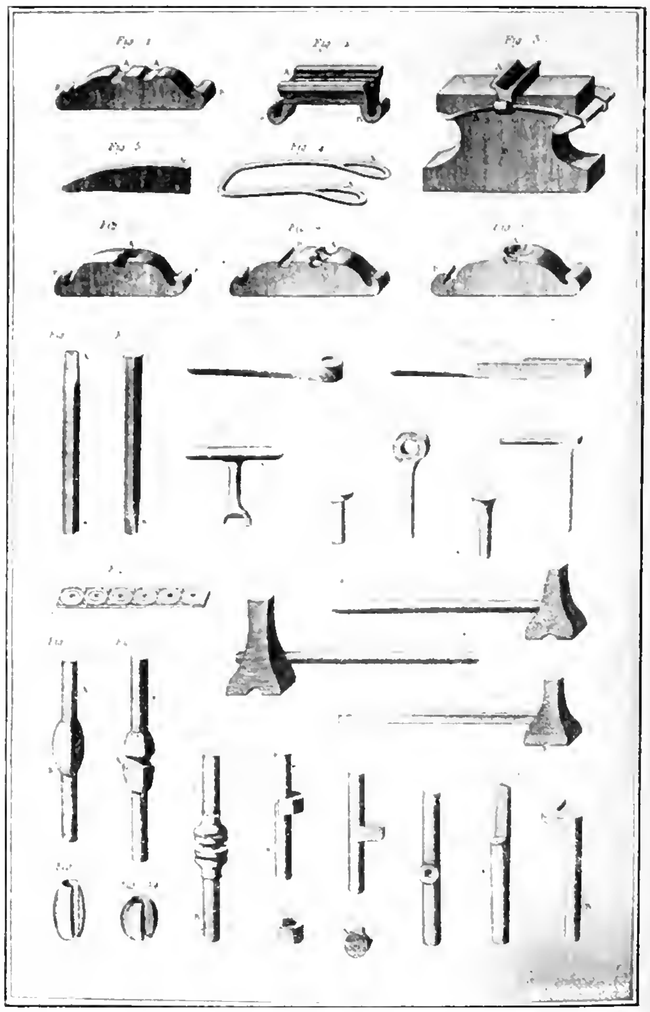

Plate VIII Early Die Forging Tools and Methods

little need to particularize. The poker, the brush, the anvils and stakes, are nearly identical. The foot of the anvil, Fig. 4, looks rather odd, being shaped into steps, and so do the grooves at the side. A stake or little anvil is shown in Fig. 5, *B* being the round beak and *C* the square one, placed on a block or billet of wood *E*, bonded at *F*. Fig. 6 is another small stake. Fig. 7 is a scroll, finished, and lying on a block of wood. An anvil stake is seen in Fig. 10, and hot and cold

The Krupp Works at Essen in Germany are constantly increasing in size. The number of men employed by the company at its works in Essen and elsewhere increased during 1909 by nearly 4,000, so that at the end of 1909 about 67,000 men were in the employ of the company. At the Essen works a total horsepower of over 73,000 is used, this power operating over 7,000 separate machine tools, over 900 cranes, 187 trip hammers, and 81 hydraulic presses.

FRICTION OF WATER IN PIPES

A writer in *Power and the Engineer* gives the following formula for the loss of head in water pipes, due to friction:

$$H = \frac{LQ^2}{1{,}000{,}000\,KD}$$

in which H = frictional head (or loss of head by friction) in feet,

Q = gallons of water per hour,

L = length of pipe in feet,

D = diameter of pipe in inches,

K = a variable coefficient, tabulated below for various diameters.

D	K	D	K
0.5	1.27	4	3.05
0.75	1.63	6	3.26
1.0	1.90	8	3.38
2.0	2.57	10	3.46
2.0	2.85	12	3.51

These coefficients apply specifically to new cast-iron pipes.

The first regular air navigation service in Europe will be begun May 15. Regular trips will be made from Munich, Bavaria, alternately to Starnberg and Oberammergau. A dirigible balloon of the Parseval type, having a gas capacity of 6,700 cubic meters and driven by two motors of 100 horsepower each, will be used. The aerial carriage will accommo-

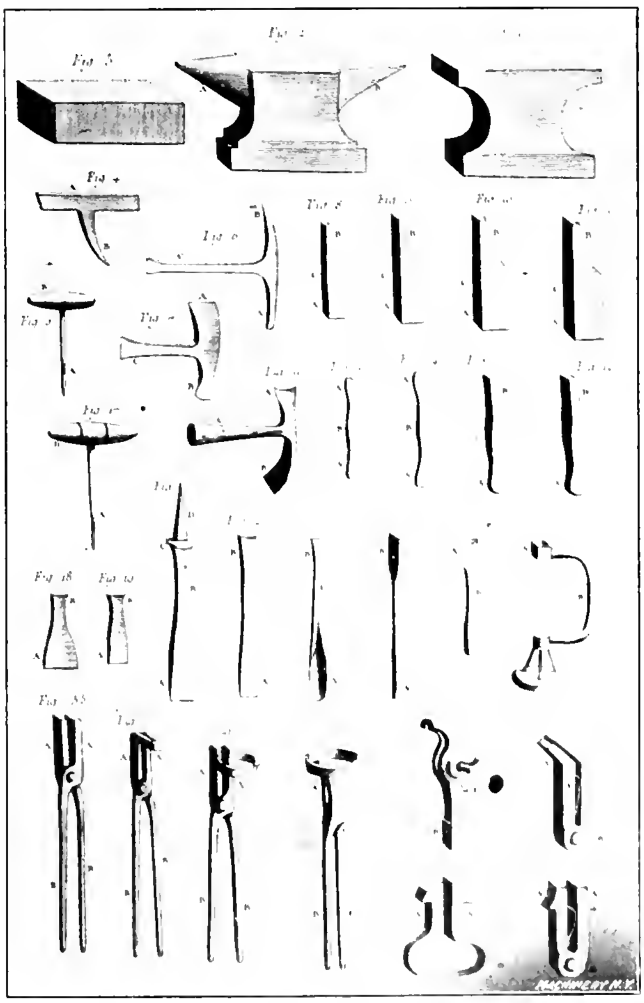

Plate X Another Selection of Early Blacksmith's and other Tools

date twelve passengers besides the crew. The fare for the round trip to Starnberg will be \$55, and for the round trip to Oberammergau \$175. The regular service will close for the season September 1. An officer from the German Aeronautic Corps has been detailed to serve as captain of the dirigible.

REORGANIZING A RUN-DOWN ASSEMBLING DEPARTMENT*—1

By ALFRED SPANGENBERG†

The present-day enthusiasm for increasing production by the use of ultra high-speed steels and by methods for "cutting time between cuts," has resulted in a disproportionate amount of attention being given to the problem of machine work in comparison with the no less important problem of assembling. Yet an investigation of the conditions existing in many manufacturing establishments will reveal that obsolete methods and processes in the assembling department nullify, to a large extent, the savings thus made in machining. The adoption of up-to-date methods of assembling may easily be expected to increase the efficiency of the average assembling department from 100 to 150 per cent, and if the department is in a run-down condition, even greater savings may be anticipated. Of course, to expect such large increases in all cases would be unreasonable, but there are many instances where such results are possible.

Fig. 1. Transfer Card

While the need for system in the assembling department is becoming more widely recognized, there are many manufacturers to whom the word "system" is indissolubly linked with "red tape." "Organization" is not their idea of economical management, because it means additional "non-producers"; and the leaks continue unchecked until some well-organized competitor forces the condition to their startled attention. This condition, however, is generally due to lack of sufficient experience or data enabling a concern to determine, with any degree of accuracy, whether or not economical results are secured from foremen, workmen, or processes.

It should be fully understood that there is no infallible system which will fit all cases alike; methods must be suited to the circumstances under consideration, since the first thought in regard to any plan must relate to its adaptability to existing needs. The reorganizer can rely but to a small extent upon any established system, and his initiative and common sense must bring a working result from a mass of conflicting conditions. With these facts in mind, the author will not attempt to describe any particular system, but will only consider certain fundamental principles.

Necessity for Analysis of Existing Conditions

Before introducing innovations in a department, it is necessary to analyze existing conditions and methods with regard to the men in the present organization, for invariably a certain amount of ignorance, prejudice, false pride, and stubbornness must be met and overcome. To win success, all plans must recognize, primarily, the human element of the men affected; methods should be instituted that are likely to elicit the support, develop the latent ability, and bring out the best that is in the workers. The best system in existence will not bring complete success without securing the support of the foremen and workmen. If these points are ignored, the tendency of the workers to gradually abandon methods with which they are not altogether familiar, will cause a partial failure of the system.

The most arduous and discouraging task, next to training the old men, is that of progressing along new lines and at the same time not interfering with the regular output. This can only be accomplished gradually; any attempt to suddenly rip up existing methods will not be effective. The old systems possess a momentum not easily overcome, and it therefore will take a long time to reorganize. However, when once a general line of procedure is mapped out and progress begun, there must be no lessening of effort. Everyone must be impressed with the idea that *every day* must show *some progress*, however slight.

The machine and the assembly departments are so closely connected that the introduction of new methods of assembling must begin with an investigation of the production conditions in the machine departments. This investigation will include the quality and quantity of work, whether or not provisions are made for inspection in the machine departments, methods of routing the work, what delays are encountered in getting work to the assemblers, whether the work is sent directly to the assembling department or duplicated in large quantities and kept in a store, etc. It is apparent that any defects in the processes just enumerated will have an immediate effect on the efficiency of the assembling department.

In the assembling department itself may be found faulty judgment regarding assembling methods, lost time in looking up work, hunting for tools, and running after drawings or to the stock-room for screws and pins, mistakes due to oversight, lack of proper instructions to the workmen, etc. The faults in organization and methods mentioned in this brief outline must be eradicated before any effective improvement can result.

The Stock-tracing System

Where there is constant trouble in getting out machines or repairs in a reasonable time, it usually will be found that some one or two departments are responsible for practically all of it. The first step to remedy the trouble, then, is to locate it. The assembling department usually is blamed, but an investigation will generally reveal that the difficulty lies in not getting work promptly to the assemblers. Many manufacturers are so accustomed to delays in getting finished parts to the assemblers that they regard the matter as unavoidable, even though the consequent losses show clearly that a remedy is imperative. A well-organized stock-tracing system is an important factor in overcoming this defect, and is so necessary that a brief outline of it is deemed advisable.

Fig. 2. Inspector's Report from which the Monthly Report is made

The functions of a stock-tracing system are: Directing the transportation of all parts in the factory; pushing the work through the foundry and machine departments in such a manner as to prevent delays to the assemblers; keeping up records that will show the location of parts in the foundry and shop, the time required by the various departments, the labor cost, and all losses, with proper explanations. The sole authority and responsibility for this work should be vested in the head of the stock-tracing department. It is obvious to the experienced shop manager that such duties cannot be left to

* For additional information on the subject of assembling, see MACHINERY, February, 1910, "Laying Out and Aligning Operations on Machine Tools," and other articles there referred to. See also MACHINERY'S Reference Series, Nos. 50 and 51, "Principles and Practice of Assembling Machine Tools."

† Address: 951 W. 5th St., Plainfield, N. J.—See biographical note in MACHINERY, April, 1909.

the department foremen if the shop is to be run advantageously. The foremen's attention should be concentrated solely upon improving their methods and their output, and their duties should be confined strictly to their own departments.

Experience has demonstrated that it is necessary to give the stock tracer *absolute control* of all parts in the process of manufacture; in addition, he should be given such authority that the foremen will understand that his requests for stock must be complied with under all circumstances, and he alone should have authority to secure parts from any department in the factory, either for any foreman, or for the assembling department. Having under his charge all the records for stock in the course of manufacture will enable him to locate all stock with certainty and dispatch. Another advantage is that the superintendent always knows where to get any information regarding the location of work in the factory, and the time it may be expected to reach the assembling department.

If the work is allowed to remain in any department after

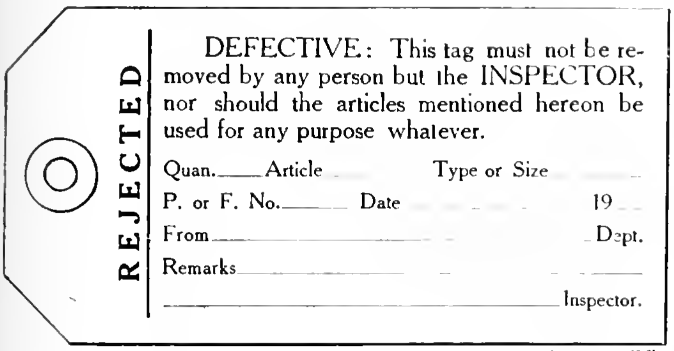

Fig. 3. Card or Tag for Rejected Work or Material

it is finished, it is apt to be forgotten, and is hard to find when wanted. Therefore, the advantages of having the work placed in central depots as soon as finished by each department, will amply compensate for the time consumed in hauling the work to one of the depots, putting it on a platform, checking it up and then taking it to the next department. This plan is especially advantageous where any system of inspection is followed; no stock can be lost; each foreman can see at a glance how much work there is ahead of him; and it aids the superintendent in getting a conception of the conditions of the work. The central depots can be located at any number of points and should contain suitable platforms for the storage of stock. These remarks apply, of course, to the smaller parts; it would not be practicable to carry out this scheme in the case of large work.

Transfer cards showing delivery of work from one department to another form a ready record which shows the date on which the articles have been received, the length of time they were retained, and the date they were passed on to the next department. A glance over this record shows if the work is pushed through with all the promptness possible. The question of giving certain orders priority over others is one upon which the stock tracer will need to exercise his best judgment. If any work is behind time, the card made out when the order was first sent to the shop is called in and replaced by a similar card of bright red color containing exactly the same information, and also the required date of delivery. An order with the red card always has precedence over those with cards of the ordinary color. Care must be taken, however, not to use these "rush" cards to such an extent that they become so familiar as to be ignored. A transfer card and the information it should contain is shown in Fig. 1.

Instead of allowing each foreman to have his own gang of truckers, the trucking force throughout the factory should be centralized and placed under the supervision of the stock tracer. This force of men will deliver work to all departments in the factory as it is called for, and upon their returning to the respective depots they will bring in the work that is on the machine room floors already finished. The fact that this work is finished is indicated by "Move It" cards, which are placed in the boxes by the workmen. These remarks apply to the handling of small parts; in handling large work, cranes are almost universally used.

Inspection

In a previous article appearing in the September, 1909, issue of MACHINERY, the writer emphasized the necessity for inspection of work in the machine departments in order to secure economical assembling. This is one of the essential preliminary steps in the revival of a run down assembling department; yet it is difficult to convince the average manufacturer that it will pay to employ a number of high-priced men to do nothing but inspect the work done by other men. The idea is prevalent that the payroll for these inspectors, who are non-producers, is but a constant expense, and it is hard to realize the very large economies which their work, if efficient, will bring. The advantages to be gained by an efficient inspection department may be given thus:

1. Imperfect parts are eliminated before the work reaches the assemblers. If the parts come to the assemblers properly inspected, so that they can be put together without unnecessary filing and fitting, the saving of time in assembling easily may reach from 60 to 75 per cent.
2. The fact that the parts are interchangeable will result not only in ease of assembling, but in case of repairs the parts can be sent out with the assurance that they will fit properly without adjustment. The last-named feature is important in that it is a splendid advertisement to any concern.
3. It instills into the minds of the workmen the fact that the work they produce must be up to a high standard, and that if it be otherwise it will be thrown out, at their loss. This one feature will result in marked improvement in the quality of the work.
4. The workmen receive pay for good work only and are charged with that which is defective, so that an inspection system provides protection to the company.
5. The elimination of defective parts by an inspector, important as it is, is only of minor significance when compared to the general effect. It would astonish the average manufacturer to find how soon his workmen will come up to any standard set by the inspection department, and how small the loss will be, no matter how close the limits are held.

Any system of inspection must be thorough, and the limits given to the work must be adhered to uncompromisingly. Weakness on the part of the inspector will immediately be noted by the workmen. The inspector's authority to reject work should be unquestioned, and the superintendent should never, unless when absolutely necessary, reverse his decision. An inspector should be placed upon as high a plane as any of the foremen in the factory, and to be successful, he should possess good judgment, firmness of character, and familiarity with the business.

A thorough system of inspection effects large economies in every direction, but principally in the assembling department. The parts can be assembled more quickly and accurately, and the saving in this department alone will pay for the cost of inspection. Besides, the machines built will be much more accurate. In many cases it is not necessary to establish a very elaborate system.

There is another phase of this question which is important from an economic standpoint; this relates to fair and consistent inspection—*commercial* inspection. Unless an inspector has sufficient intelligence to discriminate between vital and unimportant dimensions, and unless he possesses enough judgment to know when a job is commercially satisfactory, he causes a waste of time and imposes unnecessary hardships on the men who do the work. Good judgment in inspection is a vital factor, and it will pay to employ first-class men on this work. The best workmen and machines sometimes make a slip as to size, and to ruthlessly reject work which is commercially satisfactory is an abuse of the inspector's authority. An inspector is apt to forget that on the large majority of work there is often no necessity for anything closer than a few thousandths inch. Therefore, it is advisable, in many instances, to have limit gages with as wide limits as the character of the work will permit, and to have rejected work looked over by a chief inspector whose decision is final.

Reports should be made by the inspectors at least once a month, showing the amount of work scrapped by each department, together with the reasons. The effect of this upon the foremen is marked; when they realize that they are liable to censure for the excessive amount of scrap coming from their departments, they will soon give the matter their per-

sonal attention. Fig. 2 shows a blank report of this character, while Fig. 3 shows a card or tag which is placed on all defective work by the inspector. A simple system of this kind, tried for a few weeks, will prove to any manufacturer that the unnecessary waste in his factory is astonishing.

Having thus analyzed general factory conditions, attention will now be given to the methods for increasing the efficiency of a run-down assembling department. The causes of loss should be clearly recognized and logically grouped for study. This will enable us to easily see what must be done (and what *must not be done*) to secure improvements. The sources of waste already referred to may be classified as follows:

1. Defects of departmental organization—of the foremen, the job bosses, and the usual methods of management.
2. Defects of assembling systems.

1. DEFECTS OF DEPARTMENTAL ORGANIZATION

The Foreman

The first and the absolute requirement for an efficient assembling department is an efficient man to run it. No half-baked "graduate" of the existing department will bring proper results; this department calls for a man of a high type. This cannot be emphasized too strongly, for it is foolish to plan a campaign of improvement with any expectation of success unless this first step is taken. The mistakes and shortcomings of the low-priced foreman are too costly; a well paid, progressive man is the cheapest in the end. He should have a thorough knowledge of the most economical methods and of the special labor-saving devices, jigs, etc., best adapted to the work he handles, and, last but not least, the ability to handle men tactfully.

In selecting the foreman, it should always be remembered that he is to the workmen the direct representative of the firm, and that the men base their opinion of the company largely upon their opinion of the foreman; hence, the personality of the foreman affects the workmen more directly than any other factor in the shop organization, and has a direct effect upon their efficiency and disposition toward the company. The foreman must be invested with absolute authority over his men, and he should be given "his chance," which with most men means increased ability to handle the problems submitted to them. Of course, the foreman of a department should consult frequently with the superintendent regarding any important problems that arise, for it is well to observe the principle that, nine times out of ten, the joint advice of several men is superior to any plan developed from one man's brain. It frequently happens, however, that a superintendent makes the serious mistake of ignoring the vital points just mentioned, and instead of entrusting the details of the work to his foreman, gives orders directly to the workmen; in this way the workmen gradually lose respect for their foreman, and the latter becomes a mere figure-head, without any authority except in minor details.

Owing to the weakness of the ordinary foreman, the majority of up-to-date concerns have adopted the broad policy of instituting a rate-making department, and jig-designing and jig-making departments, entirely independent of the foremen. The principal reason for the adoption of this plan, however, is the fact that a foreman seldom has time to set piece-work rates, design jigs, etc., and attend to the other important duties that demand his attention. As has already been pointed out, the foreman's entire energies should be concentrated, as far as possible, upon the important duties of supervising the work and devising ways and means for increasing the efficiency of his department.

The Job Bosses and Workmen

It is evident that a foreman cannot properly oversee his entire department without assistance and still devote his attention to the larger and more important details of his work. The usual method of procedure in order that each man or group of men may receive the proper amount of attention, is to appoint the more efficient members of the working force to the position of "job bosses." Each job boss is invested with a limited degree of authority over a small group of men, and, by performing his share of the work in addition, receives a slight increase in pay. These men should be carefully selected, since they usually are next in line for advancement to assistant foremanship.

When the department is sufficiently large, the foreman should be relieved of all clerical labor such as making out time-cards, writing sub-contracts, checking up parts received, etc.; and this, of course, presupposes the employment of one or more clerks.

As a general proposition, first-class, well-paid machinists are the cheapest in the end on assembling work. This is especially true where the work varies in character. The amount of work that will be turned out by a highly skilled assembler, when compared to that of a cheap man, is astounding. An important feature to consider is also the fact that the workmen's pay is only one part of the total cost, because a largely increased production per square foot of floor area decreases the proportion of overhead cost per piece.

Where work is duplicated in large quantities, so that there are constant repetitive processes, it is possible to so train the cheaper and less experienced workmen that they in time become expert on their particular class of work. It is advisable to provide for a rigid subdivision of labor. Thus, the more particular work at the vise or bench is handled by special men who do no other class of work. These high-priced mechanics perform no work that can be done by cheaper men or apprentices, and in this way, the average rate is kept normal.

Systems of Pay and their Effect Upon the Workmen

The system of pay is one of the most important elements to be considered in the case of a run-down assembling department, because assembling work is progressing only when the workman is busy. In order, then, to stimulate production, it is absolutely necessary to offer a reward for extra efforts on the part of both the foreman and workmen. To give the foreman all the gains is manifestly unfair, and leads to dissatisfaction on the part of the workmen; in fact, an inequitable system of pay invariably causes a lack of proper results and seriously affects the cost of assembling.

The piece-work system is the one usually in vogue, but its chief evil lies in the universal practice of cutting rates when the men begin to earn large wages. This trouble is very largely caused by the practice of setting "original prices," or "original times" not based upon data mathematically determined, but either upon best previous records, an ordinary "try-out," or, worst of all, on the cost department's estimate. The workmen find that their only protection from reduction in prices lies in the strict adherence to a certain limited rate of earnings and hence of production, with the result that the firm suffers unconsciously through excessive costs and limited output and the men are discontented and determined to "get even" for unfair treatment.

It is clear that it is to the advantage of the manufacturer to get the hours down to the points determined upon. When the work of determining "standard times" is accurately done, as, for instance, in shops where an expert tester is employed who analyzes the assembling operations to the last degree, the figures obtained will be so far below the results previously secured in existing shop practice, that the workmen, in all sincerity, will refuse to believe that it is possible to attain such rates of production. A flat piece rate based upon these "times" would lead to trouble, because of the lack of stimulus. It is advisable, therefore, to offer an extra reward to the workman attaining standard time, with the guarantee that no reduction will be made unless methods be changed.

The attainment of standard time, however advantageous, will never be realized unless the assembling department is so arranged and equipped that the same conditions prevail in everyday manufacture that existed when the expert tests were made. This is a point that is often overlooked. The particular benefits derived from having an expert tester, lie not only in the accuracy with which prices can be determined, but also in that the firm is enabled to show the workmen, by actual demonstration, that the work *can be accomplished* in the time set for it.

The systems of pay in general use are as follows:

The Day Work Plan.—This plan is decidedly inefficient unless the men are rigidly supervised, or under special conditions where the work is intricate and exacting.

Piece-work.—By this the workman receives a certain amount of pay per piece. One of the greatest objections to this plan, as already stated, is that it is so often coupled with the practice of cutting rates when the men begin to earn large wages.

The Premium Plan.—This is a very efficient system of pay on many classes of work. The determination of "standard times," however, should be made carefully, for if the rates are set by incorrect methods, it is easy to imagine the results that will follow. In fact, the determination of "standard times" on assembling work is a particularly difficult proposition, since the skilled assembler can and will deceive anyone not of the highest order of expertness concerning his possible rate of production, particularly when he has worked for years on repetitive processes and thereby has gained marvelous skill. Consequently, in order to secure an extra output, the possibility of which lies concealed within the workman's skill, it is absolutely necessary that the premium be sufficiently large to stimulate his ambition.

The Bonus Plan.—This is a system of task work combined with the use of instruction cards for the workmen and a bonus for accomplishing the task within the time set for it. This plan readily lends itself to adoption in case the men already are working on the day work basis. It also has the advantage of being introduced with little opposition, because it is easily understood by the workmen; and, besides, it is adaptable in some form to almost any other system of pay already in existence in the shop. To be effective, however, it should be combined with methods that accurately determine the shortest time in which a job can be accomplished; and it also should include provision for the job bosses and foreman securing bonuses in case all the men under them earn bonuses. This will compel the foreman to immediately give his close attention to the inefficient workman for his proper and speedy training or his discharge.

This bonus system of pay has always appealed to the writer as the most effective of all systems yet devised for assembling work. But it should be remembered by anyone contemplating the adoption of a piece-work or bonus system, that in addition, it is absolutely necessary to provide a check upon the workmen in the form of an inspection system, for if this point is neglected, the quality of the work will suffer.

THE BATEMAN PLANER DRIVE

By JOSEPH G HORNER*

During recent years some very excellent designs of planing machines with cushioned reversals to the table have been built in England. Messrs. Bateman's Machine Tool Co., Ltd., of Leeds, whose machines are in the front rank, have been introducing a separate self-contained driving apparatus to be fitted to old designs of machines, both for speeding them up and cushioning the reversals. They term it "plano-drive," and a cushioning device is introduced in the form of a spring wheel, which in effect corresponds with the sliding spring rack which is used on the firm's planing machine tables. The mechanism comprises driving pulleys carried at the head of a tall steel framing for belting from the countershaft and to the pulleys below which actuate the firm's flywheel drive, spring wheels, and a complete set of gears for operating the planer table. All the existing gears on the machine to be speeded up are taken out, connection being made directly from the "plano-drive" to the last driving

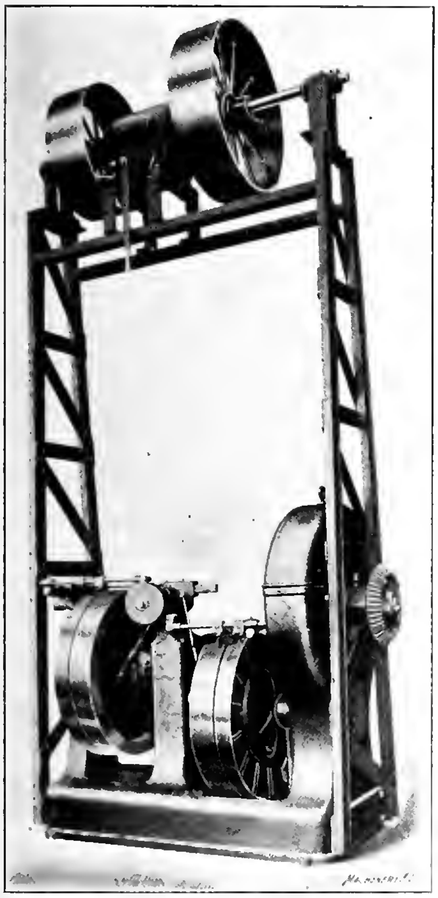

Fig. 1. Bateman's Planer Drive

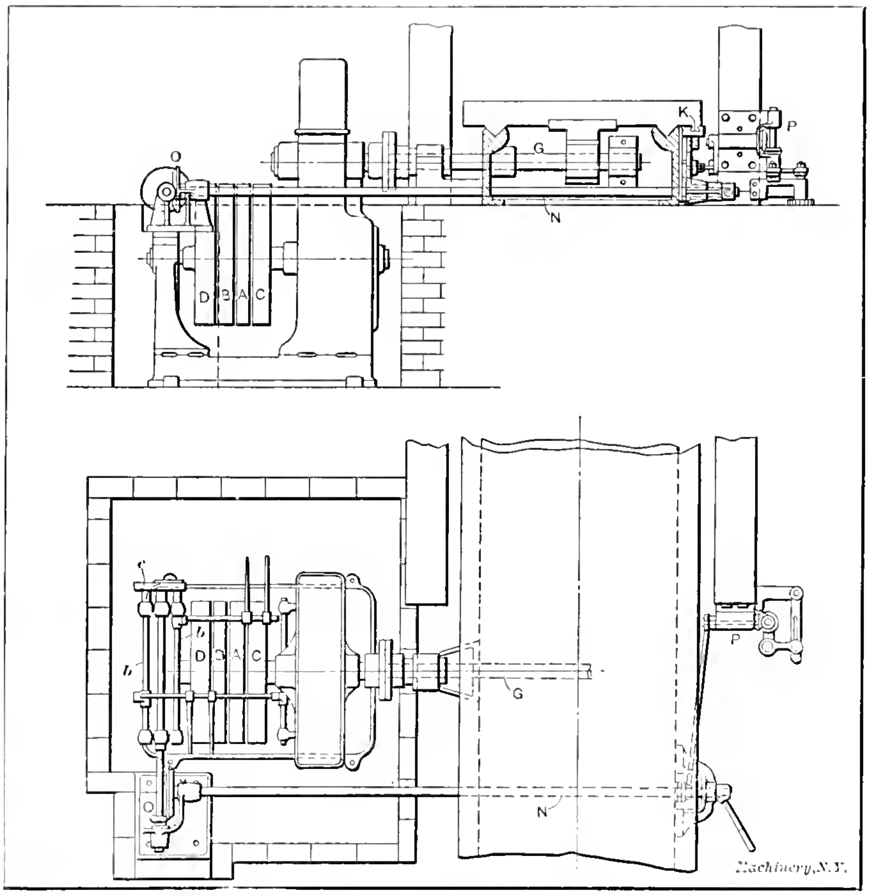

Fig. 2 The Bateman Planer Drive applied to a 4-foot, 6-inch Planer

shaft of the planer through a flanged coupling, or bevel gears. In some cases a motor is substituted for belt pulleys from the lineshaft, in which case it is coupled direct to the countershaft, special frames being fitted to the sides of the plano-drive to carry it. Several firms who have had their planers speeded up have taken the opportunity also to electrify them. In many cases the cutting capacity of the machines has been much more than doubled by the adoption of this drive.

Figs. 2 and 3 illustrate the details of the plano-drive coupled to a 4-foot 6-inch planer. The plano-drive is placed in a pit beside the machine, coupling direct onto the bull pinion shaft, thus scrapping all the old gearing in the machine. The new gearing in the plano-drive replaces all the gearing that is taken out, and obviates all risk of breakage due to the higher speeds. Owing to the use of the spring wheel, the shock at reversal is actually less after the plano-drive is fitted than before.

In Fig. 3 the two fast pulleys for cut and return are

* Address: 45 Sydney Buildings, Bath, England. See biographical note, MACHINERY, May, 1908.

marked respectively A and B, and their loose pulleys C and D. As the return stroke is always made at a constant speed, a pinion E is always in mesh with the large spur gear F, keyed on the short shaft that is connected by a flanged coupling to the bull pinion shaft G of the planing machine. The two cutting speeds are produced by change-speed gears mounted on two shafts H and J, these shafts being eccentric, and operated by a lever a, which, through lever connections and a rack and pinions, turns the eccentric shafts so as to bring one or the other pair of gears into engagement. Pinion E is thus driven in the reverse direction to that of pulley B.

The belt-shifting gear comprises a pair of forks for each set of pulleys, each pair being operated by a rod actuated from shafts B, Fig. 2, worked by a cam plate C, the part rotation of which has the effect of throwing the forks along in their proper relations for shifting the belts onto the fast pulleys for either cut or return. In Fig. 2 they are shown in the non-driving position, that is, both on the loose pulleys. The partial rotation of the shaft which carries C is effected by a lever d, Fig. 3, which is connected to the reversing mechanism of the planer.

The spring wheel is in course of modification, but the principle of action may be briefly described as follows: The large gear F is mounted loose upon its shaft. An oscillating lever is keyed on the shaft. Fitted inside the gear are spiral springs mounted in telescopic cases carried upon adjustable brackets; the projecting plungers butt against the end of the oscillating lever, and they are so arranged that when the machine is cutting, the thrust is taken against the solid metal of the spring case. When reversing, the shock is absorbed wholly by the springs. This spring wheel takes the place of the spring rack fitted in the tables of the firm's standard planing machine. (See description in MACHINERY, July, 1905). The standard flywheel pulley drive is also incorporated in the plano-drive, the flywheel pulley being at C in Fig. 3. Its endwise movement to throw it into engagement with the pulley A is effected by a lever c, worked by connections from the rods which carry the belt-forks. When the belt is shifted from C to A, C is also moved endwise to clutch it to A.

Fig. 2 shows the details of the relations of the plano-drive to the machine. In the top view the pinion and rack are shown. The reversing gear comprises two dogs, which alternately strike a "tumbler," which in turn rocks the shaft N passing through the bed. This shaft is coupled at the opposite end to bevel gears O, which operate the cam-shaft. The gear at P is for producing the automatic feeds to the planer heads, in the usual manner.

* * *

The extent to which the Walschaert valve gear, which was rarely seen in this country a few years ago, is now employed on American locomotives, is shown by the following figures: The total number of locomotives ordered during 1909 for which the Walschaert valve gear was specified was approximately 1,638; the number of those which were to be equipped with the Stephenson was 745; while the Baker-Pilliod gear was applied to about 65.

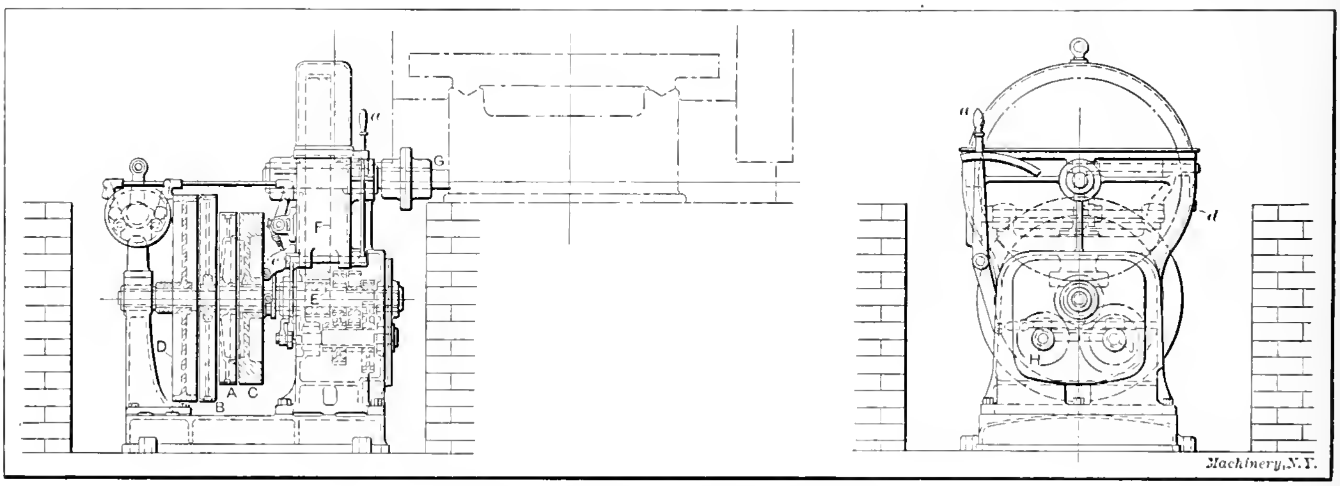

Fig. 3. General Design of the Bateman Planer Drive

METHOD OF APPLYING MOTORS TO MACHINE TOOLS

In a paper on the Economy of the Electric Drive in the Machine Shop, read at the April meeting of the American Society of Mechanical Engineers, Mr. A. L. De Leeuw reviewed the conditions which must be considered in connection with the equipment of a machine shop with electric drive. In conclusion he gave a general idea of the mode of application of motors to machine tools, the selection of motors for different classes of tools, and the lines along which economical results may be expected. The following abstract of these conclusions will undoubtedly be of interest to mechanics in general.

Bench and Speed Lathes

Bench lathes should be driven from a countershaft attached to the wall or bench and driven in turn by a motor. Any kind of motor except a series-wound or heavily compounded motor will do. The object of the motor drive is to get the machine in the best possible location without regard to the location of the lineshafting. A number of these machines may be driven by a common lineshaft, which in turn is driven by a motor.

Speed lathes should be driven from a countershaft located under the lathe, or by a direct-connected motor. In the latter case a variable-speed motor is to be preferred, if direct current is available. Motor drive is recommended when the machine is used in the assembling department, as the machines may then be placed where they are most needed; the crane service would also interfere with countershafts. There will be no material gain, if the machines are to be used for ordinary shop operations.

Engine Lathes

Various modes of driving engine lathes by motors are in use. Some makers furnish motor-driven engine lathes as standard equipment. Some have a headstock with a limited number of speeds, and depend on a variable-speed motor to fill out the speeds of the lathe. Others apply a constant-speed motor, or one with a limited amount of variation, to an all-geared headstock. In general, the use to which this class of machines is put in the shop would naturally lead to group drive. There is no material advantage in the individual motor drive, if the machines are used for regular manufacturing operations, except where the location demands individual drive.

Heavy Engine Lathes, Forge Lathes, etc.

Heavy engine lathes, and lathes of similar types should be driven by a direct-connected motor. The motor should be direct-current, as these machines are too heavy to permit a convenient all-gear drive. If no direct current is available and there is only one machine of its class in the shop, and this is used for an occasional job only, an alternating-current motor could be used, leaving a wide gap in the speeds. If these machines are used for manufacturing purposes, however, it will pay to install a small synchronous connector. The speed range in the motor does not need to exceed two to one, though a wider range is better if obtainable without complications or great expense. The position of the motor should be low, as the vibrations in the motor-support have a decided influence

on the capacity of the machine, as well as on the repair bill. The output of this class of machines may easily be increased from 20 to 25 per cent by motor drive. Further advantages of the motor drive are the possibility of placing the machine in the line of the routing of heavy work, and of placing it immediately under the traveling crane. This latter object may be reached with a belt-driven machine by placing the headstock under the gallery, if the construction of the shop lends itself to this arrangement, but the same convenience as that of the motor drive cannot be obtained.

Axle and Wheel Lathes

It is of the greatest importance that axle lathes and car and driving wheel lathes should have the highest possible efficiency, and the most convenient location. These machines are mostly used in locomotive and car repair shops, where time saved does not mean merely the saving of wages, but each day gained means an added day in the earning capacity of the engine or car. It is, therefore, important that these machines be motor-driven whenever installed in a railroad repair shop, though this does not mean that they should not be so driven if used for manufacturing. Direct current should be used. The economy of the motor drive should not be figured in increased output, but in reduction of time required to repair an engine or car.

Chucking Lathes

Generally speaking, there is little reason why a chucking lathe should be motor-driven. Most chucking lathes are provided with the necessary mechanism to shift speeds quickly. A few types handling large work may be motor-driven to advantage, though practically the only advantage lies in the fact that small gradations in speed can be thus obtained. Such machines, therefore, require a variable-speed motor.

Automatic Screw Machines

Small automatic screw machines are generally group-driven. Large machines may be individually motor-driven to good advantage. The larger sizes have generally one or two speeds for one piece of work, though these speeds may be varied when the machine is reset for a new piece of work. The speed given to the machine must naturally be proportional to the largest diameter to be turned, or in other words, to the size of stock used. This will reduce the speed for some of the operations such as drilling and reaming, far below the economical speed. The amount of time saved by the application of the variable-speed motor may be considerable. Where the construction of the machine permits, two motors, one for feed and one for speed, would give still better results. In all cases variable-speed motors should be used.

Drill Presses and Boring Machines

The only reason why the sensitive drill should be individually motor-driven is that it is often used in an assembling department, where height of ceiling and crane service would make a belt drive awkward or impossible. Most sensitive drills have, in themselves, all the speeds required for their work, so that any type of motor will be adaptable. The motor may either be directly applied to the machine or may drive a countershaft on a stand; or it may be placed on the floor by the side of the machine, in case the machine carries its own set of cones or other variable-speed device.

Generally speaking, the upright drill is used for manufacturing operations and does not require frequent changes of speed. There are, however, many exceptions, for instance, where upright drills are used to do all the operations on a piece by means of a jig. In this case frequent changes of tools, and, therefore, of speeds, are required, and an individual motor drive, whether direct-connected to the machine or operating on the countershaft, is of the greatest benefit. No great benefit can be derived from a constant-speed motor with this type of machine. Radial drills may be considered to present the same requirements as upright drills. There is an additional reason why radial drills should be motor-driven—they are often used in the neighborhood of the assembling floor.

Where the work for boring machines is specialized and the machines perform only one operation, there is no good reason why the motor drive be preferred to belt drive. Where, however, the machine is used for a multiplicity of operations, such as drilling, boring, reaming and facing, a motor drive is beneficial if a variable-speed motor is used. The range of speed of the motor should be as wide as possible, so that no gears may have to be shifted for the entire set of operations on a single hole. Especially where a boring machine is used for facing, this variable speed will be found highly economical.

Grinders

Grinders, in general, require so many various movements driven from countershafts that it is hardly possible to apply a single motor directly to the machine; the best that can be done is to attach the countershaft to the machine and drive the former from a motor standing on the floor or on a bracket attached to the machine. In isolated cases it would be well to have one or more motors, each controlling a single operation, attached directly to the machine.

Planers, Shapers, Slotters

Planers in general are not benefited by the application of a motor, as the motor only complicates the difficulties of a planer drive. However, large planers which must be placed under a crane give better results when motor-driven on account of the facility of handling the work. Another possible advantage when using a variable-speed motor and controlling the speed of the motor at the end of the stroke is that much higher return speeds can be obtained in connection with any desired cutting speed. What is true of planers is also true of shapers and slotters. Local conditions may make it advisable to drive them individually by motor, but generally speaking, there are no great advantages to be gained with this drive.

Milling Machines

The larger sizes of knee-and-column type machines, if motor-driven, will give the best results if the motor is of the variable-speed type, especially where these machines are used for gang work. This is due to the fact that the speed of the mills is dependent on the largest cutter in the gang, while the feed is dependent on the smallest cutter, not counting the limitations due to the nature of the work. It is therefore important that the speed should be as close to the permissible limit as possible. When applied to this type of milling machine, the motor should be as low down as possible, as vibrations in the machine have a marked effect on the quality of the finish. In practically all cases the planer-type of milling machine should be motor-driven, in order that it may be located under a crane. It is not so very important, however, whether the motor is of the constant-speed or variable-speed type.

Punches, Bending Rolls, Shears, etc.

This class of machinery, used largely for boiler, bridge, structural iron and ship-building work, is generally placed in high shops and under cranes, and in locations and directions most convenient for the routing of the work. The shops in which it is placed are generally large and contain a relatively small amount of machinery, so that the amount of transmission gearing required is large in proportion to the amount of machinery. It is for this reason advisable in almost all cases to drive this class of machinery by an electric motor, which, of course, does not need to be of the variable-speed type.

ANOTHER USE FOR MOVING PICTURES

We have alluded to the importance of the moving picture industry and the educational value of pictures showing mechanical processes, methods of work, etc. The players of the game of war, who are so expert on paper and never miss a chance to utilize, in theory at least, every improvement in mechanics that can possibly be twisted to destructive purposes, have seized on moving pictures as a means of improving marksmanship. The system is quite an elaborate one and has been tried with more or less success in the British army and those of other nations of Europe. By this, men are enabled to engage in practice under conditions which nearly duplicate those of real warfare. For instance, scouts in the picture are seen to come from cover and advance, fire at intervals and return to cover just as flesh and blood sharpshooters would act. The screen which is acting as a target is quite near the real marksman, but the effect is the same as practised at 600 yards. The hits are registered automatically and at the end of his practice he is shown at a glance the record made.

BRITISH TRAVERSING-HEAD SHAPERS

By JAMES VOSE*

The British machines illustrated in Figs. 1 and 2 have been patented by John H. Storey & Co., Hatcham, London, and are built by the same company. In designing the machines, the idea has been to combine the admitted handiness of the American pillar-type machine with the rigidity of the work-carrying members of the traversing-head or generic British tool. To a considerable extent the tool illustrated embodies the features which render the "open-side" or "side" planer adapted to the machining of pieces of unwieldy and heavy character. The freely T-slotted extended base, front of machine, and table sides, allow great latitude in this respect, work being easily and securely clamped, while the reciprocating and traversing portions of the machine can be kept within a reasonable size, being at the same time of great strength.

The machine is similar to the pillar style of shaper in that the whole of the driving gear and link and return motion is enclosed in the body, is carried directly under the saddle, and traverses simultaneously. Many ordinary British machines display a tendency to twist the ram owing to the side connection of the link motion, etc. In the Storey tool this objection is obviated by the driving gear being placed under the ram, giving a central thrust and drive. The rocking arm is also enabled to be of considerable length. Shafts, spindles, etc., can be passed through the body for keywaying purposes, and the back gear is thrown in or out by an eccentric lever which is always clear of the belt at any angle. The feed can be started, stopped, or reversed, while running, and breakage due to over-running of the saddle or other excessive strain is prevented by a slipping device. The stroke of the ram is adjusted by a screw, liability to slip being eliminated, and the adjustment can be made with the machine either running or stopped. The stroke index plate is level with the ram where it can easily be seen when making adjustments. The traversing screws are fitted with graduated collars reading to 0.001 inch, the tool heads are fitted with worm and worm-wheel motion for internal curves, and a circular motion in front of the bed may also be fitted if desired.

The machines are highly geared with a view to efficient use of the latest high-speed steels. If desired, a gear box drive can be substituted for the cone and countershaft, or the machines may be motor-driven. The machines are made in

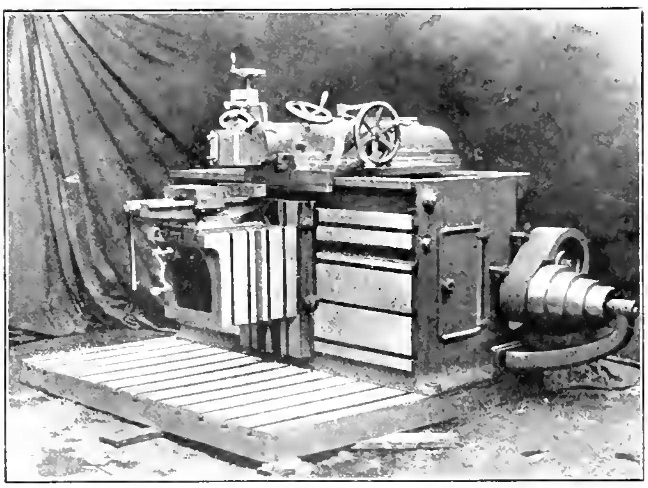

Fig. 1. Traversing-head Shaper of British Design

seven sizes from 8 to 36 inches stroke. The following details of the smallest and largest sizes of the machines will give a good idea of the capacity of the shapers generally. The 8- and 36- inch stroke machines have beds 4 and 14 feet long, respectively, the depths being 2 feet 9 inches and 4 feet. The tops of the tables are 10 x 15 and 30 x 48 inches, and the sizes of the extended bases are 4 x 2 feet and 14 feet x 4 feet 6 inches. The longitudinal traverse of the saddles is 2 feet and 10 feet. The widths of the ram bearings in the saddles are 7½ and 14 inches, and the lengths of the ram bearings are 18½ and 56 inches. The diameters of shafts which may be passed through the bodies of the 8-and 36-inch machines are 2 and 4½ inches, the number of speeds on the cone pulleys are 4 and 10, and the diameters and widths of the countershaft pulleys are 9 x 2¾ and 18 x 5 inches, the countershaft speeds being 200 and 350 in the respective machines. The horsepower required for the full duty the machines are capable of is 2½ and 20, and the weights of the machines—with fixed base and two tables—are 3,360 and 40,320 pounds, and the floor space needed 6 feet x 2 feet 6 inches and 20 x 12 feet.

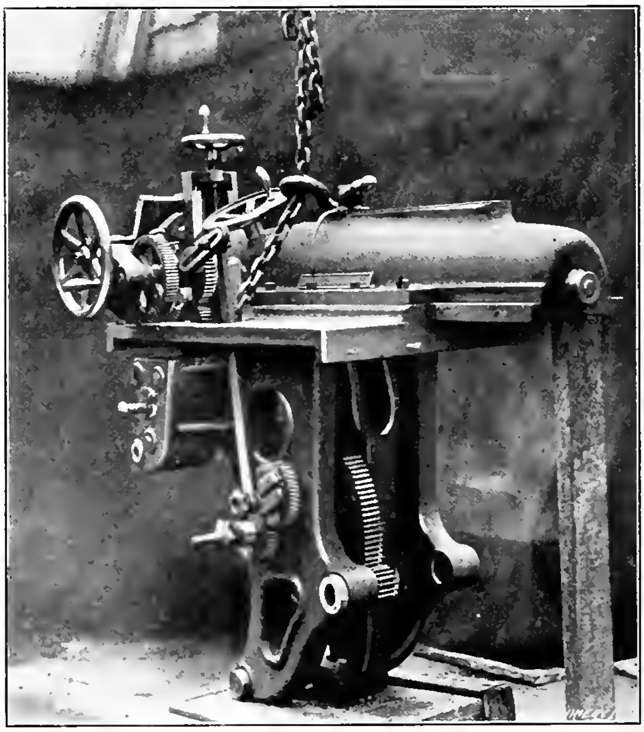

Fig. 2. Saddle, Ram and Driving Motion of British Traversing-head Shaper

It may be added that the machines are patented in various countries, and that, at the time of writing, the American and German patent rights are for disposal.

CARBORUNDUM FOR ALUMINUM MOLDS

It is mentioned in the *Practical Engineer* (London) that carborundum on account of its remarkable thermal conductivity, has recently received an interesting application in the manufacture of molds for cooling aluminum so as to rapidly chill the cast metal. Aluminum becomes much denser when it is cast in a carborundum mold, because of this rapid cooling, and the metal surface becomes much finer. The molds, it is stated, are made in the following manner: fine carborundum powder is mixed with sugar and clay; to this mixture is then applied a sufficient amount of mortar to produce a plastic mass in which the desired mold is shaped. The mold is then baked and possesses the advantage of being permanent, lighter than metal molds and readily broken up, crushed and reduced to a fine powder, which can be used again for making new molds.

* * *

The *National Telephone Journal* gives an account of the number of telephones in the various European countries. From this it appears that on January 1, 1909, there were about 2,400,000 telephone apparatuses in use in Europe, more than one-third of which were in use in Germany. Sweden has more telephones in proportion to population than any other country in Europe, there being one telephone apparatus for each thirty-four inhabitants. Denmark, Norway, Switzerland and Germany come next on the list. It is not mentioned how many telephone apparatuses there are in the United States, but the number is estimated at about 2,000,000, which would be one apparatus for every forty or forty-five inhabitants. It is interesting to note that in Sweden, where, in proportion to the population, the telephone is most commonly used, public ownership of telephones and telegraphs is an established policy.

ACCURATE GAGE WORK IN THE BENCH LATHE

By A. L. MONRAD*

It was not very long ago that the making of a gage such as is illustrated at *A* in Fig. 1, by methods which would enable practically the exact duplication of any number, was not only very expensive but quite impracticable; but now with the improved tools and methods of the modern shop, skilled workmen can produce exceedingly accurate work, but not without care and perseverance. Three of these gages were required, one for manufacturing purposes, one for the inspector, and one as a master-gage. By the simplified method to be described, each of these gages can be finished ready for hardening with one setting on the master-plate, thus insuring great accuracy.

The old way of working to lines which have been laid out on the work, is fast being abolished, as accurate results cannot be obtained by this method. To work to the highest degree of excellence, each operation must be positively gaged so that it is certain when the work is finished that every step has been correctly performed. This article, which is a detailed description of the duplicate method of making the gages referred to, is intended not only for the inexperienced workman, but for the journeyman as well; therefore the writer has endeavored to start from the beginning and progress step by step so that each point will be absolutely clear.

Making the Master-plate

In order that the three gages be exact duplicates, it is first necessary to make a master-plate. The finished master-plate is shown at *C* in Fig. 1. This plate is made from tool steel, but is not hardened when finished. It can be rough turned in an engine lathe to within 0.020 inch and afterwards finished to the required size in a bench lathe. When the master-plate is ready for the bench lathe, the faceplate of the latter should be tested for accuracy by the use of a test indicator. After the master-plate is strapped to the lathe faceplate, one side should be faced off with a side tool *D*; the work is then reversed and the opposite face and outer half are machined. Both sides will then be perfectly parallel. The master-plate is now ready for the buttons which are used for locating it when boring the five holes shown. On a center line at right angles to the line *a—a*, the holes for the screws which are to hold the buttons in place are laid off to the required dimensions and drilled for a 1/8-inch tap. The depth of these holes should be about 1/4 inch. When the five holes are tapped so that the button retaining screws may be inserted in them, the center button is screwed in place and located in the center of the plate by using a depth gage. As all the buttons are hardened, ground and lapped on the outside to the same size, they may be set the correct distance apart by using as a gage

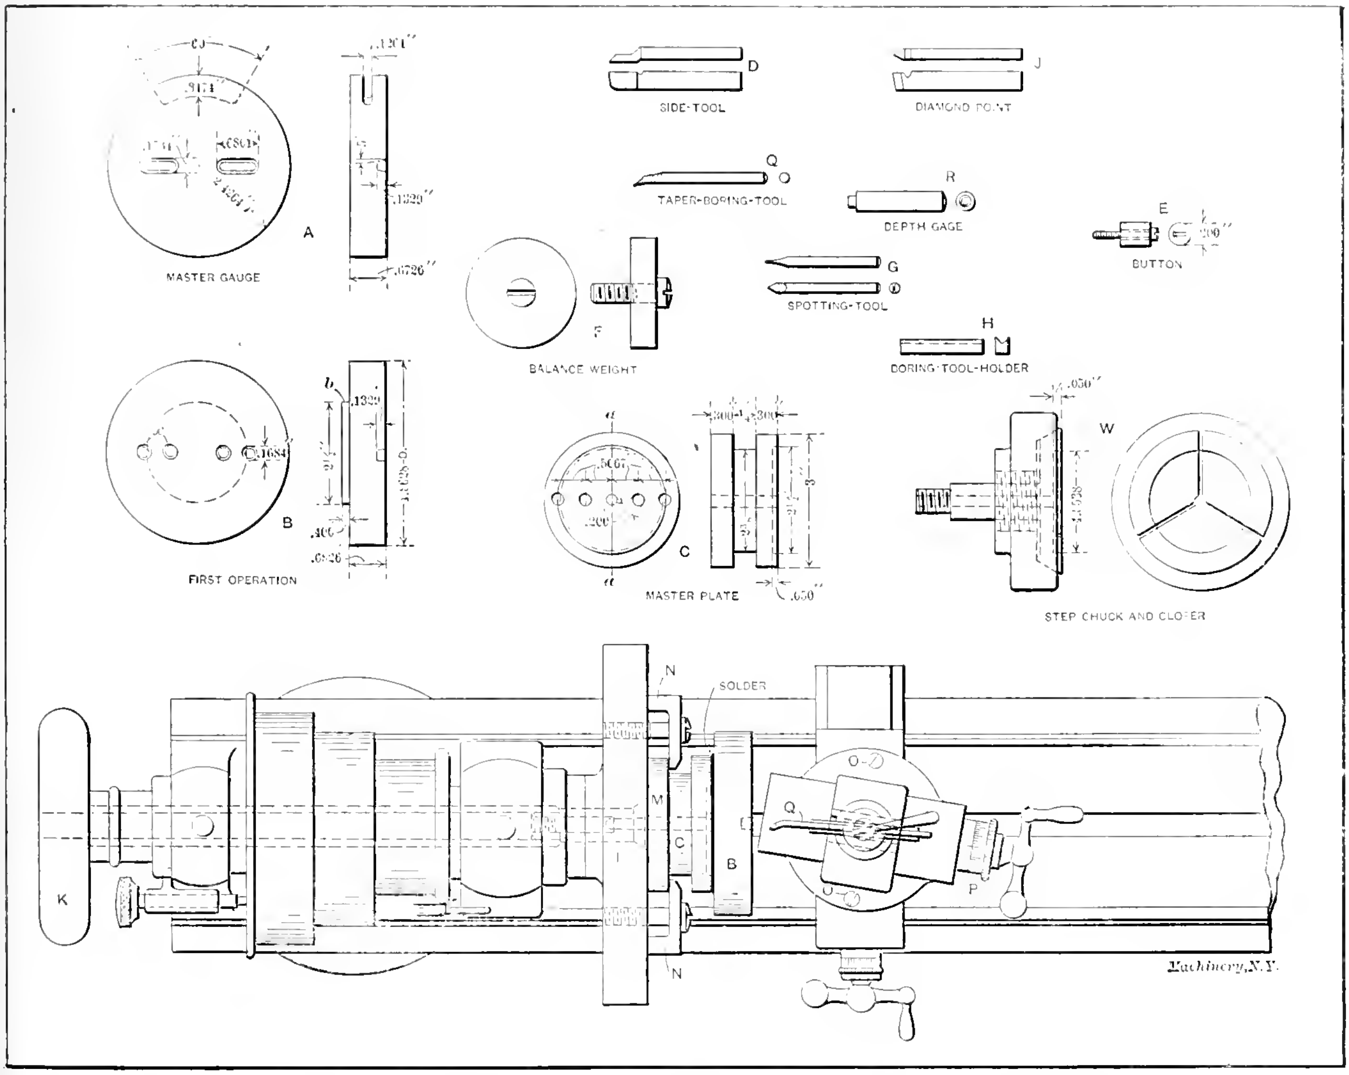

Fig. 1. Plan View of the Bench Lathe arranged for Boring the Tapered Holes in the Face of the Gage, and Miscellaneous Tools

a flat piece of steel having a thickness equal to the center-to-center distance minus the diameter of one button. The five buttons may be aligned by laying a straightedge across them.

The master-plate is now ready to be bored and reamed. After it is strapped to the faceplate, each of the holes is bored in its correct position by setting first one and then the other of the buttons true and then removing the button and boring the hole. The four outer holes should be bored first, the one in the center being machined last. Great care should be taken before boring a hole to set the button perfectly true. This is very important as the accuracy of the gages depends altogether on the accuracy of the master-plate. After a button has been set approximately true by the test indicator, balance weights *F*, which are made in different sizes, should be fastened to the faceplate to counterbalance the work which is, of course, offset with relation to the faceplate when boring the outer holes. This is essential because if the faceplate is not perfectly balanced, it will impair the accuracy of the hole

* Address: 58 Connecticut Boulevard, East Hartford, Conn.—See Biographical note in MACHINERY, September, 1901.

being bored. When testing the balance, the driving belt should be removed from the cone pulley. After a button is indicated, it is removed and a center is made by the use of a spotting tool *G*. A No. 15 drill, in this case, is fed through the master-plate after which the hole is bored out to 0.198 inch with a boring tool, which is followed by a 0.200-inch reamer, thus finishing the hole to the size indicated at *C*. In the same manner the other four holes are spotted, bored and reamed to the same size. After the central hole is finished, a recess 2.5 inches in diameter and 0.050 inch deep should be bored at the same setting of the work. A light cut should also be taken on the outer diameter with a diamond-point tool *J*.

Annealing the Gages

After the gages are roughed out in an engine lathe to within 0.020 inch, they should be annealed by being packed in charcoal in a cast iron box with a close-fitting cover luted with fire clay in order to exclude the air so that the gages will not change too much when they are hardened. The iron box should be placed in the furnace and given a very slow heat for about three hours, after which the heat is shut off and the box is left in the furnace over night. On removing the gages, they will be found very soft and easy to work.

First Operation in the Bench Lathe

The gages are now ready for the first operation in the bench lathe. First strap one of them to the faceplate with the boss *b* out, and face this end. Then machine the boss *b* to an accurate turning fit in the recess previously bored in the master-plate. The gage should then be removed and clamped to the master-plate with two C-clamps, so that the two may be soldered together. Before soldering all oil should be removed from the surfaces, which may be done by spraying a little benzine over them and afterward wiping it off with a piece of clean waste. When soldering the gage should be heated over a Bunsen burner until the solder will run freely. Plenty of solder should be used at the point indicated in the engraving. When the parts are cooled they will be securely attached to each other and the C-clamps can be removed.

The plug collet *I* is next placed in the lathe spindle and the handle *K* is tightened. A tool steel plug, *M*, tapered at one end, is then driven lightly into the collet. This plug is turned to 0.2003 inch in diameter or 0.0003 inch larger than the master-plate holes. Care should be taken to see that the shoulder on pin *M* is below the surface of the faceplate. The pin *M* is next polished with fine emery cloth until it is a turning fit in the holes in the master-plate. The latter is then fastened to the faceplate with four straps *N*, as shown in the engraving, the pin *M* being inserted in the central hole. If the spindle does not balance perfectly, a small weight should be attached to it. The gage is now faced to a thickness of 0.6826 inch and turned to a diameter of 4.8628 inch. The work is now removed and the faceplate cleaned thoroughly, after which the master-plate is again attached to the faceplate with the center plug *M* in any one of the four outer holes. The spotting tool is then used to cut a center for starting a No. 25 drill, which is sunk to a depth of 0.122 inch. The compound rest is then swung to an angle of 5 degrees, as shown, by the loosening of the screws *O*. When the point of the boring tool *Q* is in contact with the surface of the gage, the graduated sleeve *P* is set to zero and a taper hole is bored to a depth of 0.132 inch and to a diameter on the outside of 0.1684 inch. These dimensions can be obtained very accurately by using a tapered plug-gage *R* which is made with a clearance of about 0.005 inch for grinding. In the same manner, the three remaining holes which are to form the ends of the slots shown in the face of the gage at *A*, are bored. Care should be taken to balance the spindle each time the master-plate is shifted from one hole to another.

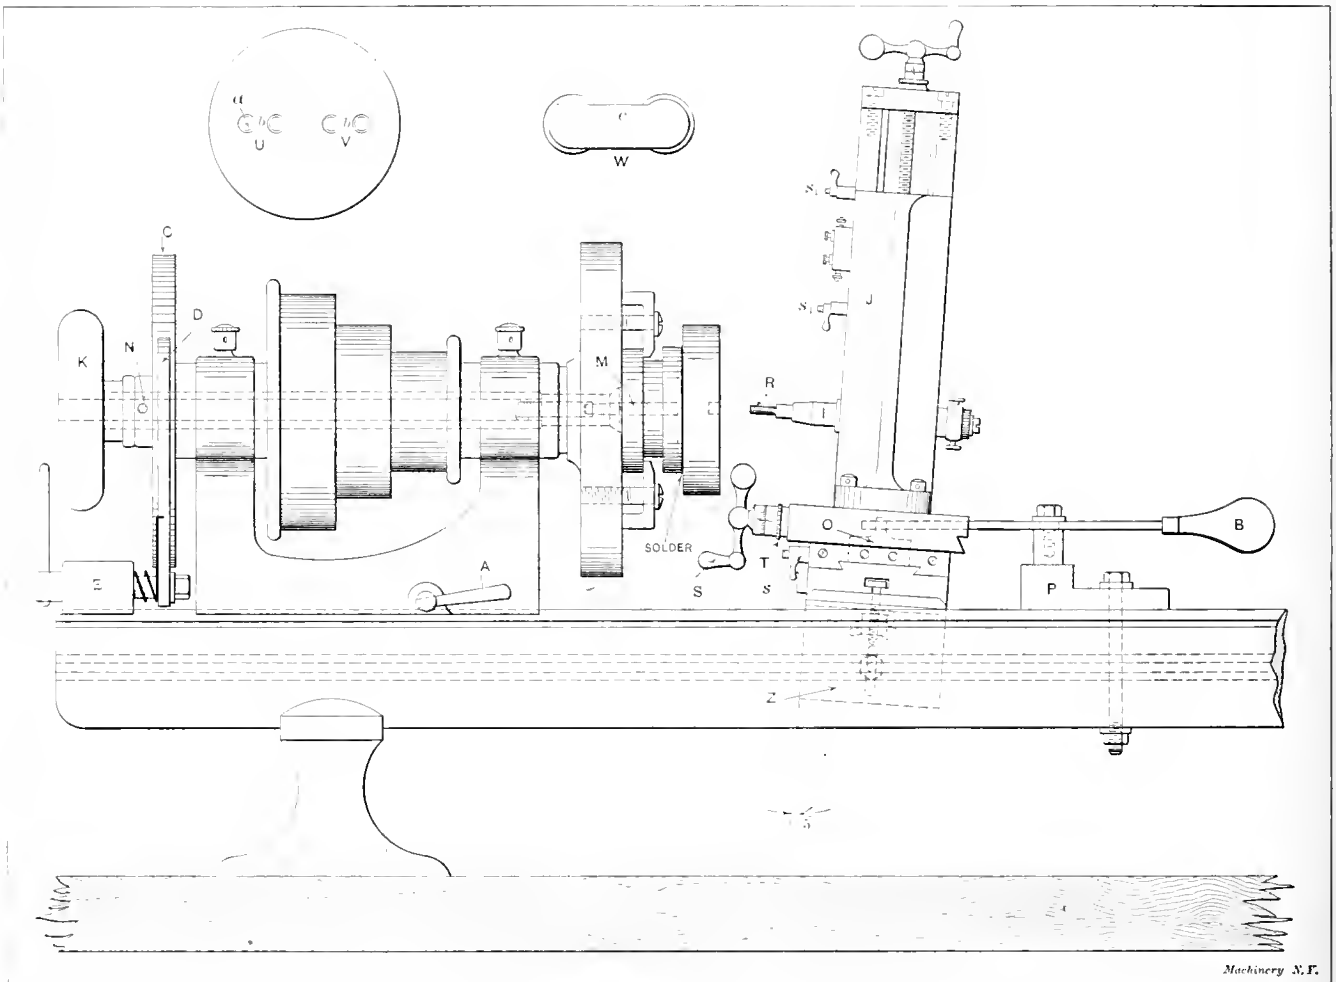

Fig. 2. Bench Lathe equipped with Indexing and Milling Attachments

Milling the Grooves

After the four tapered holes *U* and *V* (see Fig. 2) have been bored, as just described, the bridges *b* are milled away to form slots or grooves with tapering sides. The indexing attachment is first placed on the lathe headstock. The indexing plate *C* has 360 divisions. This is inserted by first removing the handle *K*. In order to make room for the block *E* with its indexing pawl *D*, the headstock is moved along the bed by

loosening handle A. Tapered plugs having outer ends which are parallel and of the same size should be placed in the two extreme holes in the gage. The master-plate (with gage still soldered to it) is then clamped to the faceplate with the plug M in the central hole. The pawl D should be inserted in the zero groove of the index-plate. An angle-iron Z is next fastened in the T-groove on the back of the lathe bed. On top of this angle-iron the milling attachment J is placed and adjusted so that the spindle will reach the two outer holes in the gage when it is moved to and fro by lever B, which is attached to stud O and fulcrumed on the stud of extension block P, which is fastened to the bed. To permit this movement of the slide by lever B, the cross-feed screw is removed. The plugs previously inserted in the end holes are now used to set the latter in a horizontal position or parallel with the movement of the cross-slide. This is done by inserting a test indicator away, the mill is fed downward until it just comes in contact with the bottom corner a of one of the holes. The movable stops s_1 on the vertical slide are now used to lock the mill against vertical movement. The mill is then fed across as before, machining the bottom of one slot as shown in the enlarged detail at W. The work is indexed 180 degrees and the milling operation described in the foregoing is repeated on the other pair of holes. Each slot would then appear as at W. In order that the sides c be cut away, the end mill is shifted so that it operates on the opposite side of the lathe center. The stops s on the horizontal slide are readjusted for this new position, the vertical stops remaining the same as before. After one side c has been milled, the work is again indexed 180 degrees and the milling operation is repeated.

The slots will now have tapering ends but straight sides.

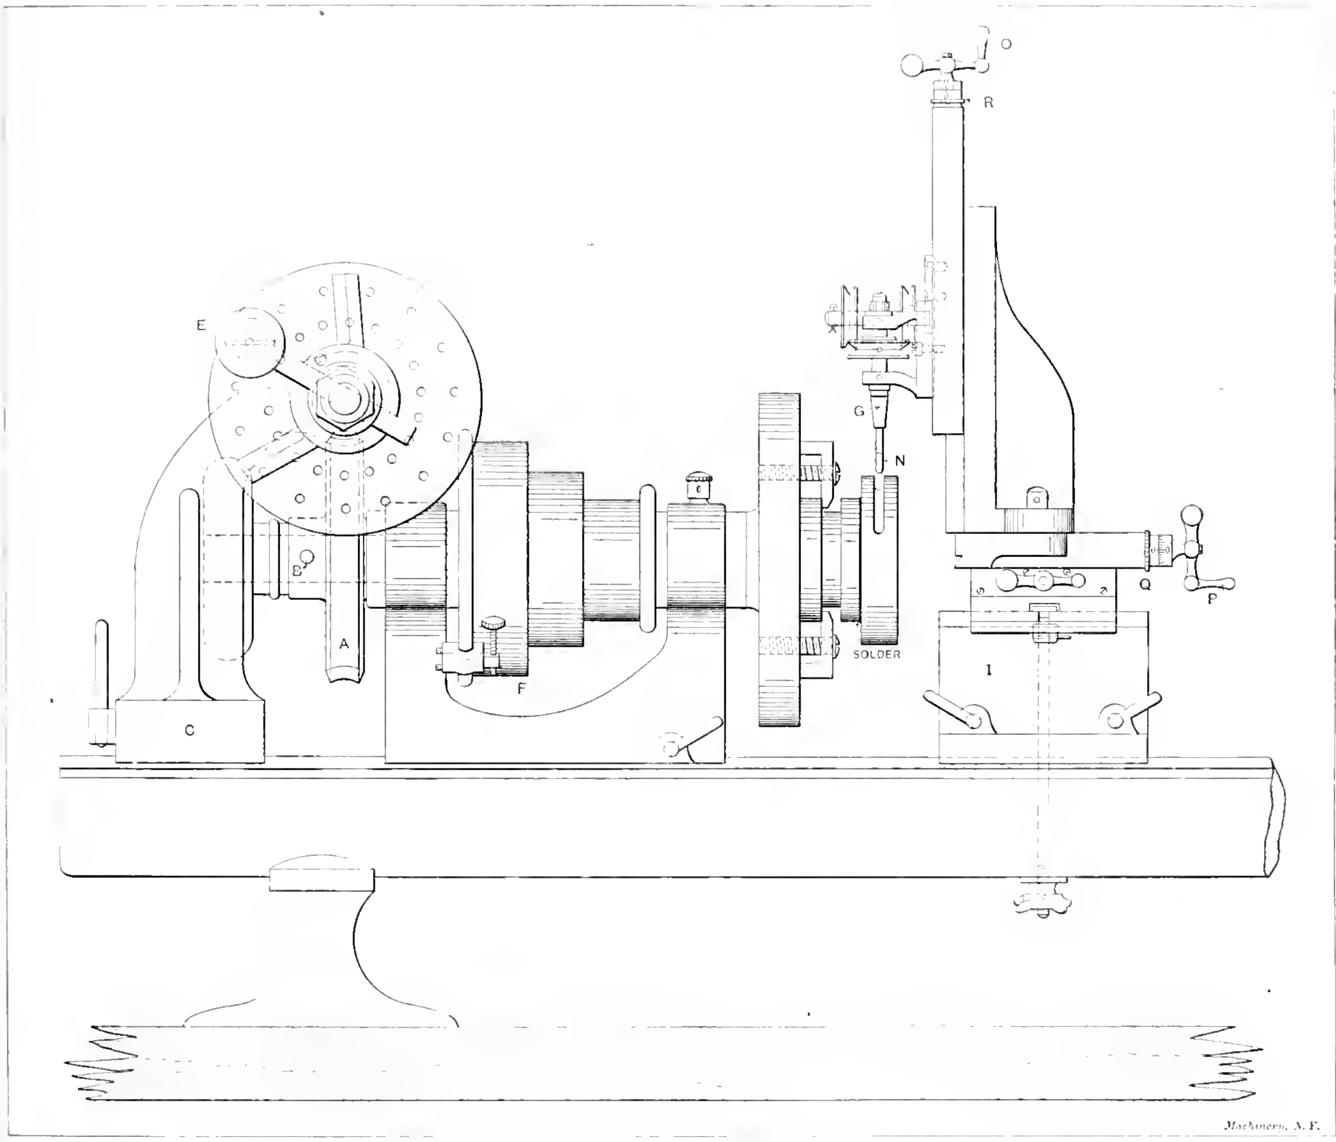

Fig. 3. The Lathe Set Up for a Vertical Milling Operation

in the spindle I of the attachment and moving the indicator across the plugs by lever B. When the indicator shows that each plug is exactly the same height, the screw X of the index-plate C should be tightened. The milling attachment should also be adjusted until the indicator shows that it is parallel with the face of the gage.

The end mill R, 0.150 inch in diameter, is now inserted in the spindle and the movable stops s on each side of a stationary stop on the horizontal slide, are set so that the mill has a horizontal movement, approximately equal to the center-to-center distance between the holes U. The mill is also set central vertically with these holes. The bridge b is then cut away by feeding the mill to and fro with lever B and inward by handle S. When the end of the mill is brought in contact with bridge b, before taking the first cut, the graduated sleeve T should be set to zero so that it may be used to determine the depth of the slot. After the bridge b has been cut

To mill the sides to a taper corresponding with that of the ends, the milling fixture is inclined to an angle of 5 degrees, as shown in Fig. 2. The end mill should then be replaced with an indicator, which is again used to test the parallelism of the face of the gage with the milling attachment. The sides of the slots can now be milled tapering in precisely the same manner as described for the end milling operation; that is, by milling one side, then indexing the work 180 degrees, and finally finishing the two remaining sides with the mill on the opposite side of the center. Very light cuts must be taken during this operation, and care should be exercised to leave a sharp corner on the side of each slot.

To Mill the Circular Groove

Before milling the circular groove in the periphery of the gage, a dividing head should be attached to the lathe as shown in Fig. 3. The index plate C, Fig. 2, is replaced with

a worm-wheel *A*. The worm meshing with this wheel should be set central by adjusting the bracket *C* along the lathe bed. An extension block *I* is also inserted beneath the milling attachment to raise it to the required height. The milling fixture is now used as a vertical miller by changing the position of the spindle as shown. An indicator is next placed in the spindle *G*, and with indexing handle *E* in the zero hole of the index-plate, the two slots which were previously milled in the face of the gage, are set parallel with the movement of the cross-slide by turning the lathe spindle; the screw *B* in the worm-wheel is then tightened. A male circular end mill 0.1164 inch in diameter is next inserted in the spindle. This mill must be set central with the sides and periphery of the gage. This can be done in the following manner: First lower the mill, which should be revolving; then turn handle *P* until a "listener" indicates that the cutter is barely in contact with the side of the work. Graduated sleeve *Q* should then be set to zero, after which the mill is raised and moved inward a distance equal to one-half the width of the gage plus one-half the diameter of the end mill. The latter is now central with the sides of the gage. By the same method, it may also be set central with the periphery. The work is now indexed 30 degrees, which will require with this particular dividing head, 15 turns of the indexing crank. A stop *F*, one of which is attached to the flange of the cone pulley on each side of the headstock, is then set against its striking point on the headstock. The work is then indexed 60 degrees or 30 turns in the opposite direction, after which the stop *F* on the opposite side is adjusted as before. These stops, in each case, should be so set that the indexing pin will just enter the zero hole of the dividing plate. Everything is now ready for milling the circular groove which, as shown in Fig. 1, has a length of 60 degrees. Prior to the milling operation, however, a hole 0.335 inch deep as indicated by the sleeve graduations, should be drilled at each end of the slot with a No. 35 drill. These holes will provide a clearance space for the end mill. A square end mill of 0.110 inch in diameter is then used to rough out the groove to a depth of about 0.295 inch. The male circular end mill is then employed for finishing the groove to the required depth. The work is fed by turning the indexing crank, and the stops *F* act as a positive gage, thus insuring that the slot will be the required length. The milling operation is now completed. After the attachments have been removed and the lathe arranged for turning, the gage should be removed from the master-plate by cutting away the solder with a side tool. One gage is now complete and ready for hardening. By the use of this same master-plate, obviously, the other two gages may be made precisely in the same manner as described in the foregoing.

Hardening the Gages

To avoid cracking or distorting the gages during the hardening operation, they are pack-hardened with ground charcoal in separate iron boxes. Each gage is laid in a basket made of 1/16-inch soft wire and wired together with a loop on one end, which is to serve as a grip for the tongs. The cover of the box is luted with fire clay to exclude the air while taking the heat. A hole should be drilled in one side of the cover for a 3/16-inch soft rod. This rod, which is to be used for gaging the heat, should extend to the opposite side of the iron box. After the latter has been exposed to a slow and comparatively low heat for about three hours, the rod is removed and if it shows that the gage has been heated sufficiently, the latter is removed and plunged into a sperm oil bath until it is perfectly cold. It is then heated a little to relieve any external strains which may have been set up, after which it should be laid on a piece of wood and allowed to cool slowly. It should not be left on a cold iron surface as the rapid change of temperature will cause excessive strains which will either crack the gage or warp it out of shape. After the gage is cooled sufficiently to permit handling, it should be polished so that the temper can be drawn. This may be done by the use of a Bunsen burner. To prevent the gage from coming into direct contact with the flame, it should be placed on a 5/16-inch steel plate and heated by contact with the plate. When drawing the temper, the gage should be turned over frequently so that it may be drawn evenly all over to a light straw color. It should then be allowed to cool naturally, wrapped in a piece of waste.

Grinding the Gages

The grinding operations are performed in practically the same way as the milling or turning, the only difference being that a wheel is used instead of a tool or cutter. The gage is, of course, mounted on the master-plate as before. Great care must be exercised before soldering the gage to the plate, that it be located in the proper position relative to the holes in the master-plate. This may be done as follows: First clamp the master-plate and gage together, with two C-clamps, then place a close-fitting plug in each of the two extreme holes in the master-plate. These plugs, which should extend about one inch beyond the surface of the plate, are next placed on the top surface of a parallel block which should be high enough to clear the diameter of the gage. This block should be mounted on an accurate surface plate so that a test indicator may be used to set both grooves in the face of the gage parallel with the plugs in the master-plate. After the grooves have been tested on one side, the master-plate should be turned over, so that the opposite sides of the plugs rest on the parallel block. If the indicator then shows the same reading as before, the gage may be soldered to the plate. The latter is then mounted on the faceplate of the lathe with the plug *M* (Fig. 1) in the central hole, and the gage is indicated on its face and periphery. If it runs out more than 0.004 inch it should be reset. If, however, the error is small enough to permit truing, rough grind the face and periphery leaving about 0.001 or 0.002 inch for finishing after the grooves are ground. This precaution must be taken to insure accuracy as hardened steel changes during a grinding operation after the outer scale is removed. In grinding the ends of the grooves, a diamond lap 0.075 inch in diameter is used. The end of this lap is charged as well as the body. When the ends are being ground, the slide-rest is set to an angle of 5 degrees and the procedure is practically the same as when the ends of the slots were bored; 0.0002 inch should be left for hand lapping. The diamond lap should run at the fastest speed obtainable and the work should revolve at the slowest. To grind the sides of the grooves, the same diamond lap is used and the machine is set up as shown in Fig. 2. A circular end diamond lap 0.115 inch in diameter is used for grinding the circular groove, and the machine is equipped with the same attachments as are illustrated in Fig. 3.

After the periphery and one side of the gage have been finished, the side next to the master-plate still remains to be ground. A step chuck and closer *W* (Fig. 1) is placed in the headstock spindle and three small pieces of sheet steel of the same thickness as the slots in the chuck are placed in each slot. The chuck is then tightened by means of the handle *K*, after which a recess about 0.050 inch deep and large enough in diameter to be a snug fit for the gage, is bored. The chuck is then loosened and the sheet steel pieces removed. The ground face of the work is next inserted in this recess, which should be very carefully cleaned, and the chuck is tightened. Care should also be taken to have the inner face of the gage against the chuck. If the work when tested on the periphery runs true, it may then be finished, first by using a coarse carborundum wheel and afterwards a No. 120 emery wheel; 0.0002 inch should again be allowed for lapping.

When the three gages have been ground as described in the foregoing, the faces should be lapped by rubbing them on an accurate surface plate, using a very little fine emery with plenty of benzine. A smooth and bright finish may be obtained by using a dry and clean plate. In this way, each gage is brought to the exact measurements required. The grooves are draw-lapped with a flat copper stick, powdered emery and sperm oil being used. For a final finish on very accurate work, the copper lap should be followed by one made of boxwood, the abrasive being white powdered oilstone.

* * *

A German company has been formed for making Wright aeroplanes. The capital is 500,000 marks ($119,000). The principal stockholders in the company are leading German firms, including the Krupp Co., the Borsig Locomotive Works, Ludwig Loewe & Co., and the General Electric Co. of Germany.

MAKING THE DeVILBISS PLIERS—1

By ETHAN VIALL*

A shop making one or more small specialties in quantities is always interesting because of the individual problems in tools and jig work that must of necessity be worked out if the output is to be produced at a profit. The cost of the tools and jigs increases, of course, with the complexity of the article or articles and consequent increased number of parts. Many comparatively simple looking manufactured articles are, in reality, very difficult to produce and a small fortune has been spent on them before a single one was put on the market. The cost of tools and the time taken to develop and make them, has proved the downfall of many manufacturers of really first-class articles that were ready sellers. A bunch of orders on hand with no means of filling, is worse than no orders, and if they are filled with articles made in any old way, it is still worse, if that be possible.

If the manager of a firm is wise, and has a fair amount of money back of him and confidence in the factory product, he will look to his tool and jig equipment and see that it is well along, before he begins to do any amount of advertising, so that he will be in a position to handle large orders with promptness before he really begins to push the selling end in earnest. However, the ideal conditions are not always obtainable and a manager often has to make the best of the conditions binding him. Few indeed are so fortunate as the general manager of the DeVilbiss Plier Co., Dundee, Mich., who has in the company with him, men of wide business and mechanical experience who thoroughly understand the principles of business success; these men know a good thing when they see it and have the money to back their opinions. It is, therefore, with unusual gratification that we are enabled through the courtesy of the manager, Allen DeVilbiss, Jr., and factory manager, W. F. Gradolph, to give in detail, each step in the manufacture of their pressed steel, cam-motion, parallel-jaw pliers, and to show every tool and jig used.

Fig. 1. Plant of the DeVilbiss Plier Co

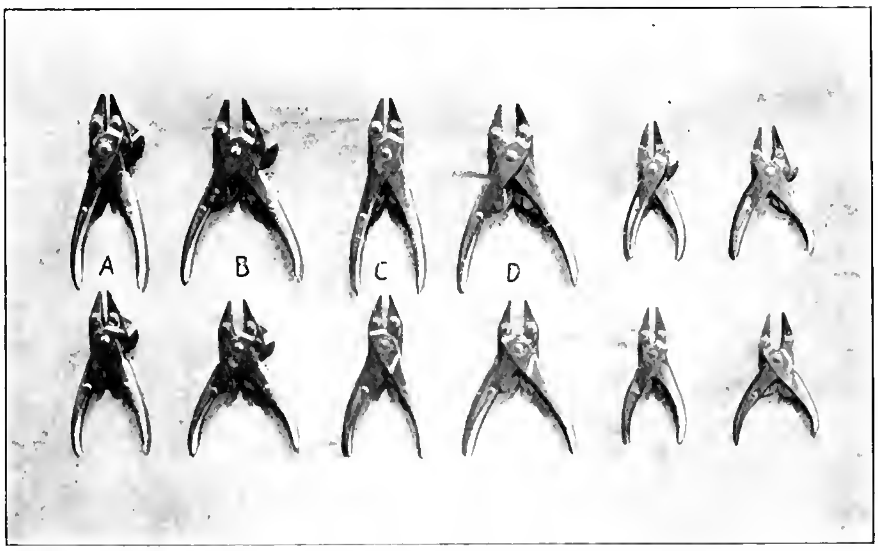

Fig. 2. Product of the DeVilbiss Plier Co

The factory building, Fig. 1, is two stories high, light and roomy and of concrete construction, having a main floor of heavy concrete, which makes an ideal floor for punch press work. This is the largest factory devoted exclusively to the making of pressed steel pliers in the country. The toolroom, Fig. 3, while not imposing, is unusually well equipped and amply large for the work required. All special tools, jigs, punches and dies, are kept in a big concrete vault, although the building itself is practically fire proof.

In order to give the reader a clear idea, from the beginning, of the kind of pliers manufactured, a number of sizes and styles are shown in Fig. 2. *A* is a parallel jaw, cam motion cutting plier; *B* is the same but with a spring inserted to keep the jaws open; *C* is another parallel-jaw, cam motion plier; *D* is the same with a self-opening spring, while the others are simply different sizes of similar types.

Taking up now the various parts that are used in these pliers, a list of which follows, we will give the order in which the various operations are performed on each one and then show the tools and jigs used in rotation.

Parts of DeVilbiss Plier

1. Handles, drawing steel. 2. Jaws (cutting), drawing steel. 3. Jaws (plain), drawing steel. 4. Cams, cold rolled steel. 5. Cutter blades (moving), tool steel. 6. Cutter blades (fixed jaw), tool steel. 7. Links, cold rolled steel. 8. Screws, rivets and springs.

In the above list, handles are divided into outside, inside and spring handles, the last named having a tongue in them for the end of a coiled spring.

Operations on the Handles

The order of the shop operations through which the handles go, is as follows:

1. Blanking. 2. Serrating. 3. Bending and stamping name. 4. Rough shaping. 5. Straightening or finish shaping. 6. Drilling. 7. Hand reaming on three-spindle drill. 8. Burring inside on 1/8-inch emery wheel. 9. Countersinking to remove burrs. 10. Tumbling. 11. Reaming on three-spindle drill. 12. Assembling.

Both the inside and outside handles pass through the same operations, except that the latter are offset between the third and fourth operations. Fig. 4 will make plain the first six operations on the inside handles, and the first seven operations on the outside handles. *A* is the blank; *B* is the serrated blank; at *C* the blank has been bent and the name stamped on it; at *D* it has been rough shaped; at *E* it has been straightened, and at *F* it has been drilled. Going back now to *C*, we follow it down to step *G*, which shows a blank with an outside offset; *H*, the outside rough shaped; *I* the outside straightened; and *J* the outside drilled. *K* shows an outside handle tongued at *T* for a spring, which is done simultaneously with the straightening operation on those intended for spring pliers.

A, Fig. 5, shows the blanking punch used, and *B* the die and stripper plate, which are of the usual form. *C* is a

* Associate Editor of MACHINERY.

blank like *A* in Fig. 4. After blanking, the handles are placed in the sub-press base *D*, and serrated with the punch *E*, producing the result shown at *F*. The top and bottom of this serrating sub-press are made of steel, for as the work is done in a board drop-hammer, cast iron would not stand the jar and strain. The hammer used has been changed so that nearly double the blow for which it was intended can be delivered, as a very powerful blow must be struck to make satisfactory serrations in this way.

The serrated blanks are next bent and the name stamped on them in the formers *A* and *B*, Fig. 6, the name of the firm being stamped on both forks of the blank by plug stencils *C*, inserted in the die. These stencils may be easily removed when damaged or worn, and replaced by new ones. The object of the bending is, of course, to give the blank the proper curve for the subsequent shaping. *E* and *F* are the punch and die used to offset the outside handle, as at *G*. The rough shaping is done with the forming punch and die *A* and *B*, Fig. 7, both inside and outside handles being shaped in the same die, though in shaping the inside handles the blocks *C* are set in. The straightening dies, *D* and *E*, are made on the ordinary "squeeze die" principle and in this case all the squeezing is done just back of the fork of the handle by the sliding blocks *F*, which are shoved in by the bevels *G* on part *E*. The punch *H* presses the handle down onto the form, coming into contact with the handle where the fork begins, just as the sliding blocks press in the sides.

Drilling the holes in the handles is done in the jig Fig. 8, which has a removable center block, the handle being locked in by an eccentric. These holes are next hand reamed in a three-spindle drill press, as shown in Fig. 9, each spindle holding a reamer for its respective hole. The burrs are now ground off on the inside with a 1/8-inch emery wheel, which will not be illustrated as practically the same operation will be shown on the jaws later. The outside burrs are removed by countersinking as in Fig. 10, after which the parts are tumbled for an hour in a mixture of sawdust, sal soda and water; then, merely as a precautionary measure, they are again hand reamed exactly as previously shown in Fig. 9, when they are stored ready for assembling.

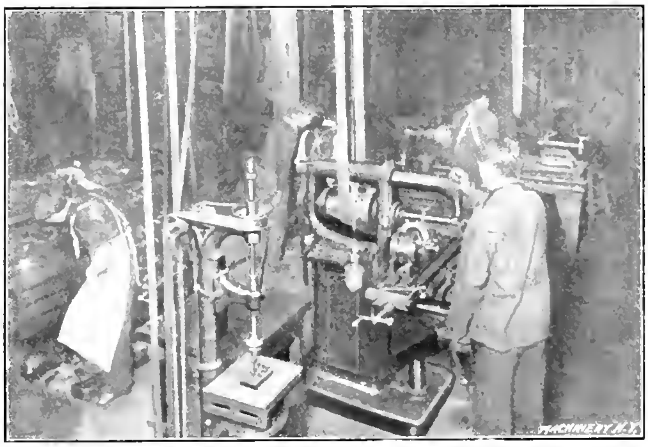

Fig. 3 General View of the Toolroom

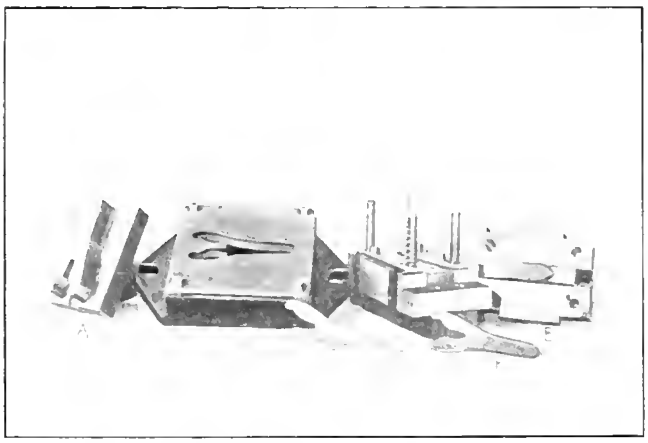

Fig. 5 Handle Blanking and Serrating Punch and Die

Jaw Operations

The shop operations on both the cutting and plain jaws are similar, but for convenience in describing the tools, the list will be arranged as follows:

Cutting Jaws	Plain Jaws
1. Blanking.	1. Blanking.
2. Slotting.	2. Slotting and piercing.
3. Forming.	3. Forming.
4. Annealing.	4. Annealing.
5. Flattening and serrating.	5. Flattening and serrating.
6. Removing burrs and squaring sides.	6. Removing burrs and squaring sides.
7. Drilling.	7. Drilling.
8. Removing outside burr on disk grinder.	8. Removing outside burr on disk grinder.
9. Countersinking cam holes.	9. Countersinking cam holes.
10. Cutting off ends in milling machine.	10. Cutting off ends in milling machine.
11. Reaming in three-spindle drill press.	11. Milling wire slot.
12. Carbonizing.	12. Reaming.
13. Removing inside burr on 1/8-inch emery wheel.	13. Carbonizing.
14. Rough polishing.	14. Removing inside burr on 1/8-inch emery wheel.
15. Drawing to a blue color.	15. Rough polishing.
16. Finish polishing.	16. Nicking outside of jaw fork for a stop.
17. Assembling.	17. Drawing to a blue color.
	18. Finish polishing.
	19. Assembling.

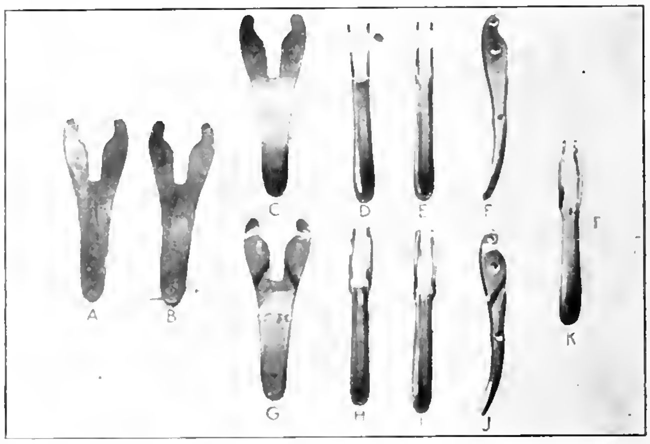

Fig. 4 Steps in the Evolution of both Inside and Outside Plier Handles

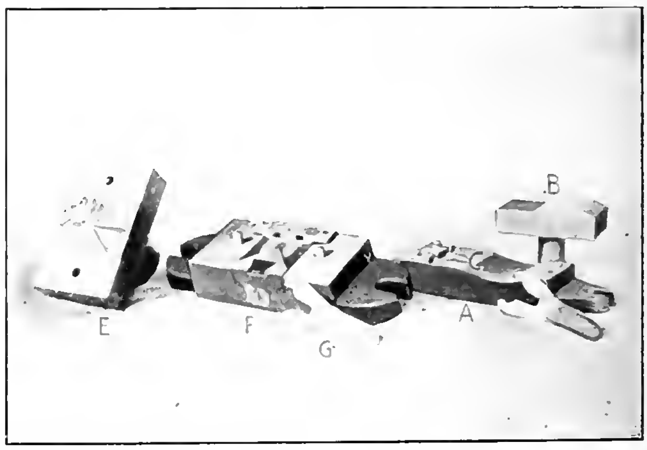

Fig. 6 Punch and Die for Bending, Name Stamping and Offsetting Handles

Most of the operations are graphically represented in Fig. 11, the upper row showing the steps in the evolution of the cutting jaws and the lower row those of the plain jaws; *A* is the blank, which at *B*, upper row, is slotted—lower row, slotted and pierced; at *C*, formed; at *D*, annealed; at *E*, flattened and serrated; at *F*, sides ground; at *G*, drilled; and at *H*, carbonized. While a few of the steps have been omitted in this illustration, they will be shown in detail when describing the tools and jigs for them.

A, Fig. 12, shows the blanking punch; *B*, the die; *C*, the slotting die, and *D*, the slotting punch used for cutting the jaws, while the same letters in Fig. 13 represent corresponding tools for the plain jaws.

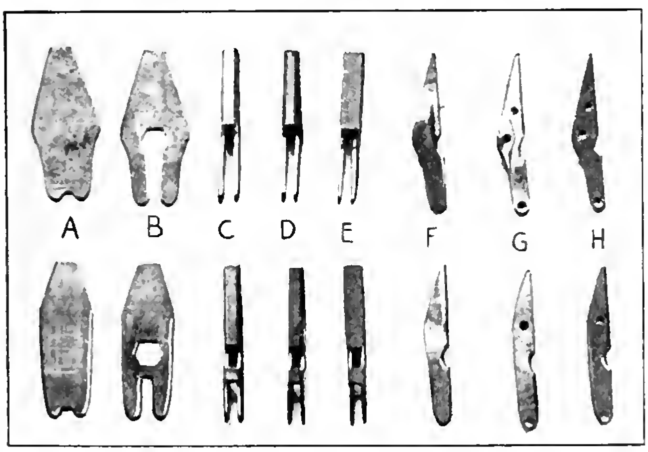

Fig 11 Steps in the Evolution of the Cutting and Plain Jaws

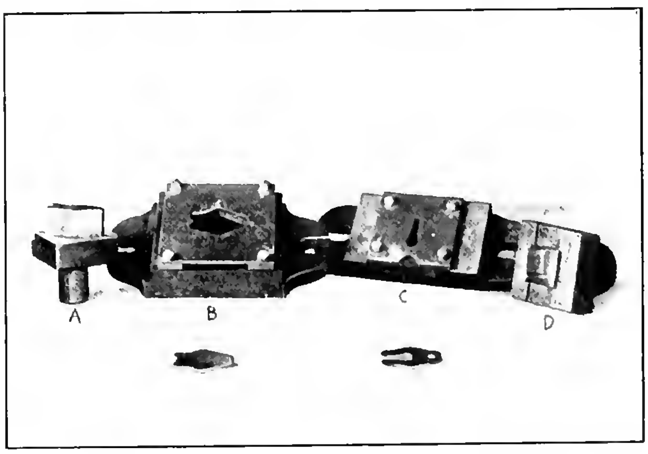

Fig 12 Blanking and Slotting Punches and Dies for the Cutting Jaws

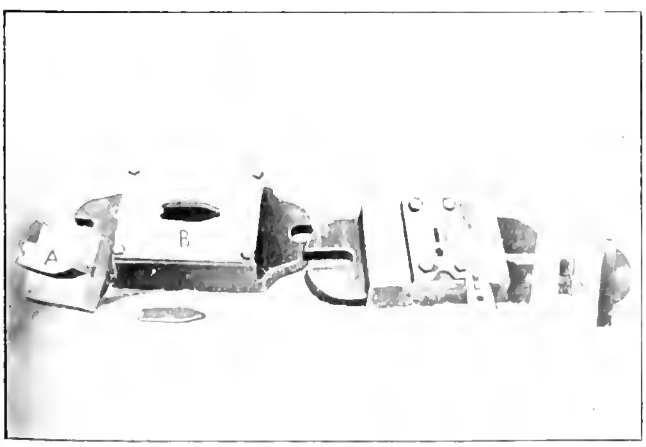

Fig 13 Blanking, Slotting and Piercing Punches and Dies for the Plain Jaws

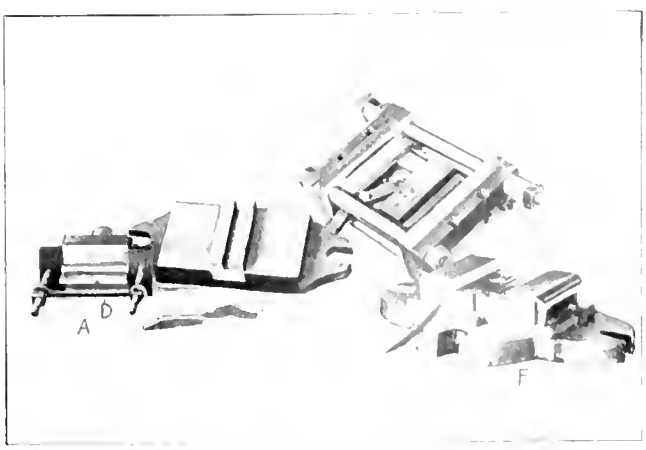

Fig 14 Jaw Forming Punch and Die and Serrating Tools

The forming is done with the punch and die, *A* and *B*, Fig. 14, both styles of jaws being formed in the same die, as the locating blocks are so made as to only come in contact with parts of the jaws that are alike in both cases. The action of the "knockout" bar *D*, is interesting, as many an elaborate stripping scheme is less efficient. When the forming punch is set, this bar is at rest in the die slot slightly below the surface of the die, which allows the flat jaw blank to be located properly. As the punch descends, the bar strikes the bottom of the die slot and since it fits loosely on the punch studs, the punch can descend the full stroke without damage or making it necessary to have a very deep slot in the die. As the punch rises, the studs slip through the holes in the bar until the nuts are reached, when the bar rises, carrying the formed jaw with it. At *E* and *F* are shown the serrating tools, but as this is one of the most interesting and important operations, the tools are shown on a larger scale in Fig. 15. Between the forming and serrating operations, the jaws are annealed by heating to a dull red and allowing them to cool slowly, as indicated in the table of operations.

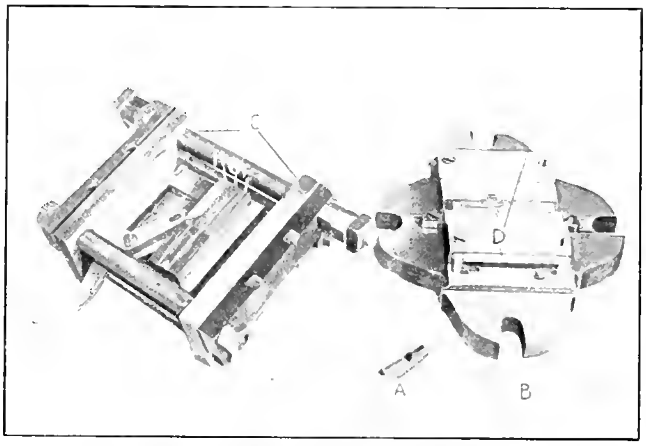

Fig. 15. Combination Punch and Die for Flattening and Serrating the Plier Jaws

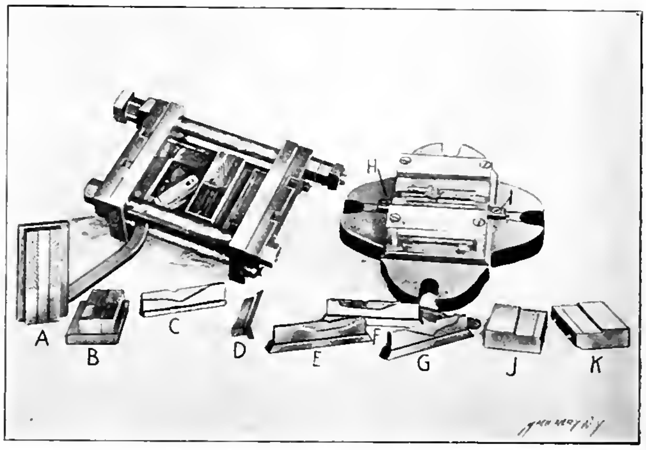

Fig. 16. Another View of Serrating Punch and Die with Attachments

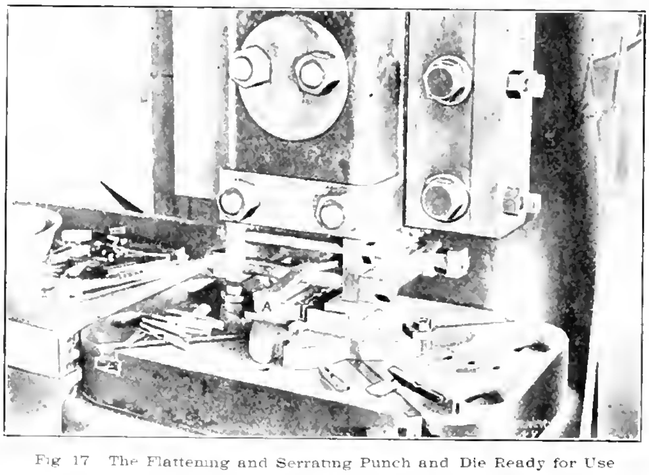

Fig. 17 The Flattening and Serrating Punch and Die Ready for Use

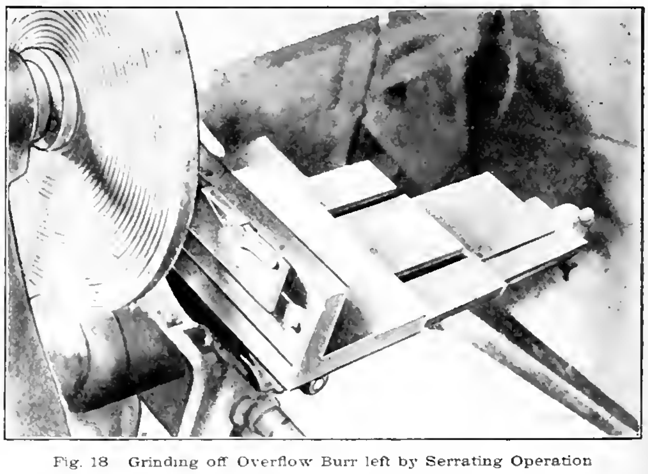

Fig. 18 Grinding off Overflow Burr left by Serrating Operation

Serrating the Jaws

The flattening and serrating of the jaw face, is done at one setting but with three strokes of the press, a formed jaw blank like *A* being held in the "squeeze" or clamping die *B*, the clamping slides of which are operated by the beveled parts *C* of the punch coming in contact with the rollers *D* which, in turn, press against the slides. In using this serrating punch, the face of the jaw is first flattened by the blank punch *E*; the lever *F* is then shifted over and the blank creased one way with the punch *G*; the lever is then pushed over as far as it will go, which on the stroke of the press, creases the jaw in the opposite direction, finishing the serrations.

The punch just referred to is the first one of this type made. It has the flattening punch at one side, but in the later ones the blank is put in between the serrating punches as at *A* and *B*, Fig. 16, which makes the handling of the shift lever much simpler, as the first stroke can be taken with the lever in a central position and then for the other two strokes it is shifted alternately to the left and right as far as the stop will let it go. At *C*, *D*, *E*, *F*, and *G* are shown forms for locating the different sizes of jaws in the die, which are made to fit a slot in the bed-plate and are held in by the two clamps, *H* and *I*. A pair of the sliding clamp blocks is shown at *J* and *K*, the releasing springs being shown projecting from the inner edges.

Fig. 17 shows the serrating punch and die set up in a punch press ready for use. Like the punch and die used in the drop hammer, this tool is made entirely of steel for the reason that cast iron is too weak. The credit for developing this tool is due to Mr. W. F. Gradolph, and the design is fully protected, but it thoroughly solves a problem that is far more difficult than it looks at first.

Finishing the Jaws on a Disk Grinder

The serrating operation just described, naturally leaves an overhanging burr on the sides of the jaw which is removed by grinding on a Besly disk grinder fitted as shown in Fig. 18. As there is considerable burr to be removed in order to properly square the sides of the jaw, a coarse grade of emery must be used on the disk to get quick results, but though coarse emery cuts fast it has a tendency to "shell off" in a case of this kind which, if not remedied in some way, necessitates frequent changes of the disk facing which is costly both in time and money; so in order to remove the burr quickly and at the same time avoid the shelling effect, a disk of number 16 emery is taken, coated with glue and number 40 emery put on which fills in and supports the coarser grains, at the same time allowing them to cut with practically the same freedom as at first.

Originally the jaws were so held in the die as to prevent the "overflow" but it was soon found that when flattened and serrated in that way they had a tendency to develop cracks along the edges which are entirely avoided by the present method.

Drilling, Milling and Reaming the Jaws

The drilling of both types of jaws for any one size is done in the same jig, two holes being drilled in the plain and three

in the cutting jaw. The style of drilling jig used for this work is shown in Fig. 19, and it will be noted that the locating of the jaw is done from the serrated face and the rounded ends, the movable or clamping slide coming in contact with the untrimmed end. After drilling, the burr left on the outside of the jaw around the holes is removed by holding it for an

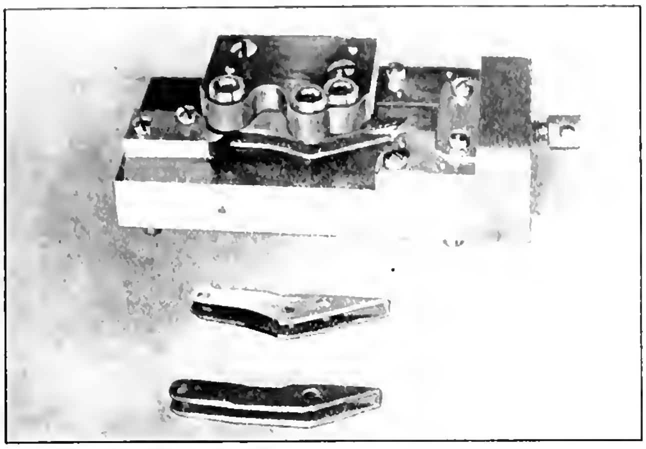

Fig. 19. Drilling Jig for the Jaws

instant against a disk grinder. Next the cam rivet holes are countersunk in a drill press, with a drill and the block *A*, Fig. 20. The outer ends of the jaws are now trimmed to exact length with a small side mill *B*, while they are held in the jig blocks *C* and *D* which are held in the milling machine

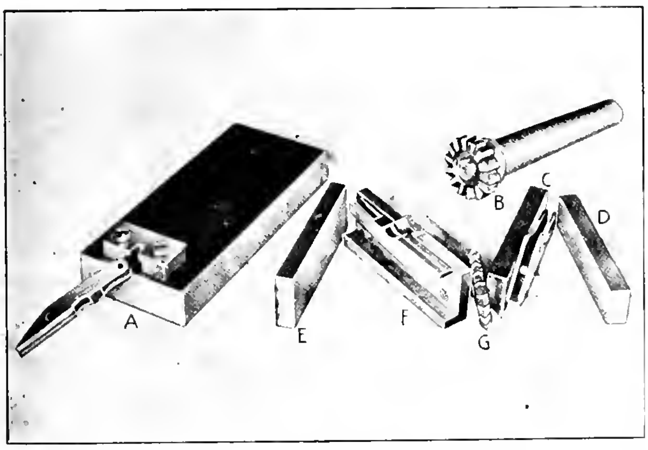

Fig. 20. Countersinking and Milling Jig and Tools

vise. The jaws are located in the block by two pins, one of which goes through the forward hole, the other supporting the cam end of the jaw. As in most of the other jigs, both styles of jaws are machined in the same jig.

Wire slots are milled only in the plain jaws, using the jig

Fig. 21. View showing Method of Bunching Jaws for Carbonizing

blocks *E* and *F* in the vise, and the cutter *G*. The idea of milling a wire slot in only one jaw is that the serrations on the jaw opposite the slot will hold the wire better than two V-slots.

The holes in the jaws are reamed out on a three-spindle drill press, in the same way as were the handles; the jaws are then strung on two stiff wires as at *A*, Fig. 21, packed with bone in boxes like *B*, placed in the furnace shown and carbonized. After being heated the proper length of time, the boxes are drawn out one at a time, the lid removed and the clusters of jaws lifted out with wire hooks *C* and plunged into water. When dried, the inside burrs are removed with a 1/8-inch emery wheel, as in Fig. 22. The plan of leaving the removal of the inside burrs until after the jaws have been hardened, is a good one, as a wiry edge is not turned into the hole as would be the case if ground when soft.

The plain jaws are then "nicked" to a uniform depth on the back edges as at *A*, Fig. 23, where they come in contact with the handles, to make sure that the jaws will all open the same distance. This is done by setting the jaws on the fixtures and swinging them around the pin *B*, against the emery wheel.

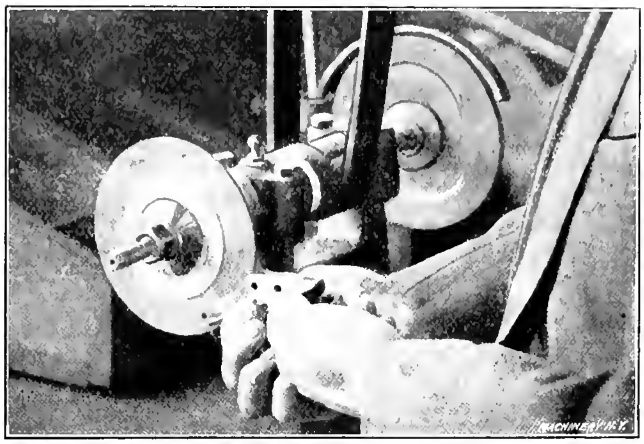

Fig 22. Removing the Inside Burrs from Jaws after they are hardened

All jaws are now rough polished, drawn to a blue color in an oil bath, then finish polished and sent to the assemblers.

* * *

THE VALUE OF BOOK STUDY

An interesting illustration of the value of book study is related by a New Jersey business man who recently advertised

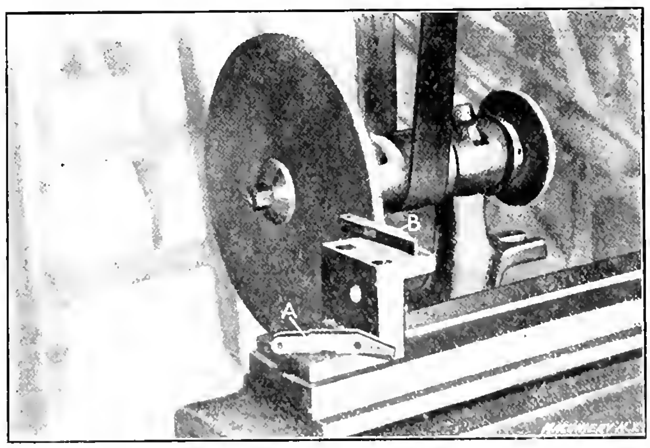

Fig. 23 Grinding a Stop on the Back of a Plain Jaw

for a chauffeur. One of the applicants was a well-educated man who had been conducting a "Queries and Answers" column in a motor journal. He was well-informed on the literature of automobiles, well-versed in thermodynamics, and familiar with the various text-books, trade catalogues, etc. Especially was he thoroughly conversant with all the intricacies and difficulties of the power plant of an automobile. He had, however, never run a machine, and wanted the experience. So he was engaged for a trial on the strength of his general knowledge, and a few days' practice was sufficient to make him a good driver; in fact he was often consulted as an expert in engine troubles. As one of our correspondents says, this goes to confirm the contention that book learning helps a man out, and a correspondence school's course is not entirely useless even in automobiling.

EXAMPLES OF BOX-TOOL DESIGN

By F. P. CROSBY*

A number of box-tools of different designs, with examples of the work for which each is intended, are shown in the accompanying engravings. While these tools are designed for some specific part, they can, of course, with slight modifications be adapted to other work; therefore a study of the different tools illustrated, will doubtless be of suggestive value to those engaged in the construction of box-tools for turret lathes and automatic screw machines. In all of the engravings the reference letters in the assembled and detailed views are the same for the corresponding parts.

A box-tool of the pilot type that is used to finish work after the surplus stock has been removed by roughing tools, is shown in Fig. 1. The work itself is indicated at *A* by the dotted lines, which represent a cone for a ball bearing. The pilot *B* enters the work before either of the cutters begins to operate on its respective surface. This pilot should be tempered and ground true. The inverted cutter *C* which sizes the flange of the cone, is held in position by a clamp *D*, which is forced down by a collar-head screw; and it is further

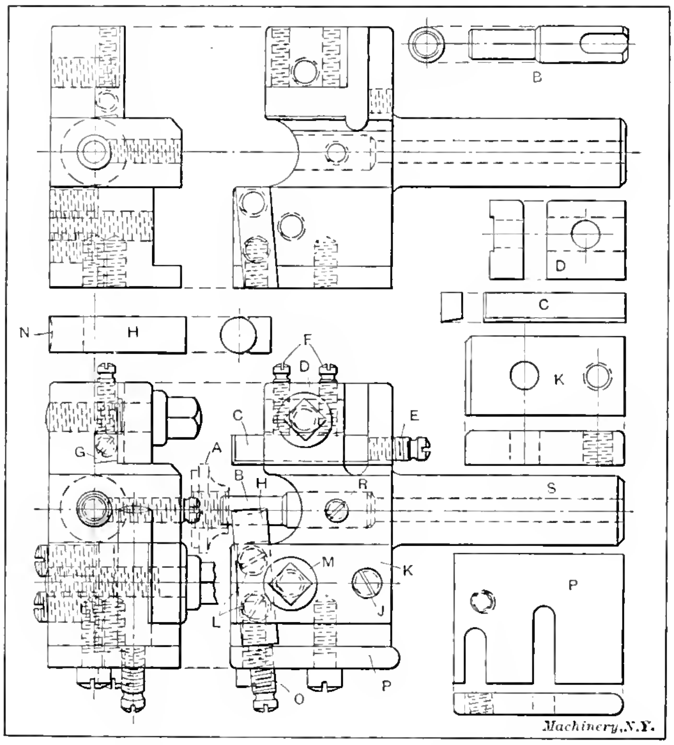

Fig 1. Finishing Box-tool for Ball Bearing Cone

secured against a beveled shoulder at *G* by the set-screws *F*. The cutter is adjusted forward by the screw *E*. By loosening the screws *F* and the collar-head screw, the cutter may be easily removed for sharpening. The cutter *H*, which rests on a bolster as shown in the detailed view, is adjusted to cut to the proper diameter by the screws *L*, after which the clamp *K* is made level by the screw *J*. The collar-screw *M* is then used to secure the tool in place. The cutter is made from drill rod, and it is slightly cupped out on the cutting end as shown at *N*. The adjusting screw *O*, which passes through plate *P*, prevents the cutter from backing away from the work. This adjusting-screw plate has its screw holes slotted as shown in the detailed view, to obviate the necessity of removing the screws when it becomes necessary to sharpen the cutter. Pilot *B* is held firmly to the tool body by set-screw *R*. The hole *S* through the shank makes it easy to remove the pilot in case this is necessary.

A pilot box-tool for finishing another type of ball bearing cone, is shown in Fig. 2. The shape of the work itself is indicated by the dotted lines *A*. This tool is somewhat similar in its construction to the one just described. The cutters *B* and *C* are inverted, and are used to face the flange at *D*, and to turn it to the proper diameter. These cutters are held by the clamp *F* and screws *G*, and are adjusted forward by the screw *H*. The cutter *J*, which operates on the top of the stock, rests on a bolster of the proper angle (see detailed view), and is adjusted up or down by the screws *K*. The clamp *L* which binds against this tool, is beveled at *M* to correspond with the angle of the tool. This clamp is secured

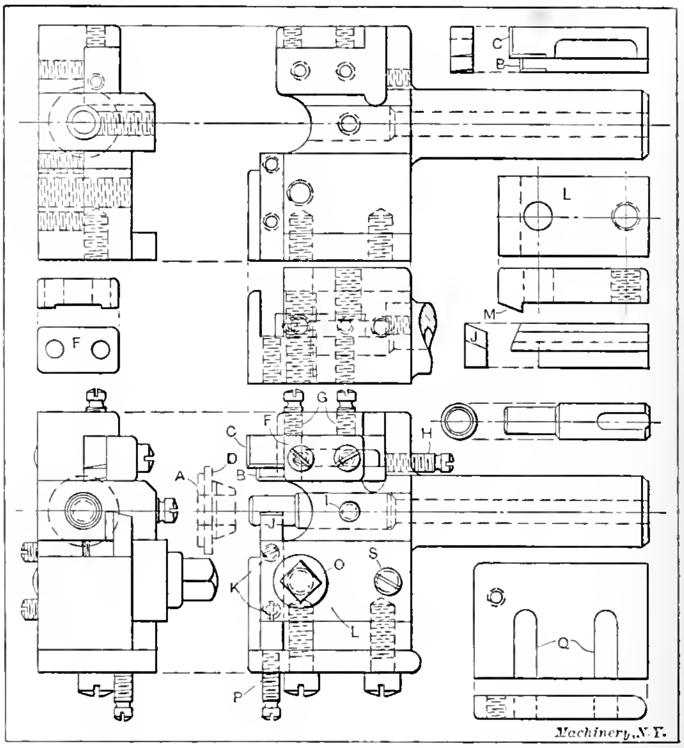

Fig. 2. Box-tool for Finishing Another Type of Ball Bearing Cone

by the collar screw shown, and it is leveled by set-screw *S*. The adjusting screw *P* prevents the cutter from slipping back. The holes *Q* in the adjusting-screw plate should be slotted as shown so that it will not be necessary to remove any screws when the cutter has to be taken out of the holder.

A box-tool for finishing a treadle rod cone for a sewing machine, is shown in Fig. 3. This tool is also of the pilot type. The cutters in it operate on opposite sides of the work which

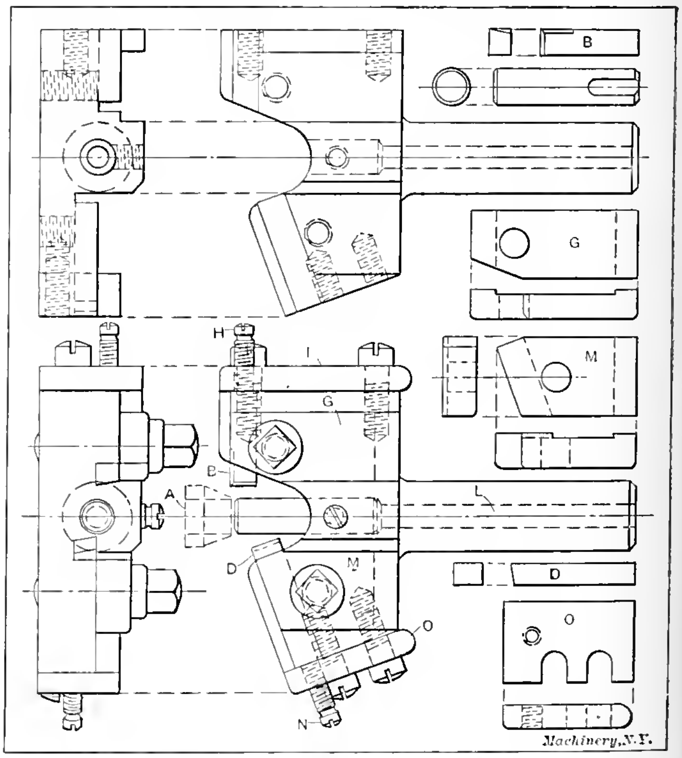

Fig 3. Box-tool for Finishing Treadle-rod Cone

is again illustrated by the dotted lines at *A*. The inverted cutter *B* sizes the cylindrical part of the cone, while the front cutter *D* is set at the proper angle to finish the tapered part. The rear cutter *B* is held in place by the clamp *G* and a collar

* Address: 433 North State St., Chicago, Ill.

screw. It is adjusted forward by the screw H in the plate I which is held by screws as shown. The pilot is retained by a set-screw, and it is easily removed by inserting a small rod in the hole L which passes through the shank. The cutter D is held by clamp M, and is adjusted by screw N, which passes through a tapped hole in plate O, the plate being held to the body or base by screws. The screw holes in both the adjusting plates I and O are slotted to facilitate their removal. The general construction of the tool will be clearly understood by reference to the detailed views of the various parts.

The design of box-tool illustrated in Fig. 4 is used for finishing the bushing of a double-taper cone bearing, the form

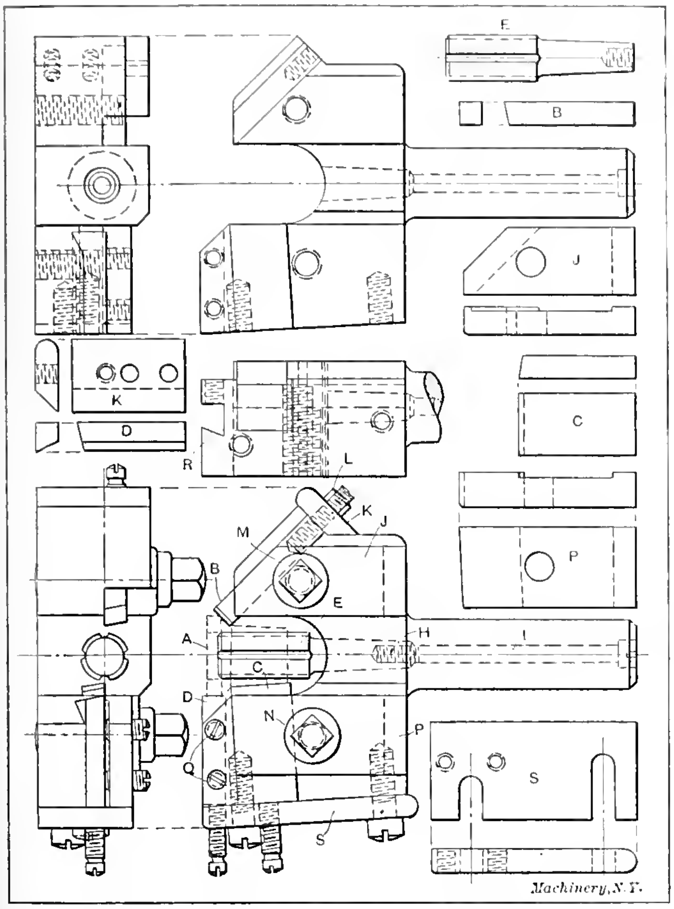

Fig. 4. Tool for Finishing the Bushing of a Double Taper Cone Bearing

of which is shown in dotted lines at A. The cutters are so arranged that they all cut on the center; that is, the cutting edges lie in a horizontal plane. The inverted cutter B, in the back, forms the short angular surface, and the cutter C in front forms the long tapering part of the bearing. The large diameter is turned to size by cutter D. The pilot E has a bearing in the bore nearly equal to the length of the work, and it is provided with oil grooves as shown. The taper shank of this pilot is tapped for the screw I which extends the whole length of the shank; this screw draws the pilot back to its seat. The adjusting-screw plate for cutter B is held in place by two screws. It is not necessary to remove this plate to take out the cutter, as the latter can be drawn out from the front after the collar-screw M is loosened. The cutter C is removed by slipping off the adjusting-screw plate S after loosening the collar-screw N. The cutter D is held in a dove-tailed slot (shown at R in the detailed view of the holder

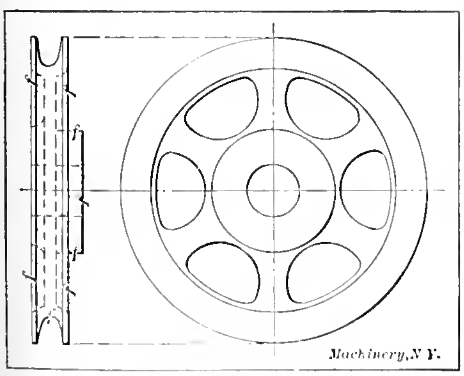

Fig. 5. Pulley that is finished by the Tools shown in Figs. 6 and 7

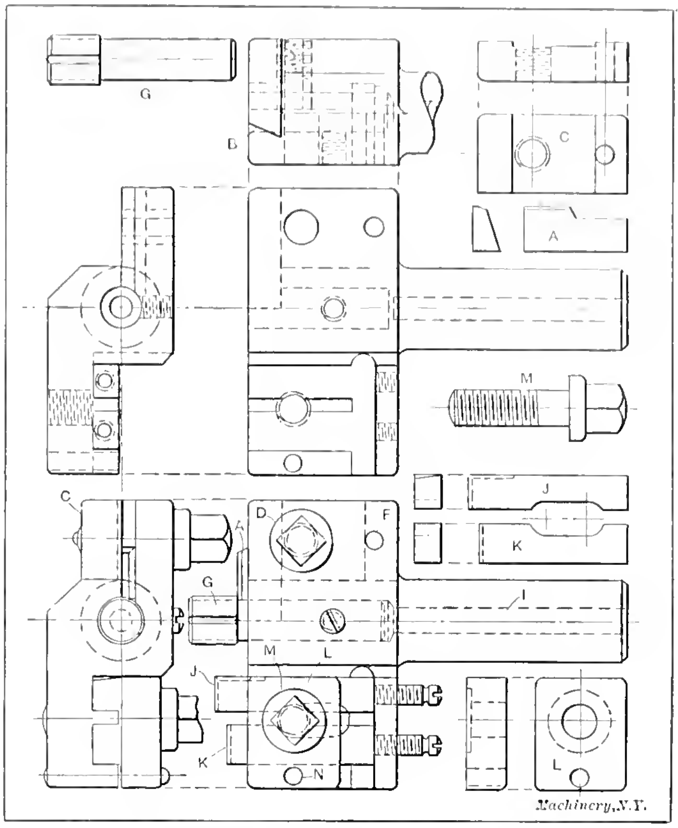

Fig. 6. Tool for Facing the Extension Hub Side of the Pulley

body) by two headless set-screws Q. It is also backed up by an adjusting screw in the plate S. These adjusting screws should all have fine threads, say from 32 to 40 per inch, and be nicely fitted so they will keep their adjustment and not give trouble.

Fig. 5 illustrates a loose pulley for a sewing machine, that is finished as indicated by the marks f. This part is completed in two operations. The box-tool for finishing the side of the pulley on which the hub projects beyond the rim, is shown in Fig. 6. The inverted cutter A which faces the end of the hub, is fitted to a dove-tail B, which is shown in the detail view of the holder body. This cutter is held by a clamp C (clearly shown in the end view) from the under side, and it has no

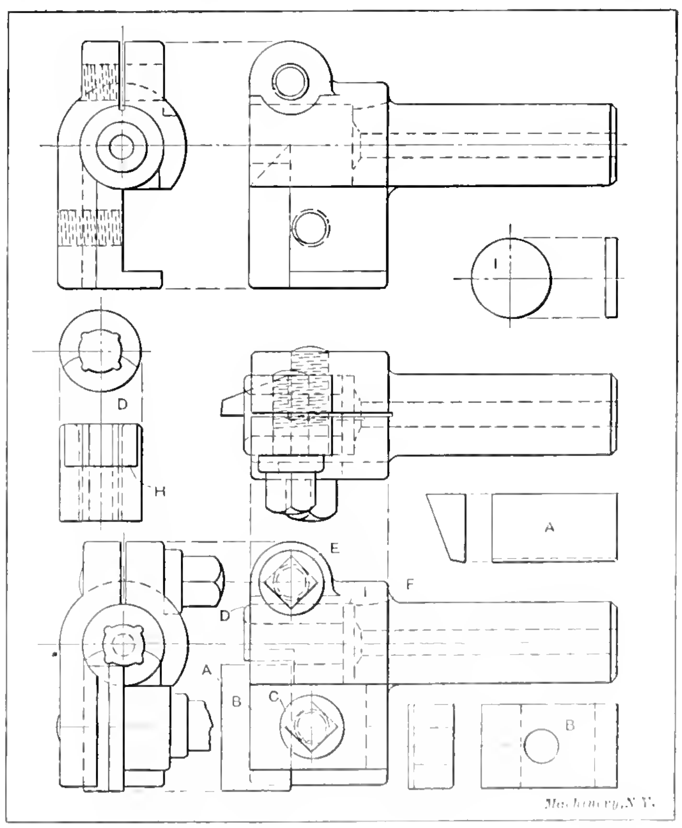

Fig. 7. Tool for Facing the Flush Side of Pulley

adjustment. The collar-screw *D* is tapped into this clamp, which is prevented from getting out of place by the dowel-pin *F*. The pilot *G* is made small in the shank, so that tool *A* may be so placed as to insure the removal of all burrs around the bore of the hub. The pilot is held by a set-screw and it is provided with oil grooves. The cutter *J* sizes the outside of the hub, and the cutter *K* faces the side of the pulley rim. These cutters are both held by the clamp *L* and the collar-screw *M*. The dowel *N* prevents the clamp from turning when the screw is being tightened. No side plates are used on this tool, and the cutters are all easily removed.

Fig. 7 shows the box-tool used for the second operation on the pulley illustrated in Fig. 5. As the hub is flush with the rim on the side for which this tool is intended, it needs only one cutter to face both. This is done by the cutter *A* which

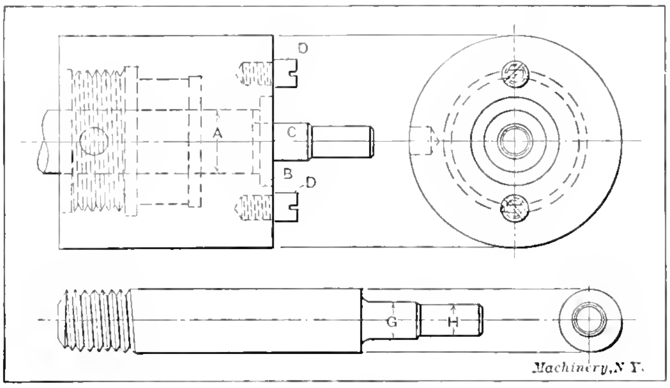

Fig 8. Chuck and Arbor on which the Pulley, Fig 5, is mounted during the Second Operation

is held in a dove-tailed slot in the front of the tool, and is fastened by the clamp *B* and collar-screw *C*. The bushing *D*, in which the end of the work arbor is supported, is held by the collar-screw *E*, and to obtain the necessary compression, the body of the tool is slotted as far back as *F*. This bushing is provided with oil grooves as shown in the detailed view, and one side is cut away as far back as *H* to clear the cutter *A*. The end of the arbor that the work is mounted on, is 1/16 inch smaller than the bore of the pulley, which allows the cutter to be set in far enough to prevent any burr forming at the edge of the bore. A disk *I* is inserted back of the bushing *D* so that the latter may be easily removed by passing a rod through the hollow shank.

Fig. 8 illustrates the arbor and chuck used for the second operation on the loose pulley, the box-tool for which has just been described. This chuck is fitted to the nose of the spindle, and the work is mounted on the projecting arbor and driven by the pins *D*. The bore *A* through which the work arbor passes, as well as the face *C*, should be ground after hardening, to insure accuracy. The arbor itself, which is shown in detail, should also be ground after hardening. The thread on the end of this arbor should be of a coarse pitch, enabling the arbor to be removed quickly from the draw-spindle, as it has to be removed for every piece operated on. The diameter *G* is made a driving fit for the work, and the end *H* is a running fit in the bushing of the box-tool. The counterbore at *B* is to provide clearance for the hub of the pulley which projects beyond the rim on one side.

* * *

The total tonnage of vessels launched during 1909 in all the countries of the world amounted to 2,006,500 tons. Of this tonnage, more than one-half, or 1,017,000 tons, was built in the United Kingdom and 258,000 tons in the United States. The total tonnage for the whole world shows a decrease of 40 per cent from that of 1906. Of sea-going merchant steamers of over 3,000 tons, about 75 per cent were built in the United Kingdom.

ECONOMY IN GRINDING*

By JOHN J. THACHER†

It is very often the case that a grinding machine falls short of its highest possible output by reason of the inattention of the operator to some of the short cuts and time-saving methods that have been highly developed in the use of other machine tools. It is the case with grinding machines as with other machine tools, that the development of short cuts and kinks of various sorts, greatly increases the aggregate output of the machines. The lack of such time-saving methods is the reason for the unfavorable attitude of some firms to the grinding process. It is almost always the experience of a demonstrator sent out by the manufacturer of grinding machines, that his results are not maintained by the operator. First one little kink is lost sight of, then another, and the time increases very slightly on each individual piece ground, but the aggregate of the day's output is soon considerably below what it should be.

A grinding machine will size work to a commercial degree of accuracy with remarkably little attention on the part of the operator, but the quantity output of a machine is very largely dependent on the ability and willingness of the operator to hustle; hence the reason for the almost universal prevalence of the "piece system" in the grinding department.

Several little kinks that I have observed at the works of the Brown & Sharpe Mfg. Co. may be of interest to those who would increase the output of their grinding machines.

Spotting Work for the Back-rests

Spotting work for the back-rests is a great help to the operator in several ways. When a piece of work is placed in the machine, assuming that the automatic cross-feed stop shield shown at *A*, Fig. 1, has been adjusted from a previous piece ground, the grinding wheel should be run back from the work about 1/32 of an inch. This is accomplished by turning the cross-feed handwheel *B* about one revolution in the opposite direction to that in which it is automatically revolved. The table carrying the work can now be moved by the handwheel marked *C*, provided for the purpose, bringing the various back-rests successively in front of the grinding wheel, as shown in Fig. 2. The wheel is then fed into the work by hand without reciprocating the table; it should be fed into the work until the diameter where the shoes of the steady rests bear is within one-thousandth inch of the

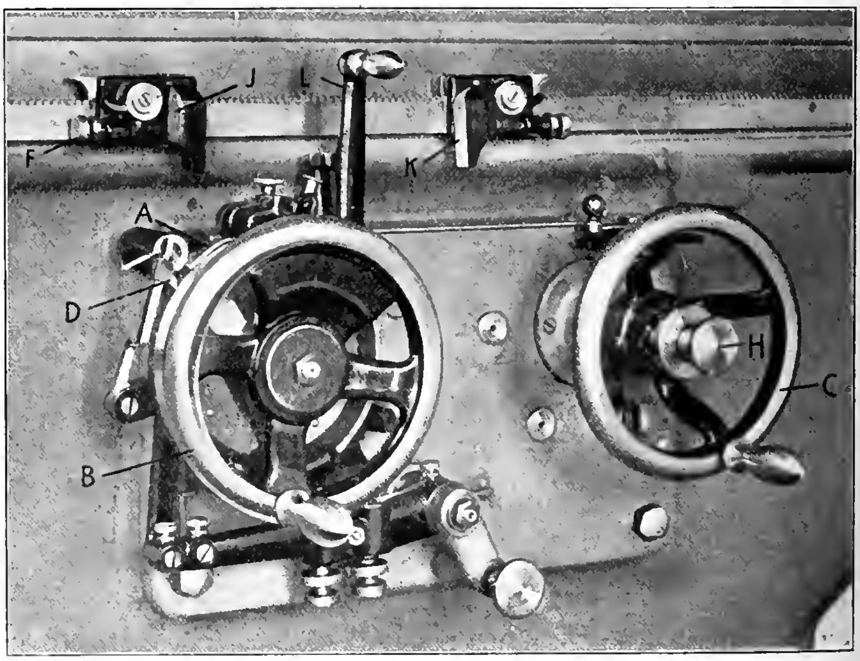

Fig 1. Controlling Mechanism of the Brown & Sharpe Grinder

† Address: Care of Brown & Sharpe Mfg. Co., Providence, R. I.

finished size. The guard A, Fig. 1, as it approaches the pawl D, serves as a gage to determine the extent to feed the wheel in. This operation takes a very short time and provides a smooth surface for the bronze shoes. This surface is so near the finished diameter that the shoes are not worn large before the work is reduced to the finished size, therefore the work is accurately and steadily supported during the finishing cuts. This is found particularly advantageous on hardened work where a large amount of stock is left for finishing and where chatter marks are more apparent if the supporting shoes of the back-rest do not fit the work very closely. It is also found to be a great saving on the wear of the shoes themselves.

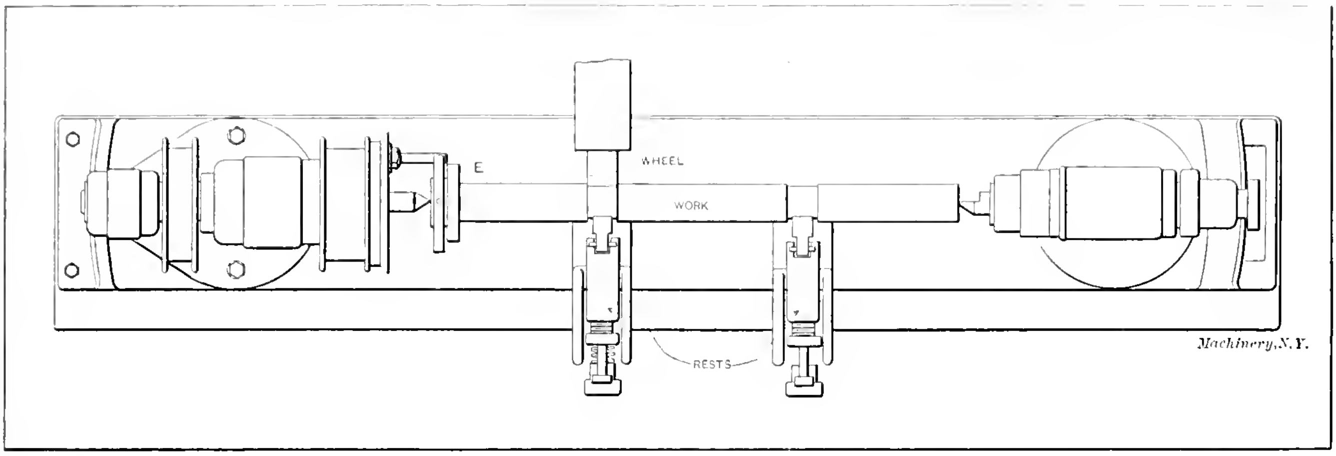

Fig. 2. Plan showing Method of Spotting Work for Back-rests

Grinding to a Shoulder

A time-consuming error among grinder operators is made on account of the prevalence of the idea that the reversing dogs on a grinding machine should be set to reverse the table traverse when the grinding wheel is within a very few thousandths of an inch of a shoulder on the work as at E, Fig. 2. It is a fact that most grinding machines will reverse within one or two thousandths of the same place each time, provided the rate of table travel is not changed. The variation in the depth of center holes in the work makes it necessary for the operator to try the reversing of the machine by hand after placing each piece in position to make sure that the wheel will not gouge the shoulder as it would surely do if the center holes were a little smaller than in the piece previously ground and a close limit for reversing were used. There are two ways to prevent the wheel gouging the shoulder on the work; one is the adjusting of the reversing dog by the screw F, Fig. 1, for each piece ground, which is a time-consuming operation; the other and better method is to bring the shoulder on the work up to the wheel by hand (using handwheel C after spotting for the back-rests as described), then feed the wheel straight into the work, reducing the diameter next to the shoulder for a distance equal, of course, to the width of the wheel, to the finished size. This is quickly and easily done by using the knock-off shield A against the pawl D for a gage as described. The table may then reverse for the subsequent complete grinding of the piece when the wheel has advanced not closer than 1/8 inch or more from the shoulder, and the edge of the wheel next to the shoulder does not become worn away or rounded because it runs off the work, or nearly off, at each end of the piece. A wasteful truing off of the wheel is thus easily avoided.

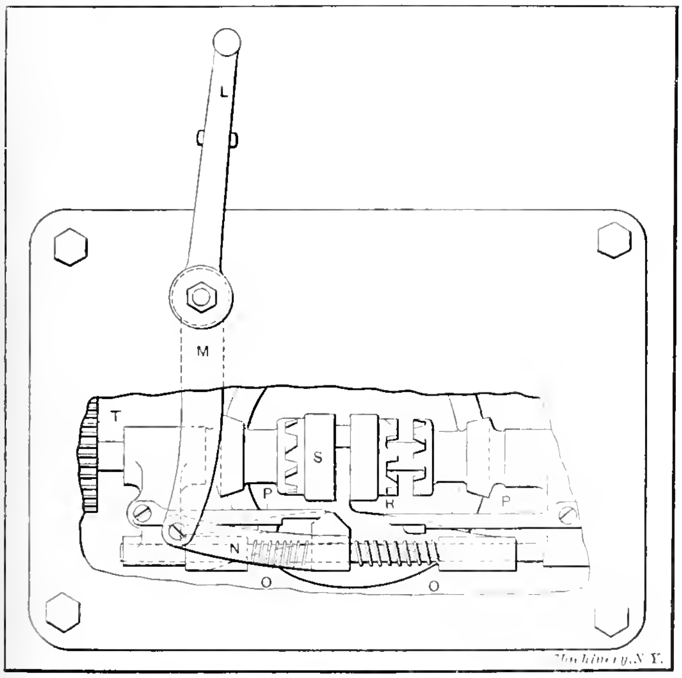

Fig. 3. Reversing Mechanism of the Brown & Sharpe Grinder

This operation of necking the work at a shoulder with the full width of the wheel, obviates the necessity of a dwell of the table at that reversing point. If a machine dwells when reversing at the shoulder end of the traverse, it must of necessity dwell at the other end where the wheel usually runs nearly off the work; here the dwell is not only of no value but it is very likely to cause the wheel to grind the end of the work undersize. While this dwell is only momentary, it is quite a factor in a day's output that can be readily eliminated.

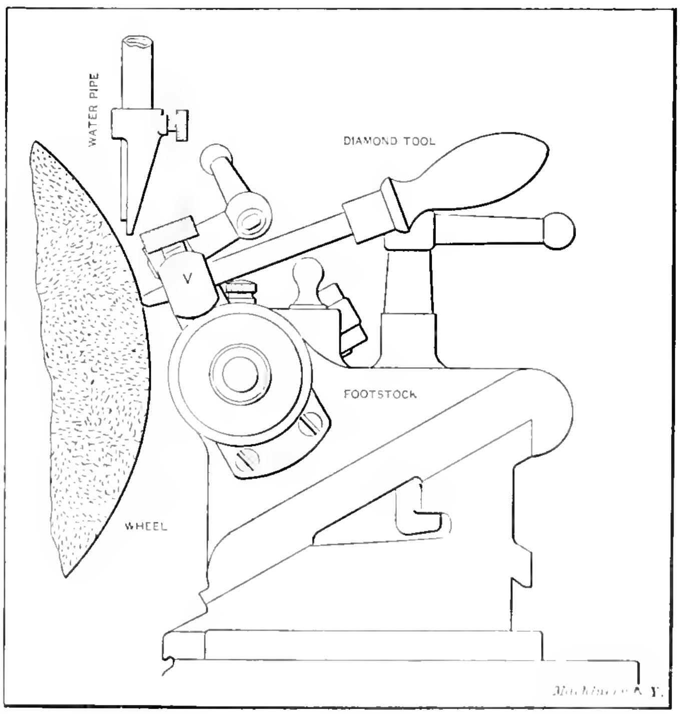

Fig. 4 The Way the Diamond Tool should be mounted for Truing the Wheel

If for any reason the necking of the work with the wheel is not deemed expedient and a dwell is required, this dwell is needful only once or twice during the grinding of a given piece and can be produced at will by the operator pressing the knob H, Fig. 1. Pressing this knob stops the power traverse

of the table, which may then be fed over by hand, using handwheel C, to face up the shoulder, and the dwell may be prolonged to allow one or more revolutions of the work as the particular quality of work and wheel may require, instead of the length of dwell being dependent entirely on the speed of the reciprocating table, as is the case when the dwell is automatically supplied by the gearing of the table. The table traverse is started after the dwell by pulling the knob H to the position shown in Fig. 1. A dwell so produced is not duplicated at the other end of the work except at the will of the operator.

It should be clearly understood that a grinding machine can be reversed with the shoulder on a piece of work 1/8 inch or more from a grinding wheel, then stopped at the reversing point and "forced over" this 1/8 inch or more beyond the normal reversing point without disturbing the reversing dogs and without subjecting the reversing mechanism to any strain.

In Fig. 3 are shown the elements of the reversing mechanism of the Brown & Sharpe plain grinders, which shows quite clearly how this traverse beyond the reversing point is accomplished. When the reversing dog J or K, Fig. 1, strikes and reciprocates the reversing lever L, the motion is transferred by its fulcrum stud and lever M to the arm N which compresses the reversing spring O. When this arm, which compresses the spring, has moved far enough to give considerable tension to the spring, the taper lug on the arm N raises the latch P thus releasing the yoke R which is connected to the reversing clutch S, this deriving its power from gear T. The spring, which is under compression, throws the reversing clutch as soon as the latch releases the yoke R. This movement of the yoke is sufficient to relieve the compressed reversing spring so that the reversing lever can traverse farther than the position where reversing takes place without unduly compressing the reversing springs. Thus the facing up of a shoulder on the work slightly beyond the reversing point without disturbing the reversing dogs on the sliding table can be readily accomplished without undue strain on any part of the reversing mechanism.

Truing the Wheel

When truing the periphery of a grinding wheel for all regular cylindrical work, a bort diamond, mounted in a suitable holder, is used, as shown in Fig. 4. This holder should be so mounted in its support that the distance from the diamond to the support V is as short as possible, thus avoiding spring or vibration in the holder which produces an irregular surface on the grinding wheel, appearing on the work in the form of a mottled effect or chatter. When work of large diameter is being ground, the wheel should be brought forward to the position shown in Fig. 4 when truing it off. The time consumed in moving the wheel forward with the cross-feed handwheel, is more than offset by the more rapid cutting of the wheel by the diamond, and, furthermore, the surface of the wheel is in better shape as stated.

For internal grinding, it has been proved economical by practice to true off the grinding wheel with a piece of a large wheel that has been worn down to such a small diameter as to render it useless for grinding; this piece of wheel must be harder than the wheel being trued off. This is a much quicker process than using a diamond, as the piece can be held in the hand and pressed to the grinding wheel as often as occasion requires. For this same purpose, bricks of various abrasive materials have been made and are generally used when pieces of a worn-out wheel are not available.

Design of the Footstock

The footstock of the grinding machine is of enough importance to warrant more attention than is generally allotted to it. The design that is in common use among grinding machine manufacturers, includes among other elements what might be called a spring-actuated spindle. The spring, which forces the center against the work, is primarily for the purpose of allowing the work to expand from the effect of the heat developed in grinding. As heat is very largely dissipated by the use of water, the more practical value of the spring-actuated footstock is to apply a firm pressure of the center against the work without force sufficient to distort it. This is very difficult to do with a screw and handwheel and is accomplished on a lathe by setting the center solid against the work, and withdrawing it until the work can be easily turned by hand. This represents a looseness between centers intolerable on a grinder and also causes a great waste of time. When grinding heavy work, there are two reasons why it is often necessary to clamp the footstock spindle solid after inserting the work in the machine. The weight of the piece of work tends to crowd the footstock center back on account of the angle of the center; also the momentum of the piece when the table reverses at the footstock end of its traverse tends to pound the center away and any looseness thus developed will render futile any attempt to produce round work.

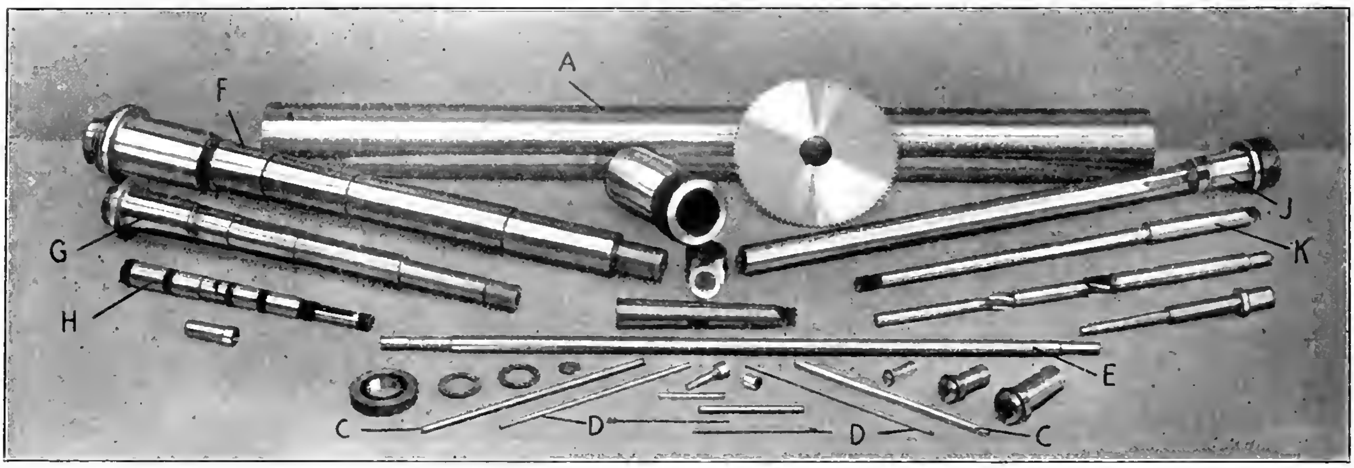

Fig. 5. Examples of Ground Work

Time Required for Grinding

In Fig. 5 there are shown several samples of work that has been finished on the grinding machine. Without exception every piece has been machined complete before it is sent to the grinding department; all threads have been cut, keyways and slots milled, holes drilled, etc., therefore all external and internal strains have been equalized in the pieces before they are ground. The grinding process is the most free-cutting process known to metal workers and should be the last cutting process as it distorts the work the least. The piece marked A is an overhanging arm for the milling machine, made of machinery steel 4½ inches diameter and 69 inches long. These pieces require an exceptionally good finish and are ground complete in thirty minutes for each arm. They are revolved in the grinding machine by a pin temporarily driven into one end near the periphery, this pin engaging the driving arm on the headstock pulley; with this arrangement pieces of sufficient size can be ground from one end to the other complete, while such small pieces as those marked C and D must be turned end for end to complete the grinding. These last pieces are about ½ and ¼ inch diameter, respectively, and 10 inches long. They are ground at the rate of fifteen

per hour and have a limit of 0.00025 inch either side of the dimension given. The shaft marked E is about 40 inches long and 1 inch in diameter where it is ground; this piece can be readily dogged at one end. These are ground at the rate of twenty minutes each with a tolerable variation of 0.00025 inch larger or smaller. The tapered collet shown in the center of the engraving is ground in four minutes. The milling machine spindle marked F is ground complete in one hour. The limits are very close, *viz.*, 0.00025 inch total variation, and the taper behind the collar is ground to a gage. The smaller spindle marked G has the same close limits as the larger one, and is ground complete at the rate of seventy in sixty-four hours. The spindle marked J, which is 34 inches long, has a threaded guard over the end and on this guard the dog is clamped. Thirty-nine of these spindles are ground complete in thirty hours. The screw machine spindle marked H, is a very difficult piece to finish owing to the fact that it is bored out its entire length so that it is practically a hardened steel shell which is cut away at the smaller end. When grinding these spindles in large lots, they are roughed out all over in large quantities then finish-ground later. It requires thirty minutes to completely grind one spindle.

This last example illustrates very clearly how difficult it is to estimate the time required for grinding a piece of work, as every feature of the piece enters into the problem and if it were not for the two slots which so cut away and weaken the small end that the grinding wheel cannot be forced into the work, these spindles could be ground in about ten minutes less time for each one. Placing the work on an arbor for grinding, very seldom increases the total length of time to grind when there are several duplicate pieces in a lot, as two arbors may be employed and the operator can insert one arbor in the work while the machine is grinding the work mounted on the other arbor.

Number of Operators

The economical operation of a grinding machine presents very varied problems. It is sometimes an advantage for one man to run two machines; this is generally on long pieces where the time of actual grinding far exceeds the time of placing the work in the machines. There are, however, some jobs where two men can work very successfully on one machine. This is the case with short, large bushings that are driven on an arbor, in which case the time of changing the arbor from a finished piece to an unground piece equals or exceeds the actual time of grinding. When these conditions exist, the operator and the machine are non-productive at least half of the time, and this non-productive period can be reduced to a minimum by a helper to assist the operator.

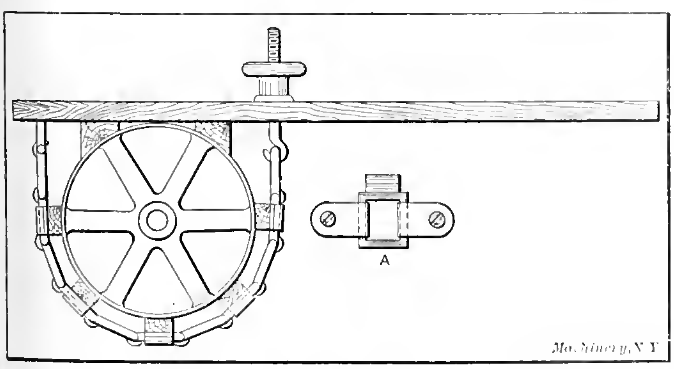
AN EASILY MADE PRONY BRAKE

The accompanying sketch shows an easily made and cheap prony brake, suitable for testing gas engines, etc. The drawing requires but little explanation. The band is made of common malleable sprocket chain links of the ordinary de-



Simple Prony Brake made of Malleable Sprocket Chain Links and Wooden Blocks

tachable variety. One of the links to which the wooden blocks are fastened by means of sheet-iron clips and wood screws is shown at A. This form of link can be bought for a few cents. It is evident that such a brake band can be cheaply made and easily adjusted to any size pulley or flywheel by taking out or putting in links as required. G. C.

THE DETAIL ENGINEER

By GEORGE P. PEARCE*

The Novelty Works had the opportunity to supply some small finished pieces at a certain contract price. The price was low and the profit on each piece would be small, but as there would be thousands of pieces ordered and the deliveries would not be rushed as long as shipments were made in reasonable time, the shop could work on the order to "fill in," and this alone was an inducement. The owner and superintendent carefully looked over the sample piece and concluded that it could be made for the price, with enough profit to make it worth while. To be more sure they called in Bill, the machinist who should do most of the work, and he looked over the piece and thought that in hundred lots the time would average one hour each. This seemed reasonable, and without the slightest misgivings the contract was closed.

On the first hundred castings the time records showed two and a half hours each. The boss sent in a "hurry-up" call for the superintendent and asked "how about it?" The superintendent explained that it seemed as if that particular lot was "hoodooed," for although everyone worked like "blazes," progress was slow; however, this was the first lot, and, of course, it took time to watch and figure out the quickest methods; the next hundred certainly would show considerable improvement.

The second hundred were made in exactly two hours and eleven minutes each. The boss told the superintendent that something had to be done, for at this rate he would lose thousands of dollars. The superintendent tried other men and rigged up jigs and fixtures of all kinds, but could not get the time lower than two hours and five minutes. The boss then "personally" saw one hundred through, and stirred up so much excitement and hustle that the time ran up to two hours and fifteen minutes each. By now it was settled in the mind of the boss that he was "caught for fair," and he wondered how much he could break the contract for, as it evidently was impossible to keep on in this way. He thought of sending for Mr. Wm. Steelworth, the detail engineer, to see what he could do, but then surely it would not be possible to cut the time on the work any lower, for had he not made every man work so hard on one lot that they could scarcely walk home, and he did not believe any man could drive them harder. The superintendent was of the same opinion, but he had heard such good opinions about this man that he suggested giving him a trial.

When Mr. Steelworth arrived, the boss took him in his private office, told the whole story, and expected that Mr. Steelworth would offer his suggestions and remedies there and then; but no such thing happened. He simply said that from what he had been told it seemed quite a proposition, but he wished to go right into the shop where he could observe all conditions and study out his own solution. This was unexpected, as the boss had supposed he would outline his plan of campaign and submit it for approval, and, if satisfactory, he would then be allowed to adopt it and possibly "see it through." The boss never allowed anyone to try anything new in the shop without his approval; however, he decided for once to break this rule, and Mr. Steelworth went into the shop.

The first move was a trip to the pile of castings, and the superintendent smiled at the length of time it took to look over the castings; nor could he see the need of examining so many, for three or four should tell the story of how they were "running." After this came a more leisurely examination of the different jigs and fixtures. There was one thing that rather rattled the superintendent. After he had minutely described every operation, how the castings were chucked and the different tools used until the finished pieces were passed to the inspection and shipping department, Mr. Steelworth persisted in following a set of castings through the shop, "counting every time a man breathed," as Bill had said. This made the men ill tempered, and they were telling one another what a "man driver" he was going to be.

The next day Mr. Steelworth asked the superintendent that aluminum patterns be made to replace the wooden ones. Both

* Address: 8 Union St., Exeter, N. H.

the boss and the superintendent explained that this was quite unnecessary, the wooden patterns were accurate and good enough, and lighter than anything else; and, anyhow, on these small pieces, weight did not count. But Mr. Steelworth said it had to be aluminum patterns or he would go no further; besides this, he wanted that central cored hole done away with, and a solid casting made instead. This meant the addition of three-eighths pound of metal and looked as if instead of reducing he was planning to increase costs.

The aluminum pattern castings were made, however, and were cleaned up, ready to send to the foundry, but Mr. Steelworth wanted the patterns machined all over and the machine marks buffed out. The superintendent thought this was going too far, and sarcastically remarked that they did not get castings with buffed surfaces and that a reasonably smooth pattern would draw well and be "good enough." Mr. Steelworth observed that he wanted these this way. After several trials, the men got the patterns smooth and accurate enough, and they were passed on to the foundry. Mr. Steelworth saw the foundry foreman, with the result that the next batch of castings was to be well pickled.

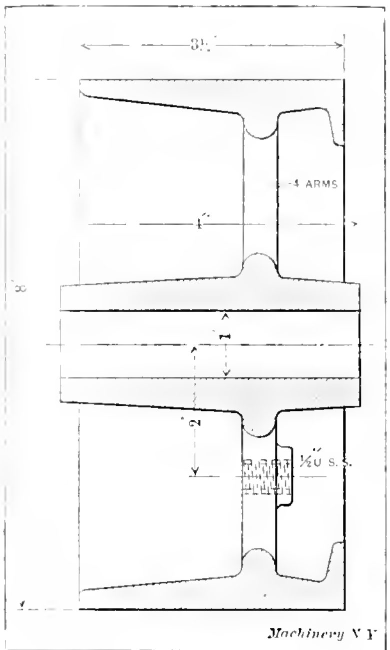


Fig. 1. Drawing of the Piece to be made

While waiting for the castings Mr. Steelworth picked up a big chunk of cast iron and had Bill fit it on the lathe nose; the front end was faced and holes were drilled and tapped so the casting could be quickly clamped to the face; the chunk of iron was also rough turned true. Soon the castings came in and a rusty looking lot they were in comparison to the nice "faced" ones that had previously been used. Bill was to machine them, and he quickly spotted that the central hole was not cored, at which he "cussed," for it meant a drilling job before he could bore them. He also had a few words to say about making the ungainly chuck, when he could catch them in the four jaw chuck and hold them just as well, besides having a better chance to true them up. His soliloquy was cut short by the arrival of Mr. Steelworth who said they would start in on the castings. "*They*," Bill muttered. "Is it going to take two men to do the job now? 'Cut time' indeed." The first thing Bill was told to do was to put the "chunky-chuck," as he called it, on the lathe nose, and then step the end of it down so as to be an easy fit in the large recess at the back of the casting. This he did and the casting slipped easily into place. Bill started for his monkey-wrench to tighten the cap screws which clamped the casting, but Mr. Steelworth stopped him and handed him a handy little ratchet wrench.

"*We'll* have to drill a hole through it before I can bore it," remarked Bill.

"*We* won't bore it at all, but will drill it small and ream it," remarked Mr. Steelworth. Get a twist drill, 1/64 inch small, and a dog." Just as Bill came back with these things, the whistle blew, and further work was postponed until after dinner.

Bill was back early and went to the superintendent as soon as that worthy appeared.

"Say! I don't want to interfere with any of your plans, but I'll be darned if I want to ape the green hand to instructions received from Mr. 'Great Ideas.'"

"What in the world has happened now?"

"Well! I don't mind clamping those castings to a piece of junk instead of the proper chuck, but when it comes to expecting castings to slip over shoulders, as if two castings ever came to within a strong sixty-fourth, and then having to drill the hole with a twist drill and ream it, as if a hole could be drilled central with a twist drill scotched by a dog, and there is no need for a reamed hole anyway. Besides this, goodness knows how much more time-wasting foolishness is coming, and it certainly is not going to be Bill who will deliberately waste castings and time to the tune of a "know nothing."

"Well, Bill, I have been noticing things myself and have talked it over with the 'old man,' and we decided to let it run this afternoon and let Mr. Steelworth trip himself on the time limit."

With a grunt Bill went and got a hammer and "round nose" to chip the start for the drill, but Mr. Steelworth arrived before he got started and told him to leave the hammer and chisel alone, and taking a tool holder, he ground the tool a kind of a cross between a facing and hogging tool which enabled him to take a quick facing cut right across the boss and then turn a countersink almost as large as the drill; he next put the drill against the tailstock center with the dog resting on the tool-post block and the heel of the tool touching the drill close to the cutting end, so that it could not run out. The lathe was speeded up way beyond what Bill generally ran it for similar work, and the drill fed in with a good heavy cut which was kept up right through. As the drill changed its "growl" when the point went through, Mr. Steelworth brought the flat part of the tool-holder against the dog and forestalled the drill's "hogging through" and twisting everything out of shape by snatching off the tail-center. Bill felt a little disappointed, as he had anticipated a broken drill, but still he smiled, for had not Mr. Steelworth ground the drill by hand in a few seconds and only sighted it up, and everyone knew it was quite a job to grind a drill so it would drill its own size and no larger. Besides he knew the drill was "loose" by the easy way it came out. He was disappointed again, for although the drill was not drilling to size, the hole was not quite a sixty-fourth out and this oversize really helped, for it only took a few seconds to put the reamer through. The drilling and reaming time was five minutes.

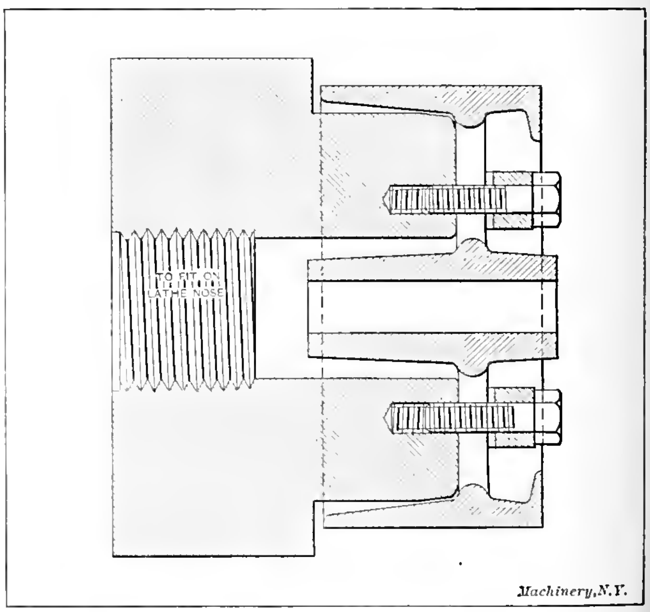

Fig. 2. Method of Chucking

Next Mr. Steelworth told Bill to take the casting out and put it on the tray at his right hand, then twist round and pick another from the tray on his left and put it on the chuck without moving his feet. Bill had some personal thoughts about such detailed instructions instead of saying "change castings"; and whoever heard of taking an unfinished casting out after once it was chucked; however he did according to schedule, and was surprised to find that the next casting went on all right; it was not often that two castings came so near. The facing, countersinking, drilling and reaming were quickly done, and ten were done in fifty minutes with only one casting refusing to go on the chuck, the only trouble being a little

snag which was quickly knocked off with the butt end of a lathe tool. Mr. Steelworth asked Bill if he thought he would have any trouble in keeping up a twelve per hour rate and Bill thought it would be easy for he had not hustled any above keeping right at it.

The next thing was facing the two sides as far as they reached down. Mr. Steelworth brought an old sleeve coupling up to the lathe and put it on a block so the top of the coupling was about 30 inches from the floor. Then he took a short mandrel he had picked out of the "pile" and drove it lightly in the casting; next he took a heavy dog about three sizes too big for the mandrel and to Bill's amazement clamped it on the driving plate, which he had put on the lathe, with its tail sticking outward. He put the mandrel on the centers, and then the convenience of the arrangement became apparent for the tail of the dog reached into the casting plenty far enough to catch the arm in the casting. Bill inwardly chuckled, for he knew that some of the castings would go further on the mandrel before they became tight, and then where would the dog drive be? Next Bill was told to get another tool-post, tool-holder and two tools which were fastened in the tool-block, one tool having been ground right hand and the other left. They were spaced the required distance, and were quickly fed across the side in one cut, thus facing both sides at once. It was but a moment's work to take the job out of the centers and put it on the sleeve; one quick blow with a soft hammer drove out the mandrel. As a block of wood had been placed in the sleeve, the mandrel just fell far enough to be loose in the casting, and was easily picked up with the left hand while another casting was picked up with the right and placed on the sleeve, the mandrel being placed in position while the free right hand was picking up the hammer. The mandrel was driven in by two light blows, and the job put in the lathe, when to Bill's surprise the dog tail just reached in to about the same distance. While he was facing the two sides Mr. Steelworth explained that as all the castings had reamed holes, they come tight enough in almost the same place on the mandrel if driven with about the same force; if Bill had any doubts as to being able to hit every time the same, he could easily mark the mandrel and drive as far as the mark—there was no need for the job to be very

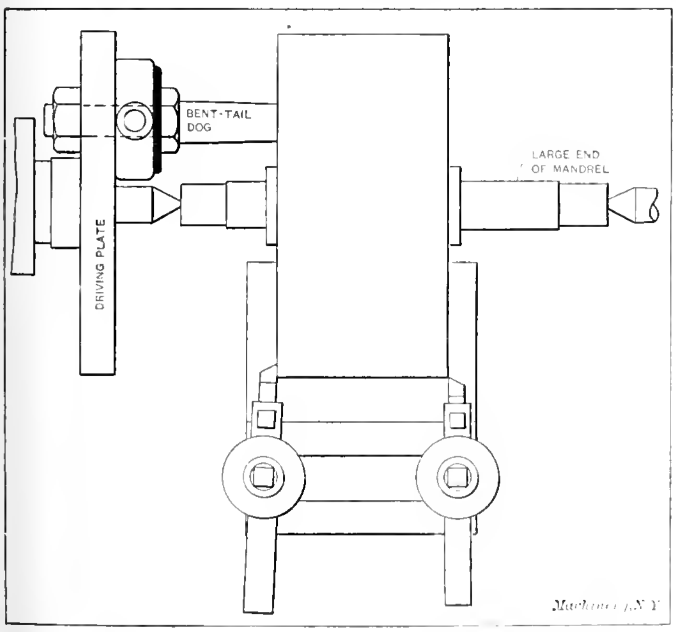

Fig. 3 Method of Driving the Work when Facing the Sides

tight, as it was not driven by the mandrel. The time for this operation was four minutes.

The next thing was turning the outside diameter and for this the two tools were again used, one set nearly to the required diameter and the other to take a light finishing and sizing cut. They were placed a little further apart than the width of the job so that both would not be cutting at the same time. The work was driven in the same manner as when facing. This operation Bill told the boys he knew how to go one better, and cut the time almost in two by placing the two tools close together so that it would only be necessary to wait the length of time for a little over one cut, instead of over two cuts. The first time he had a chance he tried it. The fellows thought Mr. Steelworth must have been slow, until the moment the roughing tool got across and the finishing tool immediately changed its cut enough to prove that the roughing tool had been springing the work, and, of course, the finishing tool had no chance to even up this inaccuracy. Thus the "improvement" fell through and Bill was glad to find that

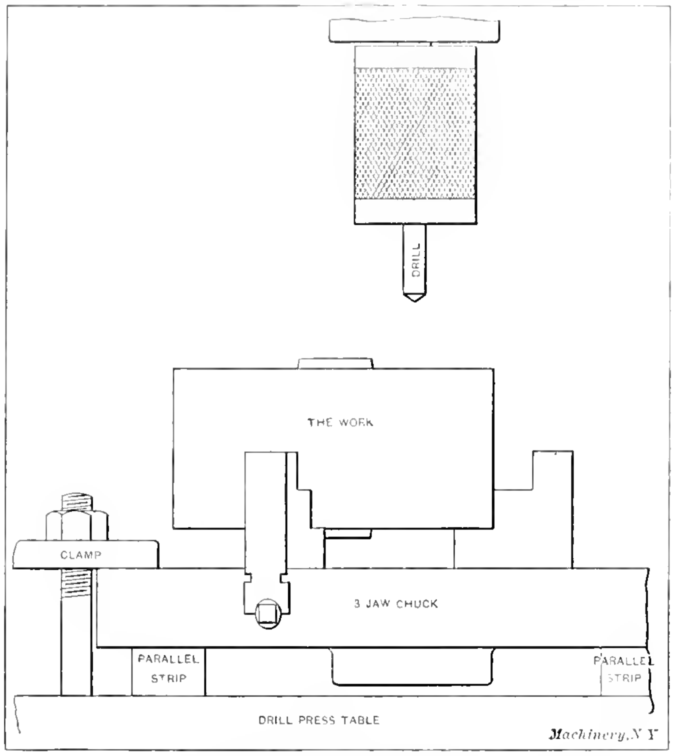

Fig. 4 Method of Holding the Work for Drilling and Tapping

another cut across saved the casting. In the future, Bill was always very careful to try things before he chased around saying what he was "going to do." The roughing and finishing cuts and changing took eleven minutes.

Next, there were the bosses to be faced to the right thickness in relation to the sides. This time the work was driven tightly on the mandrel and the two tool-holders provided with tools ground what Bill termed "right- and left-hand parting," which came as near as anyone could suggest; these were set oversize for roughing, and one of the tool-holders so twisted that when the body of the tool nearly touched the finished side of the job it would leave nearly one thirty-second of stock to be removed in finishing; of course both tools were set to reach the mandrel simultaneously. When once set up, it proved a very quick method, as four minutes each, including changing, was the average time. Bill supposed that the bosses would have the finishing cut taken in the same way, but Mr. Steelworth said that for this job it would be better to finish them on the drill press. Here the table was nicely cleaned and two parallels clamped on it so the work could lie on its finished sides and be clear of the table. A counterbore was put in the chuck and the stop collar set so as to face the boss to the exact height. Bill was instructed to let the counterbore make two or three revolutions after the collar reached the stop so as to put a nice bright finish on the boss, but not to leave it running longer than that, as it would tend to dull the cutting edges. By having the box of unfinished pieces on the left and moving from left to right, Bill was able to change and face at the rate of one per minute, or two minutes for the two bosses.

Next there was a hole to drill and tap. For this Mr. Steelworth picked up a three-jaw lathe chuck which he placed on the drill press table. In this he clamped the casting so that the hole to be tapped would come about central with the hole through the chuck body, which was carefully located under the center of the drill chuck and clamped there. Then he took an old broken drill stub which he carefully ground and also thinned the point, there being enough twist left to get

the chips out before the drill went through. This was placed in the drill chuck, and the drill press head moved down until the drill could only be lifted high enough to clear the work when it was changed. While this was being done, Mr. Steelworth had set Jimmie at work to roughly grind the castings where the drill would enter, as the place could be easily reached by the emery wheel. Mr. Steelworth said it was better to grind off the scale in this case than to have to grind the drill too frequently; besides it would allow the drilling to be done at a much higher speed than if it had to drill through the scale first, and it would not pay to keep changing the speed on this short hole. Jimmie ground four per minute and Bill drilled them at one per minute, using the power feed which Mr. Steelworth insisted upon, not because it was quicker, but because it was sure to keep the drill under a good cut all the time, and not let it scrape round without cutting and grind off the edge.

The superintendent came along at this time and nearly had a fit when he saw the drilling layout; he politely asked Mr. Steelworth what was the matter with the drilling jig he had had specially made for this operation and which cost over $50.00. Mr. Steelworth said that there were three things about it that made it an unprofitable tool; first, the hinged cover was tightened by two swing bolts with wing nuts which meant six actions in changing pieces, and the drill had to be raised nearly a foot more than necessary to let the lid open up or else the jig had to be pulled to one side and then located again; second, the casting was located on the bottom of the jig, and while there was a fairly large opening in the base it was not large enough for all the chips, and they would get onto the locating surface when the job was changed; thus the man would have to be constantly cleaning the jig which would use up quite a little time; and third, the jig was absolutely unnecessary, anyhow, as the three-jaw lathe chuck located and held this particular piece better than any jig, and it was only necessary to swing the wrench handle one-third turn to open the jaws enough to release the job, which meant only two short actions to change jobs. The very construction of the three-jaw chuck meant freedom from chips and chip troubles; the drill did not need to be raised much over an inch to change jobs; and the stub drill and close drill head meant that the hole would be drilled well within the requirements of the work. The superintendent passed along and thought that perhaps after all the jig and fixture craze is in many instances overdone.

Bill told Mr. Steelworth that they had always tapped the hole by hand, as it did not take long to catch the piece in the vise and run the tap through, and it saved the time for clamping in the jig, the broken taps, and backing the tap out. He also wished to point out that the wrong size drill had been used for the hole; why, it was almost a thirty-second larger than the size called for in the table, and he pointed out the "diameter at root of thread" in his pocket-book. This seemed to squelch Mr. Steelworth, for he meekly asked for the tap and a socket wrench to loosely fit it. Bill knew he meant "tap wrench," but he brought a "socket" and grinned as he waited around. Mr. Steelworth certainly was completely tangled up by now, for instead of putting the work in the vise he put the socket wrench there, and then, apparently not knowing what to do, he picked up a hack-saw and deliberately sawed the "socket" off. He then put this in the drill chuck, and, slowing the drill press down, he put the tap in the square hole and held it there while he brought the drill head down and followed the tap right through the casting that had been left in the lathe chuck. Just before it dropped through the hole, he placed his hand under the table and caught it. One minute each was ample time for tapping, and Bill never mentioned hand tapping again. The pieces were now finished, the actual working time on each being twenty-eight and a quarter minutes. Mr. Steelworth asked Bill if he could keep on making them at this rate, and Bill said if things went along as smooth as they had that afternoon he was sure he could, but he never knew a set of castings to be cast so near, machine so easy, and work along with so little trouble as this lot. Mr Steelworth said he did not think there would be any more trouble with hard or sandy castings; however, he made the time rate thirty-five minutes each, which enabled Bill to earn more money in the next eighteen months than he ever had before.

The boss and the superintendent were both in the private office waiting, for it was now nearly an hour after quitting time. The superintendent had told the boss the surprising news that ten castings had been put through that afternoon, and how he had secretly taken one and carefully measured it up and found it extremely accurate and nicely finished. When Mr. Steelworth came in, he was received with a smile. The boss spoke first:

"How long do you find it will take to machine those castings?"

"Your man Bill will gladly take them on piecework at thirty-five minutes each."

"I am real glad to hear that, as it will change thousands of dollars loss into thousands of dollars profit. But Bill must have had a great change of ideas this afternoon, for this morning he said no man could make them under two hours each."

"Well I should say Bill was right when working under the handicap that he has been."

"Mr. Steelworth, you would do myself and my superintendent a great favor if you will explain what you found wrong with our method of getting those castings machined, for it seemed to us to be the only right way, and surely our method of finishing each is standard practice."

"I know nothing about 'standard practice.' The failure with your method was that not enough attention had been given to details—the little things. The castings were made from wooden patterns with loose bosses, the patterns had warped, loosened up a little at the joints, and the loose bosses kept getting sand under them with the result that the castings were crooked and had tilted bosses. The chuck jaws would always pull the boss straight and throw the edge of the casting out, so the man had to put wedge pieces under half the bosses to make the casting run nearly true. Then the molds were faced, and while the castings were good looking, they had a chilled scale that took the edge off the tool in one cut, even running at the lowest speed. Then the man had to carefully caliper to get the sizes; all this measurement had to be repeated for each piece, as he changed tools every time. Besides this, he fetched the castings from the 'pile' four or five at a time, which meant many trips; he kept them on the floor near the lathe and had to stoop to pick up each one; every one as it was finished on the lathe was carried over to the drill press and placed on the floor near it. The lathe tools were placed on the lathe tool stand and mixed with the others, thus taking a little extra time to pick them out again, the drilling was done onto the hard scale, the drill was too small for tapping in cast iron, and the tapping was done by hand, it being necessary to change the taps in tapping on account of the small hole; in fact it was a minute here, a few seconds there, and a continual waste of time throughout the whole operation. This combined with the attempt to apply turret lathe methods to a common engine lathe on a job that was not suitable, all helped to consume over two hours on a half-hour job. All I have done has been to attend to the little details that often seem to be too small to be worth paying any attention to."

Both the boss and the superintendent said it was absurdly simple, but it had never been so thoroughly brought home to them before that the minute here, the second there, the short trips across the shop for wrenches and the "hunting" for tools made all the difference between success and failure. They were extremely grateful to Mr. Steelworth and the boss never asked him how much his services were but passed him a check that was over twice the amount he intended to ask.

* * *

The progress of aeronautics is indicated by the fact that the aviation department of the Motor Supply Co., Ltd., of London, England, has published a catalogue of aeroplanes containing full description and prices. The Bleriot monoplane can be had for about $2,500, and a Farman biplane for from $4,200 to $5,500, the price varying considerably according to the engines provided. The Santos-Dumont monoplane may be bought for a mere $1,500, while the Wright machine commands a price of from $5,500 to $6,000.

A FORMED TOOL POST AND A RECESSING TOOL FOR SCREW MACHINE WORK

In Figs. 1 and 2 are shown a couple of screw machine tools which have been found to be very convenient in screw machine work by the Colburn Machine Tool Co., of Franklin, Pa.

The first of these is a recessing tool of simple but rigid construction. The body of the tool comprises a shank, fitting the hole in the turret, and a head having a T-slot milled through it, to form ways for the slide carrying the boring tool which is to do the recessing. This slide is operated through a small movement by means of the handle shown. The handle is screwed into a plunger fitting a hole in the shank, and having an eccentric diameter at its outer end fitting a cross-slot in the tool-slide. By this means the rocking of the handle gives the

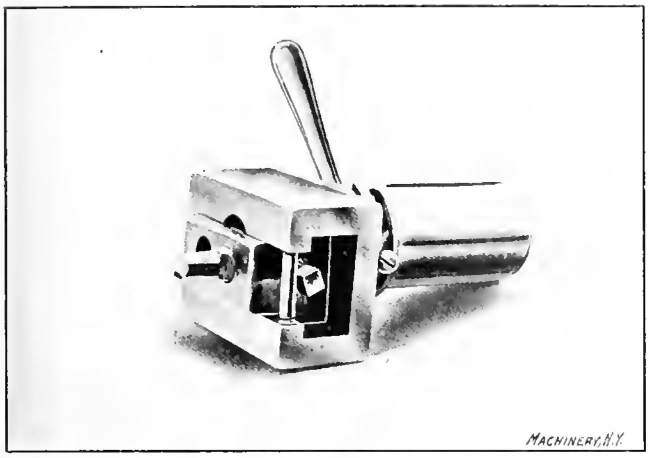

Fig. 1. A Convenient Recessing Tool for Screw Machine Work

desired movement to the tool. To limit this movement in the outward direction, to give a desired depth of recess, a slotted circular stop is provided, adjustably clamped to the side of the shank, as shown, for the handle to strike against. By adjusting this up or down, the depth of recess is changed to suit.

The T-slot in the head for the tool-block is strengthened by screws passing through from one side to the other, one of which can be seen at the front. Two holes are provided for the boring tool with which the recessing is done, thus increasing the diameter range of the device; this range is for diameters from 0 to 2½ inches. The tool is held in place in the

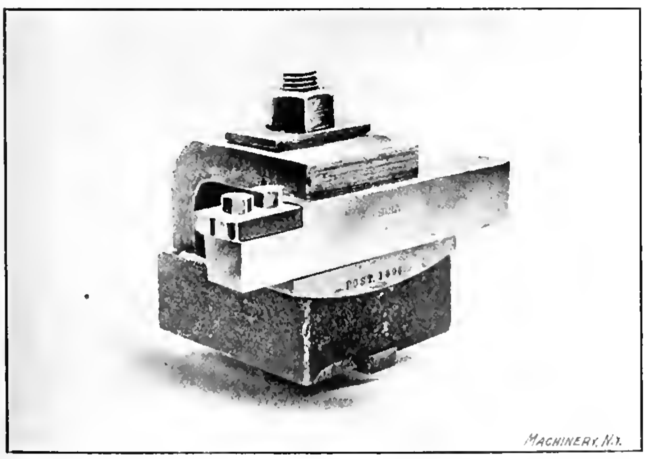

Fig. 2. Separate Blade Formed Tool, with Open Faced, Rocking Holder

socket by the set-screw shown, which is screwed into the other end of the tool-block when the other hole is used.

In Fig. 2 is shown a formed tool and holder of considerable interest. This firm follows the practice, on ordinary work, of making formed tools for use in the screw machine out of comparatively thin plates of tool steel, screwed onto a soft steel holder or shank. This method greatly reduces the amount of costly tool steel used. It is also quicker and easier to produce the desired outline on a thin blade, than it is on the end of a large tool-block of solid stock.

The formed tool-holder permits rocking the tool-blade up or down to get the proper center distance, and in addition has the advantage of holding it in such a way that it may be operated close up to the face of the chuck, as it is of the open-faced type.

The shank of the formed tool is set on a circular rocker, as shown, of a type similar to that used for the ordinary tool-post. The strap by which it is clamped is bent down at the rear end to rest on the bottom of the tool-block. The bearing at this point is also circular, on a radius struck from the same center line as that of the rocker under the tool. Furthermore, the rectangular washer used under the nut on the clamping bolt, for drawing down the strap against the tool, is seated in a similar cylindrical surface in the top of the strap, turned out to a radius from the same center line. It will thus be seen that, by loosening the clamping nut slightly, the tool rocker and strap may all be swung one way or the other, to raise or lower the point of the tool, without disturbing their bearings on the tool-block, or the bearing of the washer on the top of the strap.

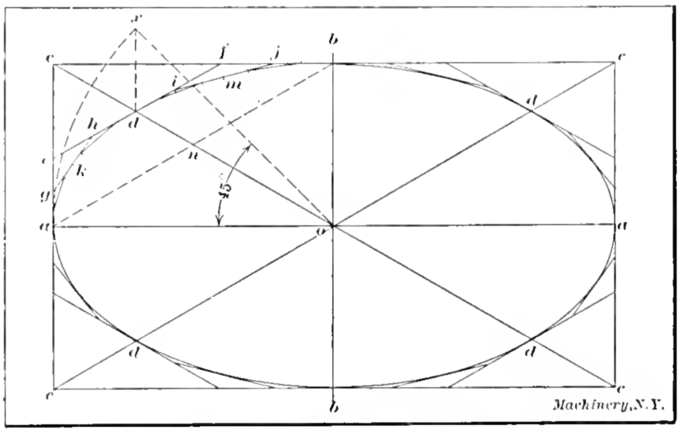
SIMPLE METHOD OF DRAWING AN ELLIPSE

In the February 24 issue of the *Engineering News*, Mr. G. W. Colles gives a method for drawing ellipses which is very simple and convenient, and which, therefore, will undoubtedly be of interest to draftsmen and designers in general. Most methods only give points upon the curve, ignoring the fact that the *direction* of the curve at the point is fully as important as the point itself. The present method is based on the fact that every ellipse may be considered a strained circle, that is, one which is distorted in one or two directions proportionately at all points. The accompanying illustration



A Simple and Convenient Method of Drawing an Ellipse

shows the method applied. Lines *aoa* and *bob* are the axes, intersecting at *o*. Upon these construct the rectangle *cccc* within which the ellipse is to be inscribed. Draw the diagonals *cc*. Draw *ox* at 45 degrees to axis *aa*, making it equal to *ao*, and drop a line *xd* perpendicular to the axis *aoa*, intersecting *oc* at *d*, which is a point upon the ellipse, and the tangent *edf* is drawn parallel to *coc*. In small ellipses, the three points and tangent on each quadrant will be sufficient to enable the ellipse to be constructed satisfactorily, but for greater exactness bisect *ae* and *ed* at *g* and *h*, and *df* and *fb* at *i* and *j*; then the lines *gh* and *ij* will be tangent to the ellipse, and will practically draw the curve, but if this is still insufficient we may bisect *gh* at *k* and *ij* at *m* and again bisect *ag*, *gk*, *kh*, *hd*, *di*, *im*, *mj* and *jb*, joining the points of bisection to give further tangents to the curve.

* * *

According to a report from Consul Albert Halstead of Birmingham, a patent for improvements in typewriting machines owned by the Yost Writing Machine Co., of New York, has been revoked under the new British patents law. Not only was the patent revoked, but the company was ordered to pay the cost of the British applicant for the revocation, this cost amounting to more than $150. Under these conditions it is advisable for inventors and firms contemplating to secure patents in Great Britain when they do not intend to manufacture in that country, either to refrain from obtaining patents, or to be sure to confer the rights of manufacture upon some firm which will manufacture the articles in the United Kingdom.

DESIGN—CONSTRUCTION—OPERATION

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS

49-55 LAFAYETTE STREET, CORNER OF LEONARD
NEW YORK CITY

Alexander Luchers, President and Treasurer
Matthew J. O'Neill, Secretary

Fred E. Rogers, Editor
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Ethan Viall,
Associate Editors.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on. All copy must reach us by the 5th of the month preceding publication.

MAY, 1910

PAID CIRCULATION FOR APRIL, 1910, 26,453 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 700 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 300 pages a year of additional matter, and forty-eight 6 x 9 Data Sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. The Railway Edition, $2.00 a year, is a special edition including a variety of matter for railway shop work—same size as Engineering and same number of Data Sheets.

MONTHLIES

More than seventy-five per cent of the readers in the machinery industry in this country are readers of monthlies. The published figures of the two leading journals in that industry show their aggregate domestic circulation to be about 56,000, of which some 43,000 is monthly; and these figures do not take into account the circulation of the other monthlies.

There must be a reason for this preponderance in favor of the monthly, and the reason is that the great majority of mechanical readers obtain all the current information they have time to digest, in a monthly at the minimum cost and in the most convenient form.

These figures are not used to boost MACHINERY any more than the four other monthlies; nor to disparage the weeklies. Both are valuable, both are needed; the weekly for the commercial end of the business where the news and markets are required, the monthly for the mechanical end where practical information is essential—and everyone knows that such matter does not lose value by being published monthly.

* * *

FURNISH PLENTY OF CLAMPING DEVICES

Too much time is lost in the average machine shop "hunting" for suitable clamps, straps and screw-jacks, for fastening work to the faceplate of a lathe or the table of a planer or shaper. Unfortunately many superintendents have not yet realized the necessity for providing an adequate supply of these devices, which, though simple, are of the highest importance in turning out first-class work. In the interest of economy every shop should be equipped with a complete collection of such devices; a convenient central place should be provided for keeping them, and each man should be required to return them to that place after use. On many classes of work more time is lost trying to find suitable tools of this kind than is used in the actual performance of the machine work; and on account of inferior clamping and supporting devices, the work itself is often not as satisfactory when completed as it would have been if proper clamping facilities had been provided.

VARIATION IN GAS ENGINE EFFICIENCY

No doubt the article on the location of the gas engine igniter by Mr. Miller in the April number was read with interest—and some disappointment by those who expected to obtain definite information on this important subject. They learned, however—if not already aware of it—that the location of the igniter depends on a number of variable factors, and under common conditions no definite rule can be laid down for its location which will give the maximum efficiency for a certain type of engine. In fact it appears that the position of the igniter may often be varied in individual engines with resulting increase or decrease of efficiency. It also appears from our correspondence with the author that the horsepower developed by two engines of the same bore and stroke may vary considerably; for example, a nominal twenty-horsepower model developed from 17 to 22 horsepower in individual engines. The reason for this variation, according to a statement received from the author, is the position of the inlet valve, shape of inlet valve, size of cored passage at inlet valve, and particularly the shape of cored passages. All these factors affect the flow of the incoming charge. The author writes:

> We were building gasoline engines in a certain shop, 8 inches cylinder bore, 16 inches stroke. One of these engines under brake test developed nearly 17 horsepower, while another made from the same drawings and patterns, exactly alike in all details, developed nearly 22 horsepower. These engines generally varied from 19 to 21 horsepower. A change in the position of the igniter on one of these engines resulted in its developing 24.4 horsepower. I claim from experience gained in building hundreds of these engines that the variation in horsepower is directly traceable to the cored passages of these engines.

If this experience proves anything, it shows conclusively the need of a reform in certain practices in gas engine construction. It shows the need of standardizing all parts and securing uniformity in sizes of passages. Perhaps this means more machine work and greater cost of construction, but surely such great variations in power and efficiency are not allowable in good practice. No doubt much of the inefficiency of gas engine performance, and resulting dissatisfaction, has been caused by variations in castings that were assembled with no machine work done where it ought to have been done, if the highest efficiency and uniform power rating were to be secured.

THE USE OF THE SECANT

There are eight regularly named trigonometrical functions, of which four (the sine, cosine, tangent and cotangent), are by far the most extensively used. In this country, however, we make considerable use of another pair of functions, the secant and cosecant. The secant is, of course, the reciprocal of the cosine. Tables for these functions are commonly given and are in everyday use here in America. In Europe the student is taught what they are, but no tables of secants and cosecants are published, and practical use is never made of them.

The reason for the difference in practice is probably a deep-seated one. The secant is useful in that it avoids, in numberless instances, the division of a simple integral number by an unwieldy decimal, permitting, instead, the simpler multiplication of the decimal by an integer. This refers, of course, to the use of natural functions only. With logarithmic functions there is not the same difference in favor of the secant, so the person who uses logarithms has no use for it. There are thousands of common everyday American mechanics using natural functions who have gone no further in their studies. For these thousands, tables of secants have been prepared, and rules and formulas printed which call for the use of these tables.

In European countries, on the other hand, the common everyday workman knows little, and cares less, about trigonometry. It is studied by comparatively few except those in the schools who take courses which include trigonometry, logarithms, and mathematical branches even more advanced. It is, therefore, on the whole a hopeful sign that the secant survives among us, when it has become in Europe of little more use than the vermiform appendix.

THE CANCELLATION OF MACHINE TOOL ORDERS

A subject which vitally concerns every machine tool builder — the cancellation of orders without forfeit — is to be discussed at the coming convention of the National Machine Tool Builders' Association at Rochester, N. Y. The difficulties of discontinuing this practice are obvious, and while it is doubtful if the discussion results in a practicable method of correcting the abuse, it will serve to focus the general attention of manufacturers on a practice which is not tolerated in any other industry, and it may result in some modifications of the present custom which will help the situation. Machine tool builders usually enjoy cordial relations with their customers and most of them will hesitate to adopt rigid conditions of sale that will offend good friends, and which if rigidly adhered to will allow many sales to pass to competitors who are not so scrupulous. But the practice of accepting orders from dealers and users for machines to be delivered several months ahead is often a sort of gamble in which all the risks are assumed by the manufacturer; because if any sudden drop in business takes place the dealers have little hesitation in cancelling the orders and throwing all the loss on the manufacturer; and the buyer is not always to blame, because he often simply accepts the terms urged on him by the salesman.

When orders are placed for machine tools they call for money to be invested in material, sometimes for equipment to be purchased, for the organization to be kept up to a certain strength and for outlay in various directions to make deliveries as promised; and the cancellation of such orders should be penalized in some reasonable proportion to the value of the machines. Machine tool builders who order pig iron for castings must take the iron no matter what changes have taken place in manufacturing conditions or in price in the interval before delivery. No cancellations are permitted; and so far as practicable buyers of machinery should be held to similar terms.

* * *

INDUSTRIAL EDUCATION AND THE SALES DEPARTMENT

Few people in the selling department realize the importance to them of industrial education. It doesn't attract them because it apparently doesn't touch their work; but they forget that mechanical ability in the men who construct the machines is as necessary to their sale as the foundation is to the building in which the selling department has an office. Imagine one selling organization representing a concern whose product is turned out by mechanics of the highest skill; and another representing a plant manned by "floaters" and half-educated machinists, with a superintendent and foreman of the same character.

Which organization would *you* prefer to represent, and why?

Perhaps you, who read this, are one of the big manufacturers who have given time and money to improving conditions which every thinking man sees will determine the future of our machinery industry; perhaps you are in the selling end of the business with only a slight interest in the manufacturing part. We say to you that whether you occupy a leading or a minor position, your future is linked with the prosperity of the machinery industry, and *that* is based on the mechanical ability of the workmen.

The reading of a good mechanical journal is an essential part of a mechanical education; but that isn't enough, and MACHINERY for several years has been building up a system for supplying inexpensive, but practical and authentic, material to mechanics who seek to educate themselves, and as a help to the various agencies which are pushing industrial education. We have at present about $60,000 worth of such material, and during the past year have sent out over 2,000,000 pieces of printed matter of an educational character. There are nearly 500,000 more-or-less skilled men connected with the machinery industry, and it takes a lot of material, systematically distributed, to reach them all, even occasionally. If you are taking no part in the work for industrial education, write us and we will suggest how you can help.

This isn't a money-making proposition.

MACHINING A GRINDER COLUMN AND KNEE

By ETHAN VIALL.*

In the manufacture of a universal grinder, the Thompson Grinder Co., Springfield, Ohio, uses several interesting jigs and fixtures. The center columns, the shape of which is shown in Fig. 1, are first strapped, small end down, to an angle-plate on a boring mill and the large end is counterbored as at *A*; the casting is then reversed and set over a centering base-plug on the boring mill table, and the center hole *B* is bored out. From here the casting goes to a Fosdick radial drill, Fig. 3, where the two large holes in the base, one of which is for the elevating screw, are drilled and reamed. The jig used is shown more plainly in Fig. 4. The casting is centered by the counterbored base which fits over the turned bosses on the jig spider.

The planing fixture used to hold the column while finishing the V's, is as simple, yet as complete and mechanically

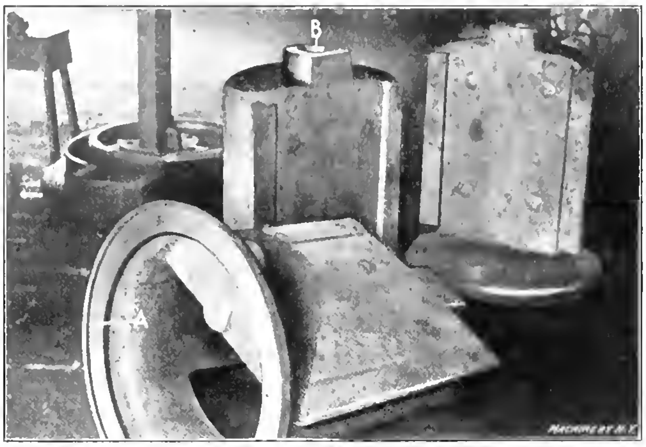

Fig. 1. Partly Machined Grinder Column Castings

correct, as it is possible to make it. The casting itself is placed on what is practically a mandrel, consisting of part *A* (Fig. 2), which passes through the bored center hole of the column, and a flange *B*, turned to fit the counterbore in the base of the column. The whole fixture is mounted on two V's and a base, and is so arranged as to be easily indexed and locked in the desired position. The casting is located on the mandrel in the correct position relative to the index holes in the flange, by means of the plug *D*, which enters the reamed elevating screw hole, previously mentioned. The first posi-

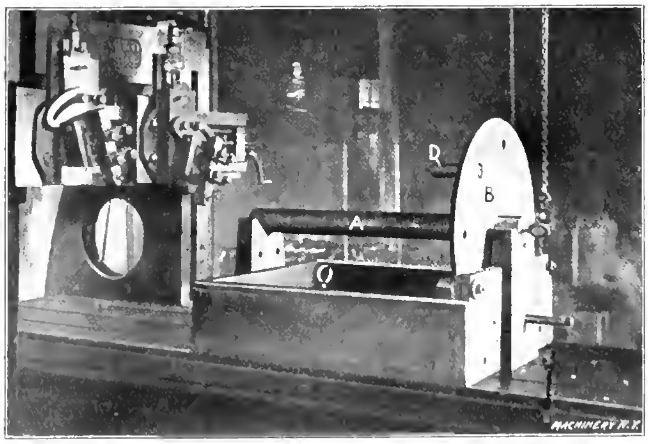

Fig. 2. Fixture used for Planing V's on Column

tion of the casting is shown in Fig. 5, where it is ready to have the flat sides of the V's planed. After this operation the jig is indexed, as in Fig. 6, by using the pin *A*; the other side of one V is then planed, after which the jig is indexed to the opposite position and the other V finished.

There are many advantages in a fixture of this kind, not the least of which is the ease with which the different planing positions are obtained, and the proper relation of the V's to the center of the column.

The knees fitting the columns are planed in gangs, using

* Associate Editor of MACHINERY.

the jack shown at *A*, Fig. 7. The first position of the knee is shown at *B*. After the dovetail ways are finished, they are used to locate the casting on the special angle-plate *A*, Fig. 8, and the pads *B* and *C* are finished.

OLD TAPER TURNING ATTACHMENT

A. J. Leatherman, 21 College St., Dayton, Ohio, has sent us a clipping from the *Scientific American*, November 29, 1851, illustrating and describing an engine lathe, built by J. D. White, Hartford, Conn., having a taper attachment. A patent was granted to Mr. White for the invention May 21, 1850. The attachment consisted of a guide bar mounted on the lathe bed top in front. This guide bar was adjustable to vary the angle of taper, and had a rack cut on the front surface. Just how it controlled the action of the cross-slide is not clearly shown in the illustration and description, but apparently the cross-slide was shifted with the bar, which, of course, would throw it out of square with the spindle and make it useless for squaring up when the lathe was set for taper turning. It would be interesting to learn if one of these lathes is still in use.

ESTABLISHING A COMMERCIAL STANDARD FOR PIPE FITTINGS*

By F. W. BARROWS†

There is no doubt that the early attempts to produce salable fittings, confined as they must have been to the filling of orders for a few of the smaller sizes, and to be used for what would now be considered low pressures only, were less hampered by competition, and the manufacturer easily produced goods which not only satisfied the customer, but also yielded a good profit. Prices were higher, and he was not obliged to count expenses so carefully. Later, competition for orders, to be obtained only at lower prices, reduced these profits; and to save himself, the manufacturer must cut down the cost. Because of the small production resulting from reduced sales, the manufacturer did not feel able to invest more capital in improved facilities, thus reducing labor cost, so a quicker and more effective method was readily found in the reduction of weight; thus saving the profit by the saving in raw material.

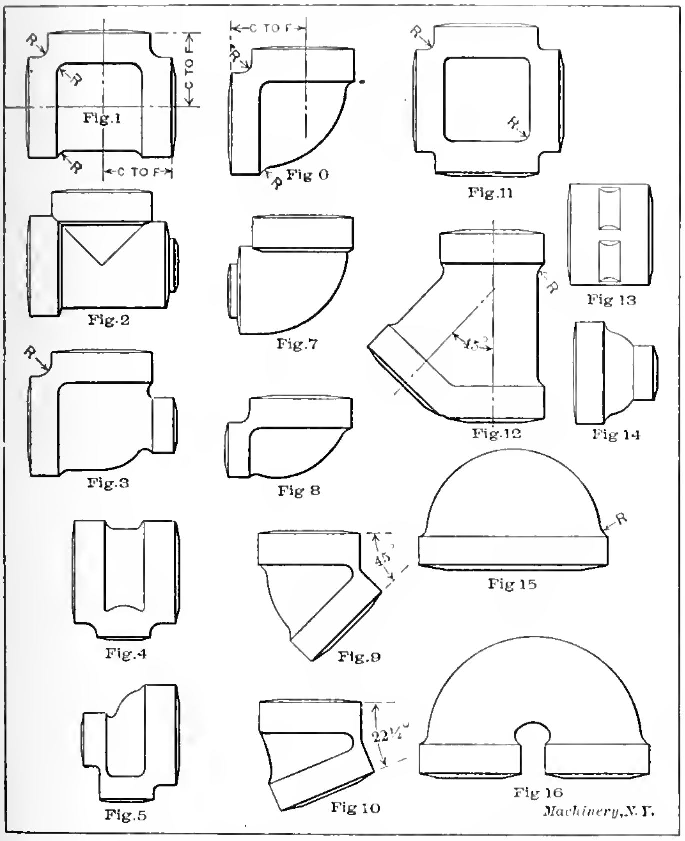

Fig. 1. 1-inch Tee. A Straight Fitting. Fig. 2. 1 x 1 2 x 1-inch Tee. Old Style Reducing Tee, Reducing on Run only. Fig. 3. 1 x 1/2 x 1-inch Tee. New Style Reducing Tee, Reducing on Run only. Fig. 4. 1 x 1 2-inch Tee A Reducing Fitting, Reducing on Branch only. Fig. 5. 1 x 1 2 x 1 2-inch Tee. New Style Reducing Tee, Reducing on both Run and Branch. Fig 6. 1-inch Ell. A Straight Fitting; sometimes called an Eighth-bend. Fig 10. 1-inch, 22 1 2 degree Ell. A Straight Fitting, sometimes called a Sixteenth-bend. Fig. 11. 1-inch Cross. A Straight Fitting. Fig. 12. 1-inch, 45 degree Wye. A Straight Fitting. Fig. 13. 1-inch Coupling. A Straight Fitting. Fig 14. 1 x 1 2-inch Coupling. A Reducing Fitting; commonly called a Reducer. Fig 15. 1-inch Return Bend. A Straight Fitting; called a Close Return Bend Fig 16 1-inch Return Bend. A Straight Fitting; called an Open Return Bend

This change in weight was the more willingly made, because it gave an opportunity to improve the pattern and core-box; heretofore, they had been all that could be desired, but now they were discovered to be entirely inadequate. The old outfit consisted of a single pattern and a half box, and the increasing demand for the goods made more patterns necessary; perhaps enough loose patterns were made to fill the flask, then the loose patterns were gated together and a complete core-box was made; the gated pattern and the solid core marking the first step towards reducing the labor cost.

These gated patterns, if for fittings made up of straight pipes, like tees, Figs. 1 to 5, crosses, Fig. 11, laterals, Fig. 12, or couplings, Figs. 13 and 14, were usually made of wood; if for elbows, Figs. 6 to 10, or return bends, Figs. 15 and 16, they were made of brass. The core-box, first made of wood, was quickly worn out, and was replaced by one of cast iron, cut by the machinist or toolmaker from the solid stock. The metal pattern-maker's work, at this time, was applicable only to soft metals, white metal and then brass. Later on the boxes as well as the patterns were cast from wood patterns, first in brass, when it was found that the brass boxes did not retain their roundness, the ductile metal being quickly hammered out of shape by the core-maker, and then in iron, which was a great improvement; later when the master patterns for these boxes were successfully made of plaster, it was thought no further improvement could be desired. Here the pattern improvements rested for some time and the efforts to reduce cost were concentrated upon perfecting the machines for tapping, and on increasing the output.

Automatic machines had long been used for the tapping, and they were constantly being improved. When a greater output was found necessary, additional machines were made, in which were embodied the changes found desirable. The first machine designed to tap all sizes was necessarily made heavy enough for the biggest fitting, with two or three changes of speed to accommodate the various sizes. This was further complicated by the changes made to suit the different pitches of thread, and when the need of more machines became apparent, one of the first improvements suggested was to increase the output by restricting the machine to fewer sizes, thus making its speed constant. It was still found necessary to provide for change of pitch; first, because of the constantly increasing number of reducing fittings (some idea of the variety of sizes may be had from the statement that at least one firm was prepared to furnish any combination of sizes possible, from four-inch down to quarter-inch, in either tees, crosses or 90-degree elbows) for all of which the new machines must be adapted; and later to suit the different standards, the Briggs, the English, the fine Casing threads used in oil and gas wells, and more rarely, fine threads for brass tubing; some small fittings were even tapped to fit standard bolt threads.

This change of the machine to suit different pitches, was very much simplified by making the lead-screw a continuation of the tapping spindle, and removable. Then when a change was called for, a lead-screw and nut, of the desired pitch, could be substituted for the regular Briggs' standard screw. As the machine reversed itself at a fixed point, no change of speed was necessary to accommodate the change of pitch. The improved machines soon caught up with the foundry. With the old machines, the foundry had easily kept ahead of the tapping-room, and thus escaped all complaints based on delay in getting out orders. Now the tapping-room proceeded to roll up its sleeves and show the foundry how to rush out the goods. To increase the foundry output, further improvements in pattern outfit were then found necessary, and how this was accomplished may be seen in what follows.

A one-inch ell was made from a gate of eight brass patterns (see Fig. 17), the molder putting out from 120 to 130 flasks per day; but even with this production, greater than ever before, the firm was unable to keep up with the orders, and it was suggested that this pattern be put on a "squeezer"; this was the only form of molding machine then in common use, and immediately the question came up as to what should be done about flasks. Let it be explained that the firm used the same kind of machines in the brass foundry, and had many of the patterns—made of brass for brass goods—mounted on stripping plates. The flasks used in the brass foundry were of iron, and were interchangeable as regards dowels; but the brass foundry ran three heats each day and one man or job required not more than twenty flasks.

The firm had already tried, without success, to use snap flasks on these molding machines (the writer does not know why it failed), and it seemed for a time, as though the use of stripping plates in the iron foundry depended on the cost of the flasks. The one-inch ell would require not less than 125 flasks, and we were hopeful of getting 150 molds a day. As the iron foundry took but one heat a day, it would therefore be necessary to provide 150 flasks, if our expectations were to be realized. Again, all the brass foundry patterns were fitted to one of two standard sizes of flasks; as a consequence, the molder could easily be changed from one job

* See MACHINERY, November, 1909: Pipe Fittings, Theory vs. Practice in Their Manufacture.
† Address: 581 Colorado Ave., Bridgeport, Conn.

to another, without any change of bottom boards or flasks. This arrangement was entirely practicable for the brass foundry, with its comparatively small run of sizes in the work produced, but would not be economical for the iron foundry, with its much greater variety of work and sizes, where the practice had been to furnish many more sizes of (snap) flasks—in fact, almost as many sizes as there were patterns. While the work might be so arranged that the molder could continue to use the same bottom boards—*depth* of flask, or a small variation only, of its size, making this possible—he was almost sure to get a new flask with the new job, and the question of being able to store so many flasks and quickly

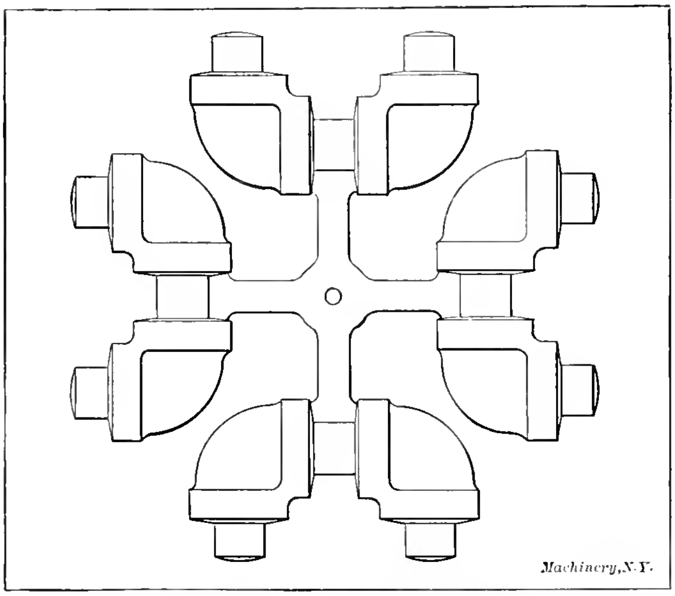

Fig. 17. Method of Gating Eight Brass Patterns

change from one size to another, threatened the success of their use. Neither was the greater cost of so many flasks to be overlooked.

Stripping plates would make cheaper help available, a fact that had already been demonstrated in the brass foundry, and as we fondly hoped, would also increase production. Both of these features would decrease cost, and therefore seemed very attractive to the firm; so it was decided to make the one-inch ell outfit and try it out with a snap flask. Taking into consideration the unskilled help we proposed to utilize, it was thought best to increase the present size of this flask and spread the patterns a little further apart, which would tend to prevent break-downs in the mold, and lessen the liability of wash by their pouring. Then it was suggested that a little more sand around the outside of the mold would make the use of bands or slips unnecessary, and the flask was still further enlarged.

The molder, like most all tradesmen, was quite conservative, and freely predicted the failure of the new pattern; but he proved to be a false prophet, for while the production went down—the result of increasing the flask size—the cost went down so much faster, that the first few days showed a saving of more than thirty per cent in molding cost, with an increasing output that promised to still further increase this saving. But in one way the molder's prophecy was verified; we had failed to increase production; in fact we had decreased it some twenty per cent, and a second set of patterns was ordered at once, as the firm could no longer afford to run the gated pattern, and this reduction of output put it still further behind its order.

The conservative molder, seeking to justify his predictions, criticised the new mold because of its, to him, unnecessary size, pronouncing it a "great big nothing," and called attention to the fact that its large size had not prevented some "run-outs." While these run-outs might well have been due to lack of skill—the new man was a laborer taken from the floor—it was thought best to use bands in the future.

Elated with the continued success of the new pattern, the molder was now in danger of becoming an extreme radical on the subject of stripping plates. He made many suggestions: the flask was too large, it took too much sand to fill it; the core-prints were too long, and the patterns could safely be placed more closely together. So a new layout, Fig. 18, was made, doubling the number of pieces, in a slightly larger flask, and shortening the core-prints. This shortening of the prints resulted finally in a reduction of core cost. Another laborer was taken from the floor gang, and given the first pattern, which had now been running some weeks; the first man who was now quite skillful, was given the new set. His first day's output beat that of the bench molder with the gated pattern, by a quarter, and reduced the cost to about one-half of what the bench molder had received.

The immediate effect of all this was a rush of work in the pattern shop, and complaints from all the rest of the factory. The stripping plates could not be gotten out fast enough; the patterns, at first made all of brass, wore out too fast, and should be made of harder metal. For this excessive wear the roughly-made molding machine was greatly responsible, the guides being very loosely fitted and thus causing rapid wear where the patterns passed through the plate when in use. Soon there was a space all around the patterns, so wide that a fin of sand would be formed on each half mold made; then when the molds were closed, these fins would be crushed together, and as the surplus sand could go nowhere else, it would be forced into the mold itself, making a very rough parting line on the castings; or perhaps the loosened sand would be washed away by the molten iron and lodge in the casting, under the core or in the top of the mold, either of these results being likely to cause its rejection by the inspector, and thus increase the percentage of bad castings far above the limit fixed by the firm. The core-prints of most patterns were too long; many of them did not match the core-box; the flask made for the first one-inch ell was too deep, and could safely be reduced, giving the molder still less sand to shovel. This question of flask size and depth, was, after some time, fixed by first allowing the necessary depth of sand for the nowel side, and then making its size as large

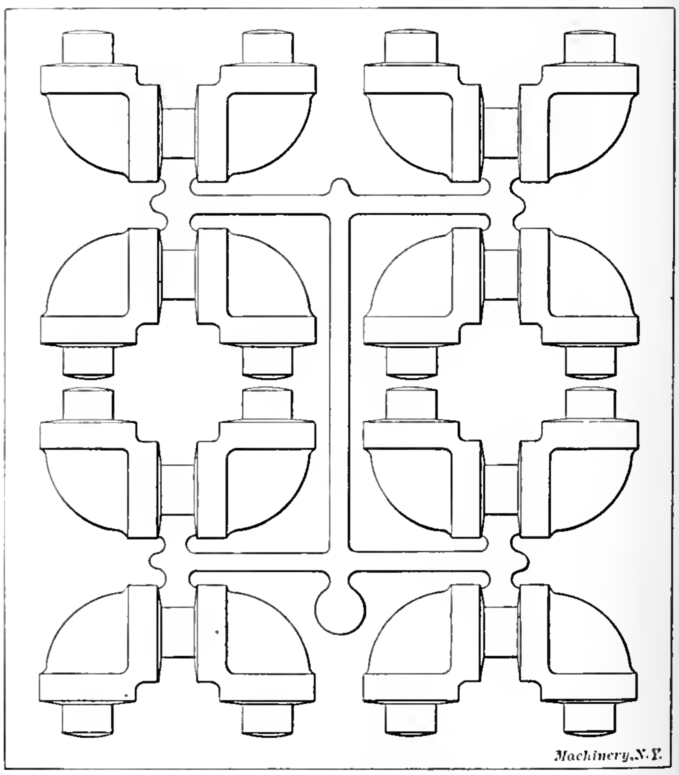

Fig. 18. Method of Gating Sixteen Patterns

as this depth of sand—and the size of the molding machine—would allow, without dropping out.

To these foundry complaints were added those from the tapping-room: such a fitting had too much stock; another wouldn't tap, *i. e.*, the hole was too large; that one was too small to clear the tap and consequently, the tap left a shoulder at the end of its run; this one couldn't be tapped through, *i. e.*, the taps would strike together if the machine allowed them to run through the thread bosses; and still another had too short a threadway.

All of these faults, it was expected, would be corrected in designing and making the new patterns; and as though the foundry complaints, supplemented by those from the tapping room, were not enough, the office added a sort of appendix by announcing that this making over of the patterns would give an excellent opportunity to grade the fittings as to weight and size. What they really had in mind was the price list, and while they did not propose to allow any additions to present weights, they were hopeful of increasing the margin on some fittings by cutting down their weight—grading, they termed it—but sad to say, this grading, like the recent tariff revision, failed to produce any noticeable change in cost.

The first visible effects of these changes were in the design,

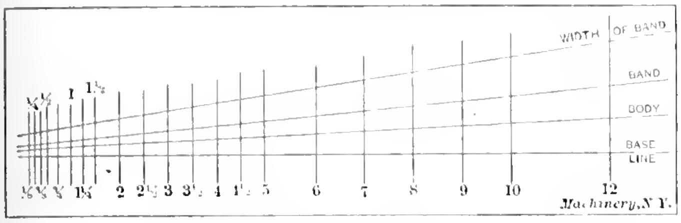

Fig. 19. First Diagram Prepared for the Design of a Graded Set of Pipe Fittings

and were most conspicuous in reducing fittings. In this designing the so-called fitting scale or diagram was used. After many talk-fests and much weighing and comparison of samples from different makers, it was decided that a set of experimental fittings, comprising tees and ells, from half-inch to twelve-inch, inclusive, should be gotten out, tested in all known ways, and criticised by all departments interested in their production. Alterations were to be made if considered advisable, and when everyone—meaning, finally, the manufacturer—was satisfied, the fittings were to be considered as standard in all respects.

To establish a temporary standard for the experimental castings, two sizes of fittings, one-inch and eight-inch, were made up, and having been corrected until their general appearance and weight were pronounced satisfactory, a diagram was drawn as shown in Fig. 19, by laying off on a base line, points through which were drawn perpendiculars marking each size of pipe. These points were spaced to correspond with variations in pipe diameter.

Having fixed, as above, on the one-inch and eight-inch sizes,

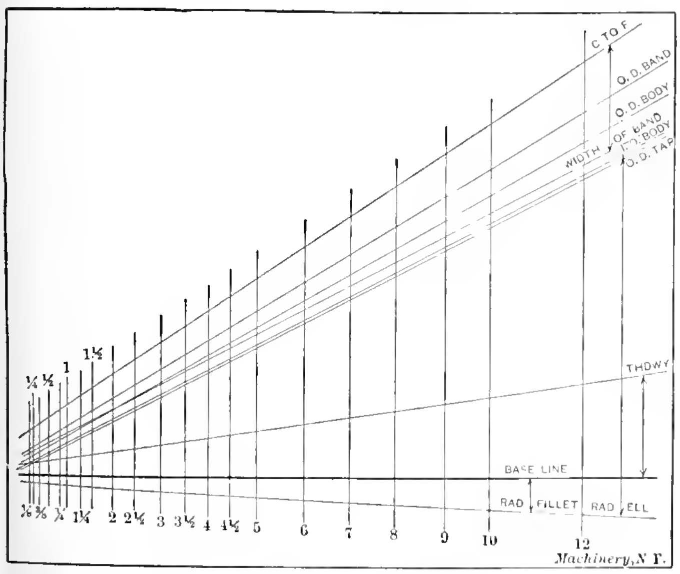

Fig. 20. Second Diagram, used for Pipe Fitting Dimensions

it was proposed to set off from the base line the dimensions of these two sizes, each on its own perpendicular; then lines were to be drawn connecting similar dimensions of the two sizes, and these lines, by crossing all perpendiculars, would fix dimensions for all sizes.

Some preliminary figuring of the thickness necessary for strength, in the different sizes of fittings, was done by using the formula $pd = 2tS$, in which

$$t = \frac{pr}{S - p},$$

p = pressure, 100 pounds per square inch,
r = outside radius of pipe = inside radius of fitting,
t = required thickness,
S = safe tensile strength of material, fixed by applying the formula $S = \frac{p(r+t)}{t}$ to the one-inch size already perfected. This gave $S = 487$, and to make even figures, the value of S was taken as 500. By the formula $t = \frac{pr}{S - p}$, the necessary thickness of the eight-inch size was found to be 0.862 inch, that of the six-inch, 0.662 inch, and of the three-inch size, 0.35 inch.

As these results were very unsatisfactory, all attempts to obtain or fix the thickness by formula were abandoned. But as all formulas for strength of pipes and cylinders fix the thickness by the diameter, other conditions being equal, the perpendiculars marking the different sizes of pipe were spaced by the normal pipe diameter, making the one-inch perpendicular the starting point.

The space between 1 and $1\frac{1}{4}$ inch was made one-quarter inch, as was also that between $1\frac{1}{4}$ and $1\frac{1}{2}$; spaces for sizes from $1\frac{1}{2}$ to 5 inches were made one-half inch; and from 5 inches up, one inch; all laid off in succession towards the right. To the left the smaller sizes were spaced, 1 inch down

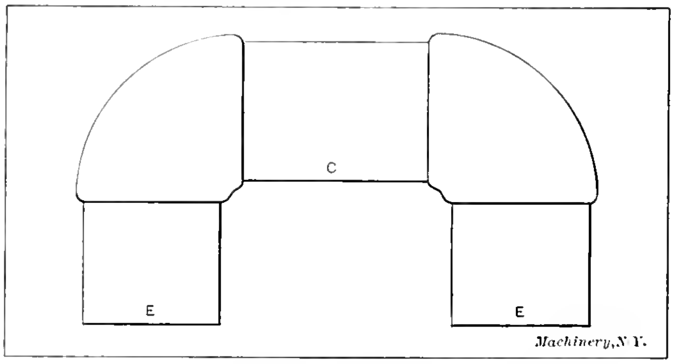

Fig. 21. Core for Ells, causing Difficulties on Account of Settling while "Green"

to $\frac{1}{2}$ inch, one-quarter inch apart, and from $\frac{1}{2}$ to $\frac{1}{8}$ inch, one-eighth inch apart.

This first diagram, Fig. 19, showed thickness at end, or "band"; thickness of body, "body"; and "width of band"; three dimensions only, all to be measured on the perpendicular for desired size of fitting, and from the base line. It was the intention of the designer to establish all other dimensions—not already fixed by usage—by the tap size. The troubles of the designer had just commenced, however, as it was soon found necessary to take into account the actual outside diameter of the pipe, at the end and after it was threaded; and then to allow some regular clearance for the tap, this clearance to increase with the pipe size. The length, which it was intended to fix by adding to the outside diameter of the tap, the regular length of thread plus three threads, to clear the "run" of the machines, was not uniform. Therefore, the first scale was discarded and a second scale, Fig. 20, was made. The base line was drawn and perpendiculars for 1 and 8-inch sizes were erected, seven inches apart, as in the first scale. On these the radius of the outside of the two pipes at the end, after threading, was laid off, and a line "O. D. tap" drawn through these points. Then perpendiculars for all sizes were erected, their positions being fixed by so placing them that the space between the base line and line "O. D. tap" equalled the outside radius of each pipe. These dimensions were Briggs' standard.

From this line, "O. D. tap," a second line, "I. D. body," was established, giving one-sixteenth clearance for radius of an 8-inch tap, and one-thirty-second for a 1-inch size. Then the thickness, fixed by the two corrected fittings, was established for all sizes by the line "O. D. body." Another line, "O. D. band," fixed this dimension, and another, "C to F" graded the length. (See Figs. 1 and 6.) "Rad. fillet" was arbitrarily fixed and applies to all dimensions marked R in the illustration of the fittings. The line marked "Rad. ell"—radius of center line of ell being understood—was drawn through points, dis-

tant from "I. D. body," a distance equal to the "I. D. body" plus the radius of the fillet, and is, therefore, the same line as that marked "Rad fillet." "Width band" explains itself and is fixed by the space between "C to F" and this line; like all other dimensions, this one can thus be taken from the base line. "THDWY," meaning length of thread, was added sometime later. A complete set of tees and ells was designed from this perfected diagram, and made up and sent to the office for inspection, each piece having its weight marked in white lead.

As a set from the old patterns, similarly marked and showing the results of competitive designing, was placed in line with the new fittings, the contrast was quite marked, and the designer of the new fittings was highly complimented upon their appearance. But when the weights were noted—the 6-inch ell, for example, was some five pounds heavier than the old fitting—all further compliments were confined strictly to the general appearance.

It was at first thought that corrections in weight—ordered at once—might be made by cutting out the excess of metal from the inside, in the space between threadways; and this was done successfully in some cases. For the 6-inch ell mentioned, this method would reduce the thickness some forty per cent, which was not to be thought of, and some other way out had to be found. The price, at the time, made it impossible to produce a set of uniformly proportioned fittings which would all sell at a profit, and much time and money was expended in the efforts to produce graded fittings. Patterns have been changed and lists corrected, until much more uniform profits are now realized, but there still remains, with some manufacturers, the tendency to reduce cost—meaning weight—that a better price may be given to secure an otherwise desirable order.

When fittings were made from a single pattern, or even when a gate of patterns was used, such changes involved a comparatively small outlay, which would be increased many fold by any change in the present costly machine patterns, and the multiple core-boxes now in quite common use; so it is quite probable that the order, if it involved a change in the pattern, would now be refused.

Other reasons for continuing the present standard in use might be given; for instance: Many special fittings were made from the regular pattern by the use of a specially constructed core-box, which added nothing to the molding cost; or they were made from a special pattern fitted, when possible, to the regular box, thus saving in cost of cores, and avoiding delay in filling orders. As any change in these special fittings could be made only by the consent of the customer, who might not object to the change in the fitting, but would always object, strenuously, to any increase of cost, it is obvious that any change of the standard fitting was the more to be avoided.

Many lines of piping are in use for high pressure (200 pounds or less) which are made up with standard weight wrought iron pipe. It is practically impossible to increase the length of thread on this pipe and still conform to the standard taper, because of its limited thickness; and the fitting manufacturers take advantage of this in producing so-called heavy fittings, which can be made to fit standard core-boxes, and be tapped with standard taps.

Because of the clearance necessary for "run of machine," in tapping, any additional length of the threadway could only be obtained by adding more length to the pattern, and as core-prints had already been reduced to the shortest possible length, a new box would also be necessary, and fewer patterns, or a larger flask must be used; more time would be taken in tapping, the standard tap—if taper—would not tap through without making the fittings larger than gage, and new taps would have to be made. Other reasons for adhering to the established standard, will suggest themselves to the practical reader, who without doubt, will admit that fittings are *strong* enough, and that changes have to do with their appearance rather than with their strength.

For some time the changes made to correct weights, or as it became the custom to say, "to grade them by the list price," were noted on the diagram; but as there seemed to be no end of such changes, and also, when molding machines came into use, as more draft was found necessary on the ends of all patterns, which made it imperative to change many boxes, because the increased length of thread could not be "tapped through" without making the fittings over-size when gaged, the scale was abandoned in favor of a list for the standard fittings; but the principle was still useful when it was desired to produce fittings adapted to some new need.

The diagram in Fig. 20 was entirely successful in producing a complete set of longturns, or water fittings, as they are sometimes called, no list of prices having been previously established for these goods.

Orders for reducing fittings, Figs. 3, 4, 5, 8, and 14, which sell at better prices, weight for weight, than straight fittings, were eagerly sought after by those makers who were fortunate in possessing machinery adapted to tapping such fittings without making separate runs for each size involved; and because it was impracticable to carry separate patterns and boxes for each of the many combinations, it was the custom to place bushings in the core-boxes, to reduce some more common size to the unusual size ordered. A disposition to accommodate the customer brought more and more orders for these goods, until the bushings used, ever increasing in number, became quite an important item in pattern outfit, and it was deemed advisable to make them interchangeable.

The first move in this direction was, necessarily, to so fix the size of all boxes that while all fittings would tap a full thread and none would have too much stock—all taps for tapping machines are arranged to ream and tap at one operation—each size must be exact, or the bushings wouldn't fit. These sizes were fixed, the smaller ones by reamers, for the iron boxes, and all were made to suit plug gages.

Then, because it had been sometimes found necessary, in making unusually great reductions, to use more than one bushing, placing them one inside of the other, the length of thread, formerly made a fixed number of threads, had to be arranged so that the use of bushings did not produce unsightly shoulders in the casting or form recesses in the core-box which must be filled up before any cores could be made. The new lengths were fixed by laying down the core sizes, in parallel lines, across which other lines were drawn for outside and inside ends of the bushings. An allowance of three degrees was made at the outside end for draft, and a line drawn for the inside end which would give the nearest average of original lengths of thread. As this involved but slight changes in length no new taps were required; and because the lengths now varied with each size of pipe and not by pitch of thread only, the change gave more uniform results when the "C to F" dimensions were to be fixed.

The cost of cores had made it necessary to reduce the length of the prints to a minimum, fixed by actual needs; and they must also be round—the reamers corrected this—to avoid the removal of excessive stock, a cause, in small sizes, of the breaking of many taps; they must also fit the pattern prints; if too large, a "crush" would result, or in extreme cases, the cope would not close down, producing "plated" molds. On the other hand, if they were too small, the core would "float," and the hole in the casting would be out of center, and this would cause "flat" threads; then, because the taps—usually fitted somewhat loosely in tapping machine spindles, to prevent breakage—tried to follow the hole, "crooked" fittings, as those tapped out of line were called, would be produced.

It is impossible to avoid slight variations in size of cores, caused by wear of the box, or by changes in core after making and in process of drying. In such as are made solid, the closing of the box affects the size; and because these solid cores are dried standing on end of prints, the weight, which limits the size that can be successfully made solid, causes the core to settle down, while it is still "green," and enlarges the ends which support it. This weight causes ell cores, Fig. 21, to settle down at the unsupported center, *C*; and while the weight enlarges the ends, *EE*, the sagging of the center spreads the ends apart; this is another cause of "crushing."

Many attempts to so arrange patterns and boxes that these faults might be overcome resulted finally in the production of a second set of gages, to be used in sizing prints, and made with a gradually increasing difference, as the sizes grew larger, between diameter of core-box gage and that of the print gage.

In some cases an allowance was made, in ell cores, for the spreading, by making the distance between the centers of the pattern prints slightly larger than that between the centers of the core prints, or rather, of the core-box.

In the tapping-room many castings were cracked in tapping, a fault not always discovered by the inspector, and therefore the cause of many complaints from customers. It is very easy to crack a pipe fitting on its parting line, as in nearly all fittings the partings of core-box and pattern are both in the same plane, making lines more or less pronounced the whole length of the casting. These lines weaken the casting just the same as scoring or nicking with a file would weaken it; therefore the dowels of both box and flask should be nicely fitted, and kept so. Some patterns were strengthened at the points marked *R* to prevent this cracking, and care was taken in fitting all false jaws in which the castings were held by the chuck while being tapped.

Twenty-five years ago seventy pounds steam pressure was considered high enough for all ordinary purposes and fittings carrying steam at one hundred pounds were few; now one hundred is about the minimum, and even this is endured, in many cases, only because the boiler inspector could not be persuaded to further raise the limit; and the manufacturer, needing more power and too poor to install an entirely new power plant, was obliged to help out this pressure by increasing the speed of the old engine, designed for seventy pounds and seventy revolutions, up to one hundred revolutions. This was all that could be coaxed from the old Corliss gear, and even at this high speed and increased pressure, steam often followed the whole length of stroke, repairs became more frequently necessary and weak spots developed in all steam lines. This brings us back to the necessity for *better* fittings, not heavier, perhaps, for a great deal *can* be done in the matter of threading; both pipe and fittings could be much improved in this respect.

The die for threading is quite commonly made too thin to cut the Briggs' standard length of thread on the pipe, and in the effort to keep the end of the pipe *small* enough, is so made that it leaves an abrupt shoulder at the end of the thread. It should be thicker, that both the taper and length of thread may conform to the standard. If the fitting is tapped slightly over-size, this shoulder comes up against the fitting before the tapered end fills the hole. If the thread holds, this shoulder may be forced hard against the end of the fitting; hard enough to make a tight joint at seventy pounds, but which *might* leak after the pressure had been raised to one hundred.

Small fittings, sizes up to ¾ and 1 inch, and in some shops, to 1¼ incn, are tapped straight, manufacturers claiming that they will make up just as tight as though tapped taper. The real reason for tapping them straight is found in the cost of taps.

Large taps are made by inserting cutters—parallel bars of steel with one side threaded—in grooves milled parallel with the surface of the tapered tap body. These cutters are held in place by a threaded ring which engages the thread on the cutters and also a thread cut upon the rear end of the tap body, enlarged for this purpose to match the cutters. The cutters may therefore be advanced to compensate for the length lost in the grinding, by unscrewing this ring, sliding them along their grooves and then replacing the ring.

As the cutters are made very cheaply, this construction saves much expense; but it is obviously impracticable to make the smaller sizes in this way, and they have to be made solid. If then they were tapered, grinding the end which has to ream out the rough hole in casting and therefore requires frequent sharpening—would soon spoil the size,' and they are consequently made straight, another effect of which the price-list is the cause.

Enough has been said to convince the practical reader that the market-price is the principal thing to be considered in designing standard fittings; and also that this designing will be confined to changes in their appearance rather than in their weight, unless the manufacturer "sits in the game."

An industrial or trade education is an education in the art of making things. A technical or engineering education is an education in the art of getting things made.

DESIGNING ECCENTRICALLY LOADED BOLT AND RIVET GROUPS*

By HARRY GWINNER†

When a beam or bracket is eccentrically loaded as shown in Fig. 1, tangential shearing stresses are often produced in the rivets or bolts, which are far in excess of the direct shearing stresses due to the vertical load. The direct shearing stress on each rivet is equal to the given load divided by the number of bolts or rivets. In addition to this there is a tangential shearing stress due to the eccentricity of the loading. The resultant of these two shearing stresses must not exceed the shearing or bearing value of the bolts or rivets. A practical example will best illustrate this matter.

Example:- A cantilever or bracket supports a load of 5,000 pounds 18 inches from the center line of the support *H*, as

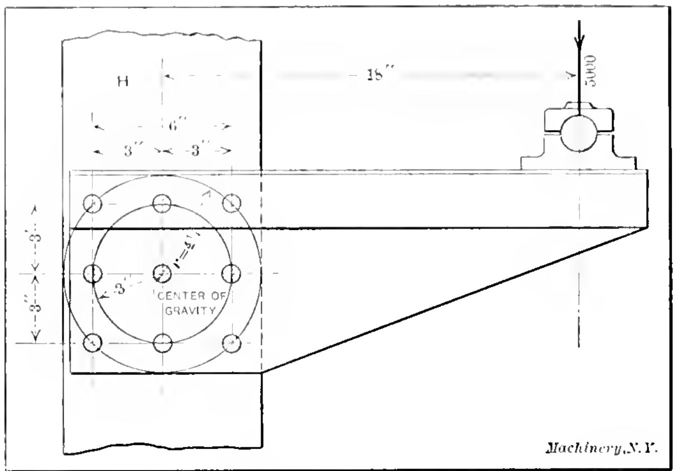

Fig 1 Eccentrically Loaded Rivet Group

shown in Fig. 1. It is required that a suitable group of rivets, giving ample safety, be designed.

In the accompanying Data Sheet Supplement will be found four tables which will greatly facilitate the solution of problems of this kind. These tables are for rivets ¾ inch in diameter, stressed at 10,000 pounds per square inch, giving a safe stress for the rivet area of 4,400 pounds. The first step in designing the rivet group is to assume a certain arrangement for the rivets. In the present case, assume that we decide upon three vertical lines of rivets three inches apart, as shown in Fig. 1. This will make the extreme distance between the outside rivets six inches. The vertical spacing of the rivets should be three inches, the tables in the accompanying Data Sheet Supplement being calculated for this spacing.

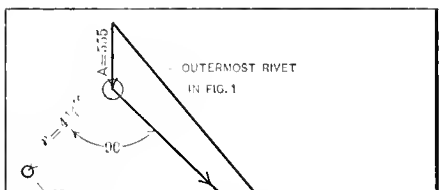

Fig 2. Finding the Total Resultant Shearing Stress on the Rivets

In Sheet III of the accompanying Supplement, a table is given for finding the number of rivets required when arranged in three lines. We locate in this table first the main section headed "18 inches" which is the lever arm of the load. In this section we follow the column under 6 inches, which is the distance between the outside rivet holes, until we come to the figure 5.6, which gives the load in thousands of pounds, or, in this case, represents a load of 5,600 pounds. This is the nearest figure in the table to the given load. Now we follow the horizontal line from 5.6 to the extreme left, and find the number of rivets required for carrying the load, which in this case equals 9.

* With Data Sheet Supplement.
† Dean of Mechanical Engineering, Maryland Agricultural College, College Park, Md.

As a check, on this work, we may carry out the following calculations:

$$\text{Direct shear} = A = \frac{5{,}000}{9} = 555 \text{ pounds.}$$

$$\text{Tangential shear} = B = \frac{W\,L}{P} = \frac{90{,}000}{25} = 3{,}600 \text{ pounds.*}$$

In the formulas above

A = vertical component of the total shearing stress on the rivet,

B = component of shearing stress caused by the eccentric loading,

W = total load in pounds,

L = distance from the center of rivet group to load,

P = polar section modulus.

The polar section modulus P is found from the accompanying table in the section headed "Three Rows of Rivets," opposite the number of rivets which, in this case, is 9, and in the column headed "6," which is the distance between the centers of the extreme rivets in a horizontal direction. This gives us 25 for the polar section modulus in this case.

The resultant of A and B is found graphically as shown in Fig. 2, and is about 4,000 pounds. This is well within the limits of the safe shearing stress of the rivet and the arrangement is, hence, a safe one. In testing the arrangement for strength, attention should also be given to the bearing value of the rivet or bolt on the connecting plates. If the resultant S should exceed the bearing value, the grouping should be re-arranged so as to make the joint safe both for shearing and bearing. The approximate formula

$$N = \frac{\dfrac{W\,L}{a} + W}{V}$$

gives results practically correct for a wide range of cases. In this formula

N = total number of rivets,

V = safe stress in one rivet,

a = average distance from center of gravity to rivets, and

W and L denote the same quantities as in the formulas previously given.

It may be of interest to some to know how the polar section modulus or the values of P given in the table above were calculated. Considering the group just designed we will find its section modulus.

$$\text{Polar section modulus} = \frac{\text{polar moment of inertia}}{r},$$ r being the distance from the center of gravity of the group to the center of the most remote rivet. The polar moment of inertia, designated I_p, is equal to the sum of the products of the area of each rivet multiplied by the square of the distance of each rivet from the center of gravity. In Fig. 1,

$$r \doteq \sqrt{3^2 + 3^2} = 4.25, \text{ approx.}$$

Each rivet is assumed to be of unit* area. In the group under consideration we have four areas at the distance of 4¼ inches from the center of gravity, four at a distance of 3 inches, and one at 0 inch. We then have

$$\begin{aligned} 4 \times 1 \times 4.25^2 &= 72 \\ 4 \times 1 \times 3^2 &= 36 \\ 1 \times 1 \times 0 &= 0 \\ \hline I_p &= 108 \end{aligned}$$

Hence, the polar section of modulus equals

$$\frac{I_p}{r} = \frac{108}{4.25} = 25,$$

which is approximately the same as the value already found from the table.

* * *

The industrial growth and development of Sweden during the last twenty years is indicated by some figures recently published by the Swedish government. The development has, in fact, been so remarkable that it reminds one rather of the boom of a new territory rather than the normal development of an old country. The value of the products of Swedish manufacturing industries in 1887 was only Kr. 191,000,000 ($51,000,000), while in 1907 this value had risen to Kr. 1,496,000,000 ($405,000,000), or an eight-fold increase in twenty years. This great development in the industries has, of course, brought with it a development in other lines as well. The assessed valuation of properties in towns and cities has increased from Kr. 1,040,000,000 ($280,000,000) to Kr. 2,800,000,000 ($775,000,000), and in the country districts the assessment of property other than agricultural has increased from Kr. 272,000,000 ($73,000,000) to Kr. 1,050,000,000 ($283,000,000). This development in the manufacturing industries is largely due to the fact that with the exception of the southern portion of the country, Sweden is not as well suited for agricultural pursuits as some other countries, while it is exceptionally well fitted for a large industrial development owing to the fact that water power is cheap and abundant and that the people in general are mechanically inclined.

In the January, 1907, issue of MACHINERY the Plauen bridge in Germany was referred to as having the longest masonry bridge span in the world. The span of this bridge is 295.2 feet long. It is now surpassed by the Grafton bridge near Auckland, New Zealand, which is 910 feet in total length and 40 feet wide, and which has a middle arch of 320 feet span, the roadway of this span being 147 feet above the valley.

* Note that the stress thus found is the stress in each ¾-inch rivet and not the stress per square inch. While the formula used is that commonly employed for finding the stress per square inch, the result in this case is due to the fact that the polar section modulus P is not the section modulus for a group of rivets of ¾-inch diameter, but for a group where each rivet is of unit area. The method of obtaining the polar section is explained later in this article.—EDITOR.

* When this is done the stress B as previously found, becomes the stress per each rivet and not the stress per square inch. See previous note.—EDITOR.

DERIHON "FRICTION MILL" FOR TESTING THE DURABILITY OF METALS

In the April number of MACHINERY (page 647, engineering edition) was described a portable apparatus for measuring the hardness of metals, designed by the firm of Usines G. Derihon at Loncin-lez-Liége, Belgium. This was used particularly for testing the hardness of metals used in automobile construction, the makers being engaged in the business of furnishing drop forgings for this work. The apparatus herewith illustrated and described was devised by the same firm for testing

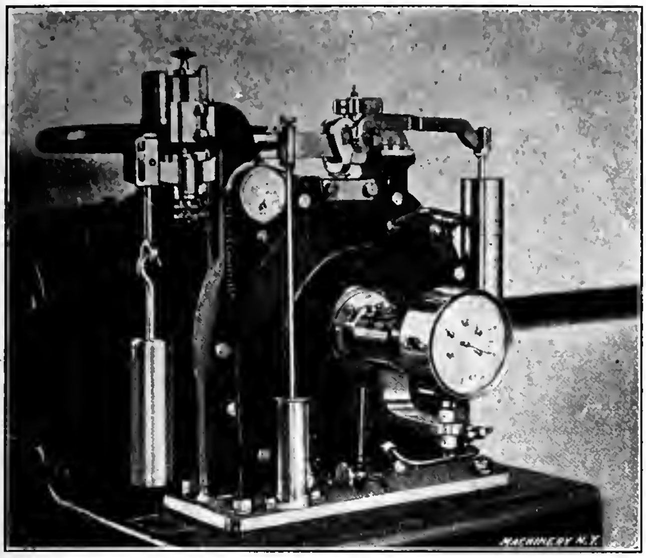

Fig. 1. An Apparatus for Measuring the Susceptibility of Metals to Wear

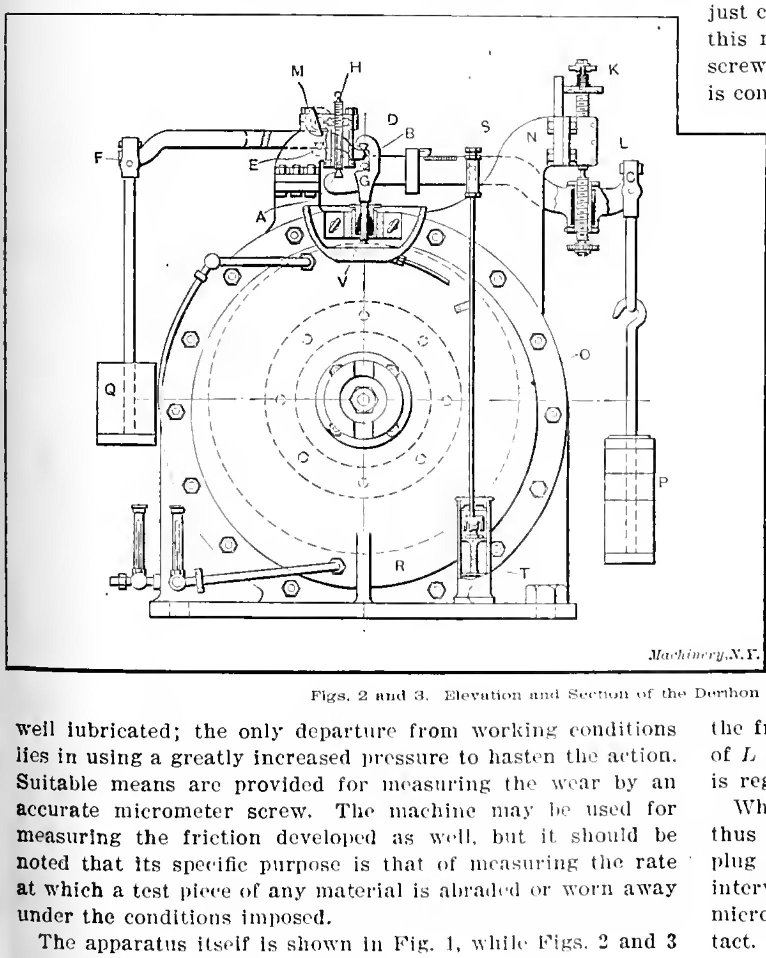
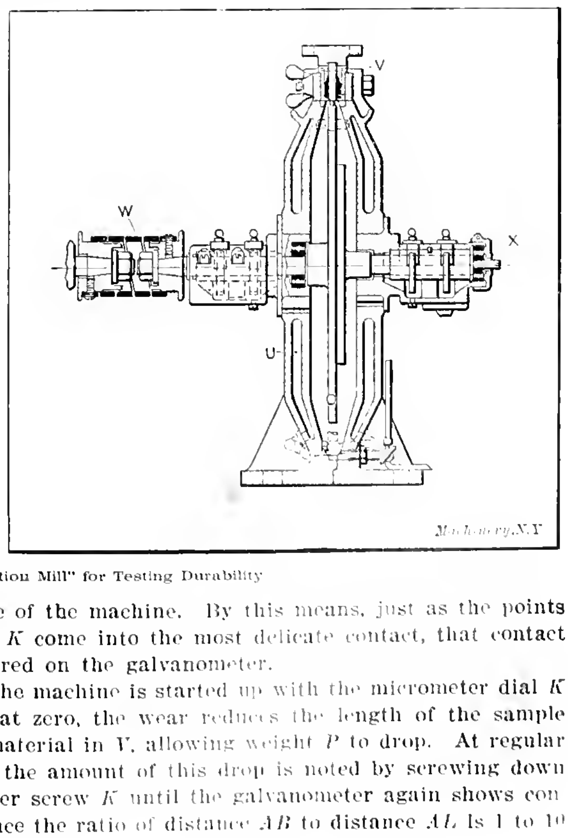
the durability of metals subject to wear. This has also found its greatest use in the hands of the makers in investigating the suitability of various materials for use in automobile construction, for such applications as gears, bearing metals, etc., where durability is a prime requirement.

With this apparatus the metal to be tested is subjected directly to wear under working conditions—that is to say, the wearing is effected by contact with a moving metal surface





Figs. 2 and 3. Elevation and Section of the Derihon "Friction Mill" for Testing Durability

well lubricated; the only departure from working conditions lies in using a greatly increased pressure to hasten the action. Suitable means are provided for measuring the wear by an accurate micrometer screw. The machine may be used for measuring the friction developed as well, but it should be noted that its specific purpose is that of measuring the rate at which a test piece of any material is abraded or worn away under the conditions imposed.

The apparatus itself is shown in Fig. 1, while Figs. 2 and 3 show the construction. It comprises a casing R, in which is mounted a disk O of extra hard steel rotated from a motor or other prime mover at a constant rate of speed. A holder V, containing the sample to be tested, is pressed down on the periphery of the revolving disk by an accurate and adjustable set of weights, P and Q. The amount that has been worn off from the sample by the revolving disk is tested from time to time by micrometer screw K.

Casing R is filled about one-third full of oil to give the condition of lubrication desired. This casing is water-jacketed, space for this being provided at U as shown. By regulating the water supply, the temperature of the casing is kept constant so that the factor of temperature does not have to be considered in comparing various tests. Disk O is one meter in circumference, and may be revolved at from 500 to 3200 revolutions per minute, giving a surface speed varying from about 27 to 175 feet per second.

The test piece is in the form of a small cylindrical plug, set into the square shank V of stirrup G. This square shank is carefully adjusted and fitted in the stuffing box guide shown, to avoid vibration and oil leakage. Care in the latter particular has to be exercised owing to the high centrifugal force with which the oil is thrown from the revolving disk.

The pressure is applied to the sample by means of weights P, hung on the outer end of the lever whose knife edges are shown at A, B and C. The fulcrum is at A. This bears on an abutment having a screw adjustment by means of screw H and worm M; by using this, lever A, B, C may be brought to the horizontal position at the beginning of the test. The upper end of stirrup G carries a knife edge D, which receives the upward pressure of a lever pivoted at E and carrying weight Q at its outer end. The purpose of this lever and weight is simply to balance the system before weights P are put in place. A sliding scale on the weighing lever provides the fine adjustment necessary for effecting this equilibrium. Weight Q, by furnishing another point of contact for stirrup G at D, serves also to hold the latter firmly in position.

With the test piece in place in V, and the levers set to the horizontal position by adjustment M, as described, the first thing to do is to set the micrometer screw to read from zero. Disk K being set at zero, screw L is turned until the points just come into contact. No dependence is placed on feeling in this matter, as that would not be delicate enough. Instead, screw L is insulated from the lever in which it is seated, and is connected by wire with a battery and galvanometer through the frame of the machine. By this means, just as the points of L and K come into the most delicate contact, that contact is registered on the galvanometer.

When the machine is started up with the micrometer dial K thus set at zero, the wear reduces the length of the sample plug of material in V, allowing weight P to drop. At regular intervals the amount of this drop is noted by screwing down micrometer screw K until the galvanometer again shows contact. Since the ratio of distance AB to distance AL is 1 to 10

and the graduations on dial K read to 0.01 millimeter, actual changes in the length of the test specimen as fine as 0.001 millimeter are read directly, and with accuracy. A dashpot T is supplied, as shown, connected with lever A, B, C, by spring connection S. This steadies the action of the lever, tempering the vibrations and making fine measurements possible. The ratio of distance AB to AC is 1 to 12, so that the pressure applied is easily found.

The apparatus is shown ready for work in Fig. 1. It is provided as shown with revolution counters, galvanometer and thermometers for indicating the temperatures of the jacket water. A motor is shown direct connected to the apparatus. This may be provided with volt and ampere meters if it is desired to make records of the power absorbed in friction. Since, however, this frictional loss is largely due to the friction between the plate and the oil bath, rather than that between the plate and the test piece, such use is not recommended.

In using this apparatus in testing the durability of metals, some investigations were made to see if there is any relation between hardness as measured by the Brinell apparatus, and durability as measured by this machine. No direct relation between the two characteristics was discovered. The accompanying table gives particulars of a series of experiments along this line. In these experiments the test piece was subjected to a pressure of 48 kilogrammes per square centimeter (682 pounds per square inch), with the friction disk turning at 3200 revolutions per minute or 175 feet per second, for a period of ten million revolutions.

An examination of the table proves that the presence of carbon has an unexpectedly small effect on the resistance to wear as compared with manganese and silicon. This is in accordance with the experience in railroad work, in which rails high in manganese and silicon have been found to wear less rapidly than when these elements are lacking. It would seem that the carbon has practically no effect at all, since half hard steel having a high percentage of manganese and silicon wears much less than hard steel having a small percentage of these two elements. Compare, for instance, samples 1 and 2 in the table, the latter of which was worn out nearly twice as rapidly as the former. Not until this second sample had been hardened, as shown in test No. 7, could it be compared with respect to the wearing of sample No. 1.

It is evident and, in fact, proved by experience as well as by these experiments, that heat treatment has an effect on the resistance to wear. Mild steel which in the natural state wears 0.325 would only wear 0.025 if casehardened and tempered. Similar improvement occurs in nickel chromium steel.

Similar tests have been made on bronze and other bearing metals. Bronzes containing lead and antimony are of the kind which resist wear best, in spite of their weak cohesion. One of the test bars was so soft that an 8 millimeter ball under a weight of 12 kilogrammes made an impression on the metal. This same test bar, however, gave the smallest coefficient of wear. Hard bronze, on the other hand, such as phosphor-bronze, wears more rapidly. Hard bronzes have broken down and abraded as soon as the pressure reaches one kilogramme per square millimeter (1422 pounds per square inch) in the machine. On the contrary, soft and anti-friction bronzes have never acted in this way, whatever the pressure used.

The designers of this apparatus are now studying the effects of elements other than lead and antimony for bearing metal purposes, and expect to be able to publish valuable results in the near future. The information here given was sent us by the American representative of Usines G. Derihon, Mr. H. A. Elliott, 7502 Carnegie Ave., Cleveland, Ohio.

RUSTPROOF FINISH ON IRON

The so-called "Coslettizing" process for producing a rust-proof finish on iron is referred to in a recent issue of the *Brass World*. This process consists in boiling the iron or steel article to be treated in a solution of one gallon of water, four ounces of phosphoric acid and one ounce of iron filings. By this means a black coating is produced on the iron or steel which protects it from atmospheric and other corrosive influences. This formula gives good results when care is used, but when carelessly handled a certain amount of undissolved iron filings may be left on the surface of the article being treated. As far as the protection of the coating against corrosion is concerned, it is stated that a piece of steel treated by the process and immersed in salt water for nearly a year has resisted its attacks so that it is practically free from corrosion, while a similar piece untreated has become badly rusted.

* * *

The rifle barrel rollers in the Springfield Armory, Springfield, Mass., evidently are not superstitious; at least they seem to have no fear of the hoodoo "13." The billets from which the barrels are rolled are passed between a pair of rolls having eleven grooves, the grooves being shaped so as to roll the barrels large at the breech and small at the muzzle. A barrel is passed once through each groove, except the finishing groove, through which it is passed three times, thus making thirteen passes in all.

IRREGULAR SPACING OF THE CUTTING EDGES OF REAMERS*

By "A"

The question of the proper manner in which to "break up" the flutes of reamers (spacing the cutting edges irregularly), is one which has puzzled mechanics considerably. Some claim that if the flutes of half of the reamer are broken up exactly alike with the other half of the reamer, opposite cutting edges hence being exactly diametrically opposite, the object sought, i. e., the elimination of chatter and the possibility of reaming a round hole, would be obtained. Others maintain that the cutting edges around the whole reamer should be irregularly spaced so that no two cutting edges are diametrically opposite.

The advantages obtained by having the two halves of the reamer identical are that the reamer can be exactly measured, and that an equal width of the land of all the cutting edges can be more easily obtained if desired, as the milling machine table on which the reamer is mounted while fluting would have to be raised or lowered only half the number of times for obtaining this result than would be the case if every tooth were irregularly spaced. The writer, however, does not believe that these advantages in any way outweigh

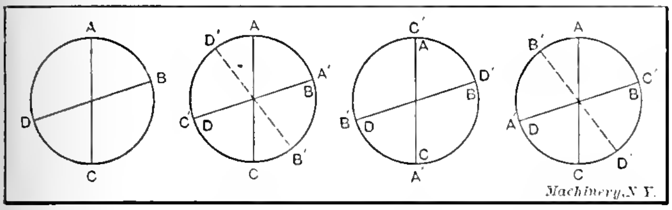

Fig 1 Fig 2 Fig 3 Fig. 4
Four-fluted Reamer, with Cutting Edges Diametrically Opposite. Note Coincidence of Cutting Edges at Various Times during the Revolution

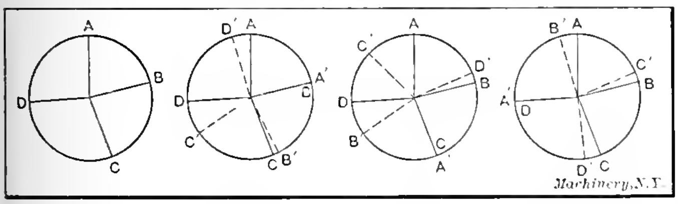

Fig. 5 Fig 6 Fig. 7 Fig 8
Four-fluted Reamer, All Cutting Edges Irregularly Spaced Note that there is no Coincidence of the Cutting Edges during the Whole Revolution

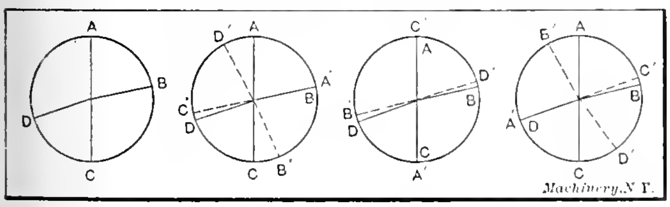

Fig. 9 Fig. 10 Fig. 11 Fig. 12
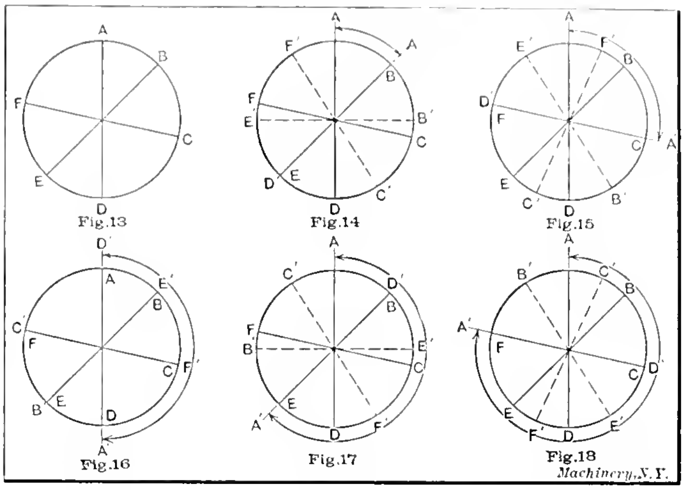
Four-fluted Reamer, with only Two of the Cutting Edges Diametrically Opposite. This gives Practically as Good Results as shown in Figs. 5 to 8

the disadvantages resulting from this method. When the flutes are not irregularly spaced all around the whole reamer, the tool is liable to chatter, and if it once starts to cut a "cornered" hole, it will continue to do so.

The accompanying illustrations will show why this happens. First, take as an example the case of a four-fluted reamer. Assume that the cutting edges are irregularly spaced as shown in an exaggerated manner in Fig. 1. When this reamer is revolved the cutting edges *A* and *C* will simultaneously occupy the positions originally occupied by *B* and *D*, as shown in Fig. 2. When it is revolved further, *B* and *D* will simultaneously occupy the positions originally occupied by *A* and *C*, and when it has been revolved half a revolution, as shown in Fig. 3, all four cutting edges will occupy the same relative positions as in Fig. 1. In Fig. 4, again, cutting edges *A* and *C* occupy the original positions of cutting edges *D* and *B*. This action is conducive to the production of a four-cornered hole.

* The following articles dealing with the construction and making of reamers have previously been published in MACHINERY: "Hand Reamers," January, 1906; "Reamers," August, September, October, November, and December, 1907.

In Figs. 5 to 8, again, are shown the relative positions occupied by the cutting edges of a reamer having four flutes irregularly spaced all around the whole circumference. It will be seen that here no two cutting edges at any one time will occupy the same position as has been occupied previously by any other two cutting edges, letting alone the fact that the positions of all four cutting edges never coincide except at the end of a full revolution. In Figs. 9 to 12 is shown a method of spacing the cutting edges where two

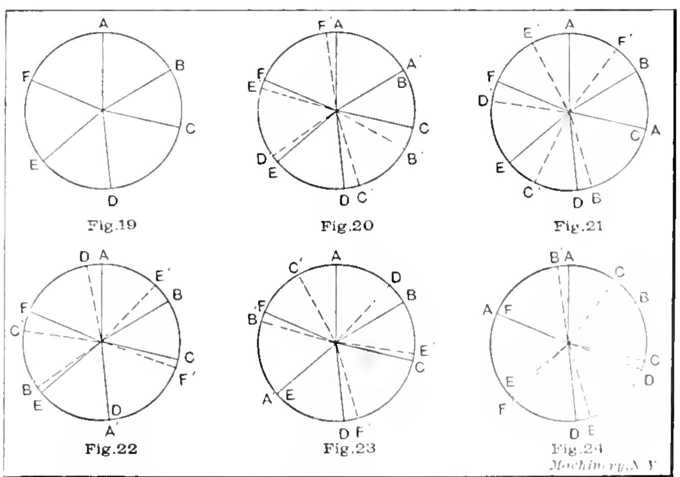


Figs. 13 to 18. Reamer with Six Flutes. Cutting Edges Diametrically Opposite

of the edges *A* and *C* are diametrically opposite, while *B* and *D* are not. This method of spacing the flutes is practically as effective as that shown in Figs. 5 to 8, and when the reamer revolves, the positions of the four cutting edges will never coincide, except when the reamer has been turned around a full revolution. If the reamer starts wrong or commences to chatter, a reamer of the type shown in Fig. 1 has no possibility of correcting itself, whereas reamers broken up in the manner shown in Figs. 5 and 9 will do so.

The illustrations, Figs. 13 to 18 and 19 to 24, show reamers with six flutes. In the first case all the cutting edges are diametrically opposite each other and in the second case all of them are irregularly spaced so that no two are diametrically opposite. The illustrations shown in connection with these, indicate how in the first case, the positions of two and two cutting edges coincide constantly, and how after half a revolution all the cutting edges coincide, whereas, in the second case, there is no coincidence of position of any two cutting edges until the reamer has been turned around a complete revolution.

The error in measuring a reamer when all the cutting



Figs 19 to 24 Reamer with Six Flutes. Cutting Edges Irregularly Spaced

edges are irregularly spaced, and when no two are diametrically opposite, is very slight. The irregular spacing should be so small that the error in measuring should not exceed 0.0003 inch. It has been the experience of a toolmaker of both mechanical and commercial experience that this is rather an advantage, as the reamer, when new, will be a small

amount oversize, providing a slight allowance for wear which is not too great even for a hand reamer. In general, there is no need of a greater irregularity in the spacing of the flutes than that the error may be limited to 0.00025 inch.

As far as concerns the difference in the width of the land of the reamer edges, which is the inevitable result of breaking up the flutes if the table or the cutter is not raised or lowered between consecutive cuts so as to make up for the difference in spacing, the writer does not consider this matter of enough importance to warrant any deviation from the best practice of spacing the cutting edges. The only reason for lands of even width would be for the sake of appearance, as the unequal width of the lands in no way interferes with the efficiency of the reamer. The commercial difficulties in making the lands of equal width, however, are rather too great to warrant unnecessary expense on account of a matter which has no mechanical importance.

MACHINE SHOP PRACTICE*

TOOL GRINDING—2

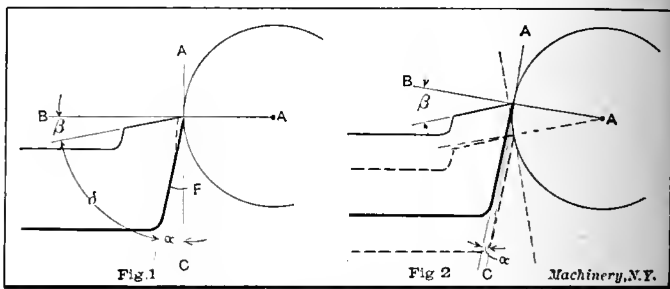
In the preceding installment of this article which appeared in the March number, the shape which should be given the cutting edge of a tool was considered in a general way and it was also explained that the slope for tools which require slope, should be back from the *working part* of the cutting edge, as this is necessary in order to give keenness to that part of the edge which does the work.

Now, in order that the cutting edge may work without interference, it must have clearance; that is, the flank *F* (Fig. 1) must be ground to a certain angle a so that it will not rub against the work and make the cutting edge ineffective. This clearance should be just enough to permit the tool to cut freely. A clearance angle of eight or ten degrees is about right for lathe turning tools, while three or five degrees is sufficient for planer tools.

As was explained in the Shop Operation Sheet accompanying the March number, the back slope of a tool is measured from a line *A-B* (Fig. 1) which is parallel to the shank, and the clearance angle, from a line *A-C* at right angles to line *A-B*. These lines do not, however, always occupy this position with relation to the tool shank when the tool is in use. As shown in Fig. 2, the base line *A-B* for a turning tool in use, intersects with the point of the tool and center of the work, while the line *A-C* remains at right angles to the first. It will be seen then, that by raising the tool, the effective clearance angle a will be diminished, whereas lowering it, as shown by the dotted lines, will have the opposite effect. The effective angles of slope and clearance of a planer tool will also change when its position with relation to the work is varied; thus, in Fig. 3 a tool is shown in a normal position; if this tool were inclined as in Fig. 4, evidently the effective clearance would be greatly increased while the slope angle would be zero, with the result that the tool instead of cutting or shearing the metal, would work with a scraping action. A planer tool is, however, always clamped in a fixed position with the shank at right angles to the table as shown in Fig. 3, whereas a lathe tool, the height of which may be varied, is not always clamped in the same position. This is one reason why a turning tool is given more clearance than one used for planing. The turning tool also requires more clearance because it has a continuous feed and cuts along a spiral path instead of along a straight path, as in the case of a planer tool which is fed at the end of the stroke.

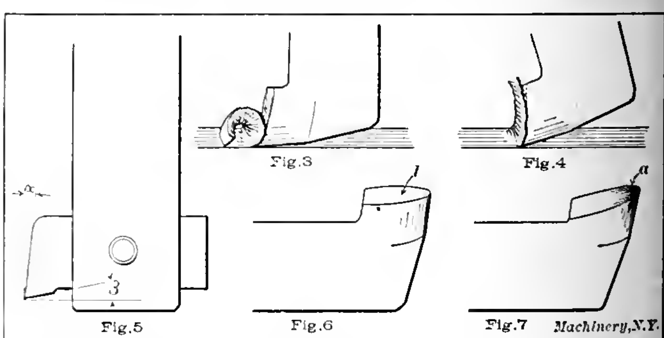
A turning tool for brass or other soft metal, particularly where considerable hand manipulation is required, could advantageously have a clearance of twelve or fourteen degrees, as it would then be easier to feed the tool into the metal; but, generally speaking, the clearance for turning or planing tools should be just enough to permit them to cut freely. Excessive clearance means that the cutting edge will be weakened by a lack of support which may result in its crumbling under the pressure of the cut.

The lip angle or the angle of keenness δ (Fig. 1) is another important consideration in connection with tool grinding, for it is upon this angle that the efficiency of the tool largely depends. By referring to the illustration it will be seen that this angle is governed by the clearance and the slope β, and as the clearance remains practically the same, it is the slope which is varied to meet different conditions. Now, the amount of slope a tool should have depends on the work for which it is intended. If, for example, a turning tool is to be used for roughing medium or soft steel, it should have a back slope of eight degrees and a side slope ranging from fourteen to twenty degrees, while a tool for cutting very hard steel should have a back slope of five degrees and a side slope of nine degrees. The reason for decreasing the slope and thus increasing the lip angle for harder metals is to give the necessary increased strength to the cutting edge to prevent it from crumbling under the pressure of the cut. The tool illustrated in Fig. 6 is much stronger than it would be if ground as shown in Fig. 7, as the former is more blunt. If a tool ground as in Fig. 6,



Figs. 1 and 2 Illustrations showing how Effective Angles of Slope and Clearance change as Tool is raised or lowered

however, were used for cutting very soft steel, there would be a greater chip pressure on the lip surface *l*, and consequent greater resistance to cutting, than if a keener tool had been employed; furthermore the cutting speed would have to be lower, which is of even greater importance than the chip pressure; therefore, the lip angle, as a general rule, should be as small as possible without weakening the tool so that it cannot do the required work. Experiments conducted by Mr. F. W. Taylor to determine the most efficient form for lathe roughing tools, the results of which were previously published in MACHINERY (January to August, 1907, engineering edition) showed that the nearer the lip angle approached sixty-one degrees, the higher the cutting speed. This, however, does not apply to tools for turning cast iron as the latter will work more efficiently with a lip angle of about sixty-eight degrees. This is because the chip pressure when turning cast iron comes closer to the cutting edge which should, therefore, be more blunt to withstand the abrasive action and heat. Of course, the foregoing remarks concerning lip angles apply more particularly to the tools used for roughing cuts.



Figs. 3 and 4. Effect of Change of Position on Action of Planer Tool. Fig. 5. Slotter Tool. Figs 6 and 7. Lathe Roughing Tools Ground for Turning Hard and Soft Steel

In order to secure a strong and well-supported cutting edge, tools used for turning very hard metal, such as chilled rolls, etc., are ground with practically no slope and with very little clearance. Brass tools, while given considerable clearance, as previously stated, are also ground flat on top or without slope; this is not done, however, to give strength to the cutting edge, but rather to prevent the tool from gouging into the work, which it is likely to do if the part being turned is at all flexible and the tool has been given slope.

Slotter tools for general work, such as the one illustrated in Fig. 5, are ground in practically the same way as a planer tool.

* With Shop Operation Sheet Supplement.

If we consider a slotter tool, which is, of course, a vertical planing tool, under working conditions, we shall see that the angle *a* represents the clearance and β the slope, which is given, as with lathe and planer tools, to that surface against which the chip bears while it is being severed.

Often a tool which has been ground properly in the first place, is greatly misshapen after it has been sharpened a few times. This is usually the result of attempts on the part of the workman to re-sharpen it hurriedly; for example, it is easier to secure a sharp edge on the turning tool shown in Fig. 1 by grinding the flank as indicated by the dotted line, than by grinding the entire flank. The clearance is, however, reduced and the lip angle changed.

There is great danger when grinding a tool of burning it or drawing the temper from the fine cutting edge, and, aside from the actual shape of the cutting end, this is the most important point in connection with tool grinding. If a tool is pressed hard against an emery or other abrasive wheel, even though the latter has a copious supply of water, the temper will sometimes be drawn, which will be indicated by a dark blue color at the point, as at *a* in Fig. 7. Burnt tools are, however, sometimes discolored so slightly that the discoloration is scarcely discernible, for naturally it is the fine cutting edge from which the temper is first drawn, and it is also this fine edge which does the work.

When grinding a flat surface, to avoid burning, the tool should be frequently withdrawn from the stone so that the cooling water (a copious supply of which should be provided) can have access to the surface being ground. For the same reason a curved surface should be constantly rolled about on the face of the wheel. A moderate pressure should also be applied, as it is far better to spend an extra minute or two in grinding, than to ruin the tool by burning it in an attempt to sharpen it quickly. Of course, what has been said about burning, applies more particularly to carbon steel, but even self-hardening steels are not improved by being overheated at the stone.

As to the kind of abrasive, the writer believes that there is nothing superior to a free-cutting grindstone for tool grinding. A little more time may be required when a grindstone is used, but the fineness and quality of the edge obtained which results in increased tool efficiency, is by far the more important consideration.

* * *

THE GROWTH OF CAST IRON

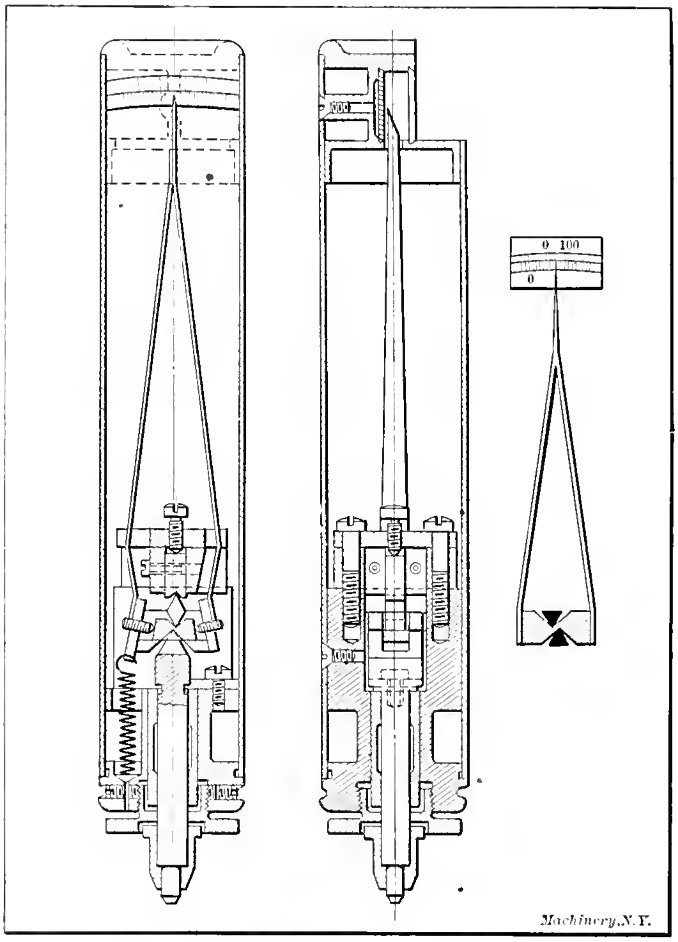
In an article entitled "The Growth of Cast Iron" in the March, 1910, issue of MACHINERY, a comparison was made of the results obtained in the experiments made by Prof. H. F. Rugan and Prof. H. C. H. Carpenter with those obtained by Mr. A. E. Outerbridge, Jr. It was stated that Mr. Outerbridge's experiments did not show an increase in weight of a sample which had increased in volume after repeated heatings, while the other experimenters' samples showed an increase in weight as well as in size. As an explanation of this condition it was stated that Mr. Outerbridge had his samples enclosed in an iron pipe sealed at the ends with clay. Our attention has been called to the fact that the other experimenters heated their samples in the same manner, using an iron muffle furnace sealed with fire clay, so that in this respect there was no material difference in the manner of heating the samples. While the specimens were thus completely protected from the direct action of the flame, the results of the experiments indicate that the gases entered the muffle. Iron heated to the temperature used, about 1470 degrees, becomes permeable to gases. Hence the manner of heating does not account for the difference of the results obtained by the different investigators.

* * *

From the preliminary reports of an industrial census recently taken in Great Britain, it appears that the value of the machine tools built in that country in 1907 was $13,575,000. Of other classes of machinery, locomotives were built valued at $22,100,000, this, however, not including the locomotives constructed by the railway companies themselves. The total value of all classes of machinery built in Great Britain was $450,000,000 in the year mentioned.

THE HIRTH MINIMETER FOR ACCURATE MEASUREMENTS

The accompanying illustrations show a measuring apparatus devised by Mr. Albert Hirth of the Fortuna Works, Cannstatt-Stuttgart, Germany, intended for a comparator to indicate differences of fractions of millimeters existing between the piece measured and a standard gage block, or between the piece measured and a sample piece of arbitrary dimensions. The general construction of the minimeter is shown in Figs. 1 and 2, and the principle of its action in Fig. 3, this principle being the introduction of a long lever arm which at the same time serves as an indicating needle, and a short arm the length of which is determined by the distance between two knife edges. The bearing points of these two knife edges may be varied in order to provide adjustment for the apparatus. One of the advantages of the device is that it eliminates the necessity for lubrication and overcomes the disadvantages of play on dead centers. As indicated in Fig. 1, a spring holds the lever against the knife edges and returns it to its normal position after measuring. The whole mechanism is



Figs. 1 to 3. Construction and Principle of Action of the Hirth Minimeter

enclosed in a tube, the upper part of which is provided with an opening which permits a graduated scale to be seen and the indications of the pointer to be read off. The scale is provided with graduations corresponding to hundredths of a millimeter (about 0.0004 inch). The measuring instrument proper can be mounted in different holders so that it can be used with equal facility for measuring flat and round pieces as well as inside diameters of holes.

In Fig. 4 the minimeter is shown arranged for measuring, or rather comparing, dimensions of flat pieces. In this case the instrument proper is mounted on a standard or upright, carrying at its upper end a clamp for holding the minimeter and at its lower end a small circular table placed on a bracket adjustable for height. When cylindrical pieces are to be compared, the instrument is mounted as shown in Fig. 5. In this case the location of the measuring instrument proper is adjusted by means of the adjusting mechanism shown on the side of the holder, so that the indicator points to zero when the sample or standard gage is placed in the holder. Then

the differences in dimensions of the various pieces are noted by inserting them in the instrument in place of the sample or gage. For measuring inside diameters the instrument is mounted as shown in Fig. 6. In this case the minimeter is held in a bracket having a two-point support provided with means for adjustment so that it can be easily applied to the required diameter.

It is evident from this brief description that the apparatus is a very convenient one for machine shop use. It permits of a comparison of different measuring instruments and gages at given intervals, without the employment of relatively costly standard measuring machines. When standard gages are at hand it indicates exactly the size that the piece of work must have in order to obtain the desired degree of accuracy. It is so simple in its application that it may be employed by the ordinary mechanic as easily as any of the ordinary measuring instruments with which he is familiar. It is evident that this instrument can be applied to many special uses not directly referred to in this description.

MAKING FILMS IN A VACUUM

A new method of producing thin metallic films by volatilization in a vacuum was described at a recent meeting at the Academy of Science by Prof. L. Houllevigne, which may have an important commercial influence on the production of gold leaf. The metal to be deposited is first deposited on platinum wire which is then heated in a high vacuum. The film forms on a glass cylinder which is kept in constant rotation near the heated wire. In this manner thin films have been produced of gold, silver, platinum, copper, zinc, tin and cadmium.

* * *

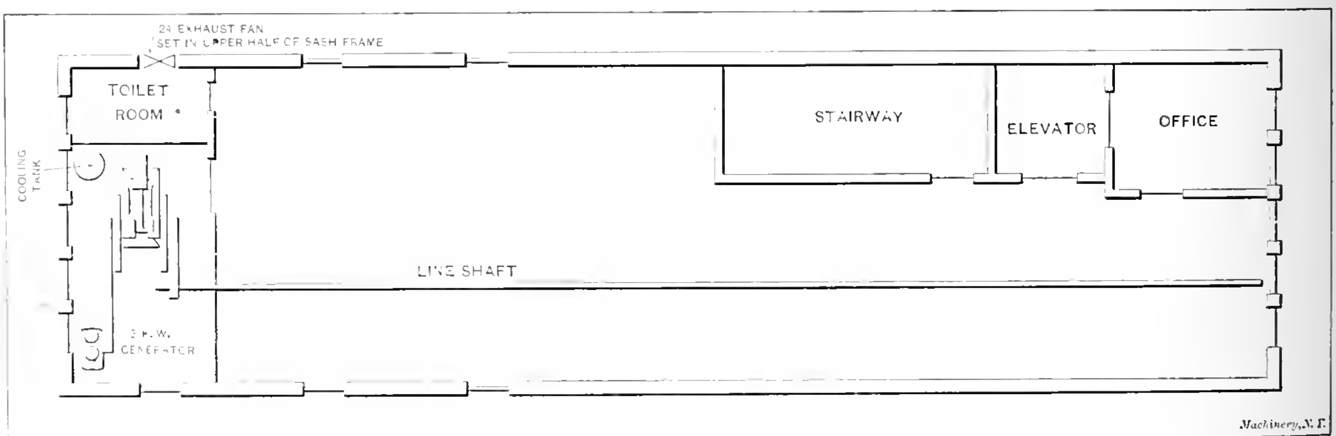
Barney Oldfield drove a 210-horsepower Benz racer one mile in 27.33 seconds at Daytona Beach, Fla., March 16. He broke the former world's mile record of 28.23 seconds made by Fred Marriot with a Stanley steam car in January, 1906, on the same course. The speed attained by Oldfield averaged 131.72 miles per hour.

INSTALLATION OF STATIONARY GAS ENGINES FOR FACTORY USE

By H. J. BACHMANN*

The use of stationary gas engines for industrial purposes in New York state, has been made difficult where the provisions of the factory law are not complied with. It is a well-known fact that the burnt gases which escape from any explosion engine will soon contaminate the air to such an extent as to render it unfit for breathing purposes. The law requires that al work-rooms be provided with sufficient means of ventilation, and it is therefore necessary to make provision for exhausting the foul gases and admitting a constant supply of fresh air.

In the accompanying engraving a typical floor plan of a small loft building such as is used for a large variety of manufacturing purposes, is shown. It is a mistake to place a motor, especially a gas engine, in an out-of-the-way dark corner of a room and expect satisfactory results. In such a location, the motor is neglected, often becomes over-heated, and repairs are made with difficulty. When the engine is located as shown, it takes up a large amount of otherwise available floor space and light, but the benefits derived from such a location more than compensate for the additional expense involved. In the first place, the power plant is in a large, light room, entirely separate from the manufactory, so that it is easy to keep it clean and well ventilated. There is also room for a small generator, which will furnish current for electric light and such small portable electric tools as are used in the shop. This will also do away with another source of vitiated air; namely, the burning of gas jets at each machine, to say nothing of the additional safety and comfort to the operator. If it is desired, this current may also be used for ignition purposes in place of batteries or hot tubes.



Plan of Small Factory driven by Gas Engine, showing Ideal Arrangement

The opposite side of the engine is belted direct to the lineshaft, as shown, from which a drive is taken for the 24-inch

* Address: 1234 Theriot Ave., New York City.

exhaust fan which is set in the upper part of the sash frame in the toilet. All the partitions shown, run up to the ceiling except the one between the engine room and toilet. With this arrangement the fan will keep the air of both these rooms in as good condition as outdoors without perceptible draft.

If a forced circulation of air is also desired in the factory, a register may be placed near the ceiling in the partition between the engine and work-room, which may be opened or closed to secure the desired result. Furthermore, provision may be made for the supply of fresh air through the windows by opening each sash slightly at the top and bottom. To prevent a draft from this source, the windows may be fitted with any good make of window ventilator.

A manufacturing plant arranged as outlined will come up to the strictest requirements of the health and factory laws and may be run in the most economical manner as regards expense for power consumption. Incidentally, the working conditions will be favorable toward securing the steady services of high-grade, intelligent workmen.

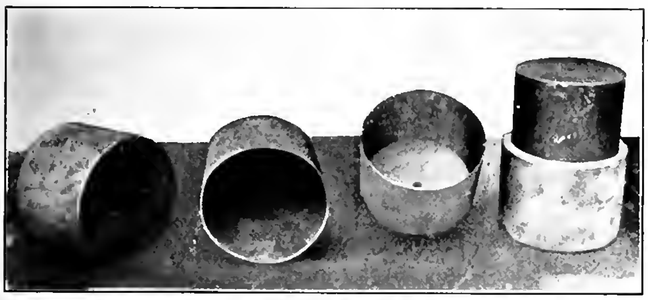
THIN CASTINGS

By WILLIAM PAINTER*

The gray iron castings which are shown in the accompanying illustration do not exceed 1/16 inch in thickness at any point, and they are made commercially in quantities to take the place of sheet metal cups. These castings have practically no draft and they must be without blow holes as they are required to be water-tight. They are made in five different sizes, but only two sizes are shown in the illustration. The four larger ones of those illustrated are 8 inches in diameter



Cup-shaped Castings which do not exceed 1/16-inch in Thickness

and 6 inches deep, and the smaller one is 7 inches in diameter and 5 inches deep. The weight of the larger size is 3 pounds 4 ounces, while that of the smaller one is 2 pounds 8 ounces. The smallest size which is cast is even less than 1/16 inch in thickness and its weight is only 1 pound 4 ounces. This smallest cup has a diameter of only 6 inches and a depth of 4 inches, while the two larger sizes have a diameter of 9 and 12 inches and a depth of 9 and 10 inches, respectively. The weight of these castings must not vary more than 4 ounces.

The work is done under the direction of our foreman iron molder, Mr. Fred Hockenberry, and the process is as follows: First, the pattern which is of metal, is turned to the weight required, the patternmaker allowing from 2 to 8 ounces over the weight of the casting for which the pattern is intended. They are made perfectly straight on the outside, with 1/32-inch draft inside, so a molder will see at once the necessity of rapping the pattern when removing it from the sand.

There are three ways of molding these floats. A two-part flask cut in the middle and having a cope and drag may be used, or a three-part flask having a cope, cheek, and drag, or a two-part snap flask, where flask is removed, and a slip or outside box is forced over the mold; this latter method is not safe, as in forcing the box over the mold, a crush is likely to follow.

The sand used for this job was one-half No. 0 Albany and one-half No. 0 Dresden thoroughly tempered. The greatest care must be taken in wetting and thoroughly mixing the sand, so there will not be any wet or dry parts to come in contact with the pattern, as they will cause blowing or scabbing of the casting.

When molding a float in a two-part flask the molder places the pattern on a plain board; the drag half of the flask, which should be 2 inches deeper than the pattern, is then placed over the latter, and filled about half full of sand sifted from a No. 6 riddle. The sand is then peened around the pattern evenly, care being taken not to leave hard and soft spots that might cause a blow or swell in the casting. After the molder has the first course of sand peened evenly, he makes the second riddling. Care should be taken to see that the pattern is covered, and that there are no soft spots between the two riddlings. The flask is then filled with sand, and rammed properly, and the loose sand is struck off on the bottom board. This board must be set level on the sand edges of the flask. The board is next removed and the sand is vented inside and out of the pattern, so that all gases such as steam and air may escape, as in castings as thin as these any gas that cannot escape will cause a hole in the side wall of the casting. After the venting is done, the board is placed on the flask which is then rolled over. We now have the pattern in the drag half of the flask. The parting is made, care being taken that the sand be firm around the top of the pattern; parting sand is put on the mold, and the cope half of the flask is placed on. The ears should be tight on the pins so that the cope cannot shift. Sprues are placed in opposite corners for pouring, and also in the remaining corners for risers. Enough sand is then riddled to cover the top of the pattern, the sprues are thoroughly tucked around, and the cope is then filled with sand and well peened to get the sand firmly back of the sprues so as to prevent a "run out." The sand should not be rammed too hard over the top of the pattern, as it will cause blow holes and cold shots. The sand is next vented, care being taken not to strike the pattern; the pattern is then rapped through the cope. It should not be rapped much, however, as there is only an allowance of 4 ounces to go on.

After the sprue-pins are removed, the cope is lifted. The gates can best be cut before the pattern is drawn, as then there is no danger of loose sand dropping down the side wall. The gating is one of the important points in casting these floats. A runner should be cut to the right and left of the sprues about 1 inch wide and ½ inch deep.

Leaders to the casting 1½ inch wide and 1/16 inch thick at the point of entering the mold, tapering back to a size of ¾ inch wide by ¼ inch deep where they join the runners, will allow the iron to flow into the mold easily, saving the cutting of the green sand core. The gate should be well thumbed down, so that no loose sand can wash into the mold, as a small particle of sand flowing with the iron and dropping down the side, will leave a hole in the casting. A straight gate is cut into the riser to relieve the strain as the mold has to be forced very hard.

The pattern is drawn with two screws, and great care has to be taken not to break the sand, so as to allow any loose particles to fall in, as it is impossible to remove them. After the pattern is removed, the cope is closed onto the drag, the mold is placed on the floor, and enough weights are placed on the flask to insure the cope not rising when the iron is poured.

The best hot iron is used, and the mold is poured two up; after pouring, the mold is allowed to stand until it is thoroughly cold. As the castings are very thin they should not be exposed to the air while hot, as they are likely to crack by cooling too quickly.

The iron which is used is high in silicon and low in sulphur. Some manganese is added for strength and phosphorus for fluidity. An analysis of the iron used is as follows: Silicon, 2.75; sulphur, 0.005; manganese, 0.20; phosphorus, 0.60; coke, 0.60 to 0.75 in sulphur.

* * *

The dangers of atmospheric electricity in aerial navigation are attracting considerable attention. While an ordinary balloon without metal parts is not exposed to any danger as long as it floats in the air, the modern dirigibles are provided with much framework made of conducting metals. Even a balloon, however, may be charged with electricity and a spark produced when contact with the ground is made, thus setting fire to the gas.

LETTERS ON PRACTICAL SUBJECTS

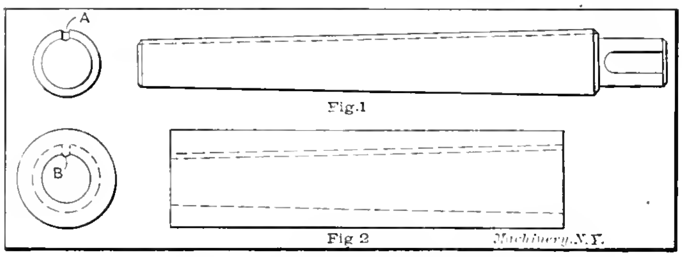
We pay only for articles published exclusively in MACHINERY

LAPS AND THEIR USE

I have read carefully the interesting article on "Laps and Points on Lapping" by Mr. F. P. Crosby in the February number, and no doubt he has successfully used the method described. However, my experience has been that copper is not a metal to be quickly and accurately worked, and I am sure that Mr. Crosby's method would not be practical in a shop where nearly every hole is finished by lapping—by all classes of workmen. I should be afraid that the split lap, as shown in Fig. 3 of the article referred to, would expand and revolve on the arbor, possibly causing particles of emery to become loose and lodge in the work, especially if it were of brass or aluminum. This style of lap and method of holding might be suitable for very small tool work, but even then it would be expensive.

In consideration of the above article, and in view of the fact that accurate lapping is a very difficult operation for many machinists, it would seem fitting at this time to again consider it in a light possibly new to some. Lapping is not, however, as difficult as it would seem, providing the proper methods and tools are used in the process.

I consider the material used for holding the abrasive one of the most important factors when the work is soft; and it is very important that this material should be softer than the work, which would make it easier to charge. In shops where nearly every hole is finished by lapping, lead has been adopted as the best known metal to use. It is inexpensive and can be remolded by apprentices; besides it charges very quickly, which is a much desired and important feature.



Figs. 1 and 2. Lap Arbor and Lead Lap with Driving Key

The lap arbor illustrated in Fig. 1 is used for holding the lead laps, which may be molded in as many sizes as desired. The molding arbor should be an exact duplicate of the working arbor. A small groove *A* is milled the entire length of the molding arbor, producing a driving key *B*, Fig. 2, which fits the working arbor. This driving key is very necessary, as it is almost impossible to prevent considerable lap friction between the work and the lap. Without the driving key, the lap would surely revolve on the arbor and become tight in the work.

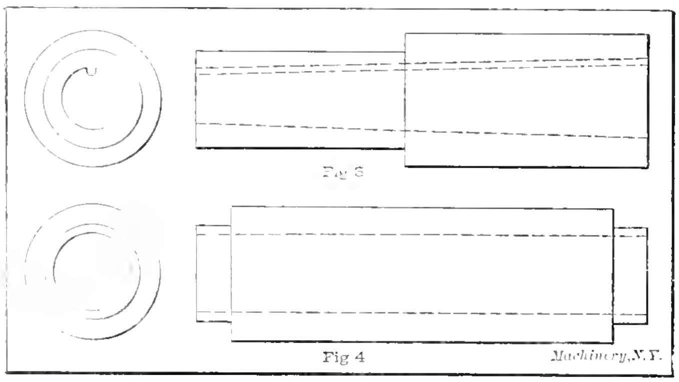


Fig 3 Lead Lap with Two Diameters Fig 4 Method of Preventing Bell-mouthed Holes

It is very convenient to have laps with two or more diameters, as shown in Fig. 3, which enables the operator to readily find a size without a waste of metal for each job. It may be necessary, of course, to slightly reduce one of the diameters to obtain the desired size. The usual custom is, when a lap is a little too small, to flatten it between two parallel plates in an arbor press, which forces the metal outward on the open sides.

For outside lapping or "ringing" a cast-iron adjustable lap is used, similar to the one shown in Fig. 5. Any piece of cast iron will do, but it is much better to have special castings of several sizes for this purpose, with holes in each end as shown. The slots and holes serve to hold the loose particles of the abrasive.

Fig. 4 shows a method of preventing a "bell-mouthed" hole (large at the ends). A shell about 3/16 inch long is left on each end of the work, which is cut or ground off after the lapping is finished. This will remove the bell-mouthed part, which is otherwise practically unavoidable. The causes of a bell-mouthed hole are as follows:

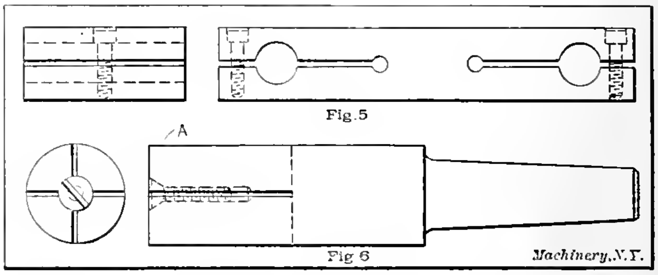

Fig. 5. Adjustable Cast-iron Lap. Fig. 6. Form of Lap for Blind Holes

1. Too much loose emery and oil at the mouth of the hole, which assists in cutting faster.

2. Lapping too long in one position, causing the cutting medium inside the hole to become dull, so that the abrasive which is outside, being sharp, cuts faster.

3. Lap arbor under-size, not straight, and too long. When possible, the contact portion of a lap should be shorter than the work, which will greatly assist in preventing a taper hole.

Fig. 6 shows the style of lap to use in a hole which bottoms, or does not extend through the piece to be lapped. It is slotted and tapped for an expansion screw, which makes adjustment very easy. The slots hold the loose particles of abrasive. This style of lap is usually made of cast iron, and has a taper shank which is fitted to the drill press or lathe spindle. With it a hole which bottoms can be lapped straight, as the point of contact on the lap extends back from the end about 1/4 inch to a point *A*; beyond this point it is slightly tapering.

If the methods given in the foregoing are not in accordance with the best practice, I shall be very glad to read in the columns of MACHINERY of any which have been actually and successfully used in high-class and very accurate machine and tool construction, where quality and quantity have been the guiding powers.

PLAINER LETTERS AND FIGURES IN DRAFTING-ROOM AND SHOP

Everybody will agree that letters and figures too plain and distinct would be difficult to obtain. Many will also agree that certain small details properly attended to would contribute much to a quicker and clearer understanding of written characters of all kinds. Is it not a curious truth that characters representing sounds—letters—are in the case of the twenty-six used in our language, so diverse in form that each may easily be distinguished from any and all the others —though few mistakes would occur if this were slightly otherwise—while in the case of the nine digits where one character gives absolutely no clew to the identity of any other when used in groups, and where the identity of each character is of relatively great importance, we use forms that not only may be but often are mistaken one for the other?

Even on the printed page, that in all cases is viewed from the bottom only, the use of sixes and nines which are the same inverted, is to be condemned; and in shop drawings and tool marking it is utterly indefensible. The forms of numerals used by most persons in writing are far superior to those

in use by most draftsmen on their drawings or by the designers of typewriter type, or the designers of stamps in general. Not only should the nine be different in *form* from the six and all other figures, but eights, threes and fives should each be so distinct in form from all the others that a slight failure to print clearly or a slight wearing or dirtying of a print, or carbon copy, would not lead to error or that annoying uncertainty so often met with in the shop.

It is needless to say that no radical change can be undertaken. An attempt on the part of the writer to distinguish the figure seven by the use of a short horizontal line across the center of its stem soon led to its abandonment because sevens so treated were persistently read F.

A brief review of the nine digits as used by draftsmen,

Fig. 1. Suggested Changes in the Form of Figures

diesinkers, type designers and some others, leads to the following suggestions: Avoid the use of the "Roman"; it has perverted so upright a character as the figure one and made it look like other things. Two has suffered also.

The figure three is good with flat or a curved top, with a wide open low-hanging lower lip or a return curve making the lower opening more like a slightly enlarged upper opening of a curved top three, but care should be used that the fives and eights used therewith are so different as to make confusion of the characters difficult. A good combination would seem to be a flat top three—no Roman on the left end of the flat—and an open lower part (see specimen A, Fig. 1). The five to be used with this three should be fairly well

862	551	556	561	566	571	576	581	586	591	596

Fig. 2. The Clear, Open Style of Figures commonly used in Mathematical Tables

closed (see specimen B). Then the eight of the usual form would not be mistaken for either three or five.

Six as usually made is not open enough. Many steel stamps of medium and small size have the figure six of such a closed form as to make reading uncertain even where there is no question of confusion with nine. An open figure six (specimen C) is certainly much clearer and less liable to misreading than one of those would-be artistic affairs (specimen D).

The figure seven has suffered slightly at the hands of the vertical writer who sometimes forgets to be even vertical, and makes his stem take on a reverse angle (specimen E) when he should make this member an exception (see specimen F). The distinctive mark at the left end of the horizontal member should be retained (as shown) as it prevents mistaking seven for one when it stands too close to the right of a five.

Eight would certainly be more distinctive and less likely to be taken for something else if it retained the stem used in script. Even when threes and fives are made as suggested, the beautifully rounded and symmetrical outlines of eight, as usually made, are not sufficiently characteristic for the purpose.

As made, the nine is perhaps the worst offender of all. Not only must it be helped out with prick-punch marks, dots and bars, but it is often so closed as to resemble its neighbor, the characterless character, eight. A straight stem nine has everything to recommend it from the shop man's viewpoint.

The writer hopes the foregoing may lead to a discussion of the subject. Its importance is not likely to be overestimated.

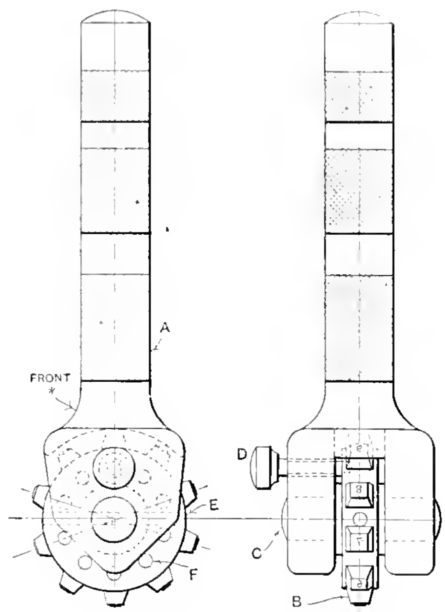
Wm. S. Rowell

Morton Park, Ill.

[The different styles of figures shown in Fig. 2, which is reproduced directly from a page of Gauss' logarithm tables, are commendable because of their clearness and dissimilarity, which tend to lessen mistakes. Figures of this kind are generally used in mathematical tables. It will be noted that there is a decided difference between all the figures, which are not only of a very open style, but, in some instances, of different heights as well.—Editor.]

NUMBERING TOOL

The numbering tool shown in the accompanying engraving is made to be used as if it were a single die. This tool will be found very convenient in the machine shop for numbering machine parts. The handle *A* is turned from tool steel and is hardened on the upper end. The hardened wheel *B* contains around its periphery the numbers from one to nine and a cipher. This wheel is fastened to shaft *C* by a pin *E*, which is driven through both parts. A screw *D* with a conical point fits in the holes *F* in the side of the stamp wheel, thus holding the latter in position when the tool is in use.



Numbering Tool with Rotary Stamp Wheel

This screw is hardened and knurled. Shaft *C* is casehardened and it should be well fitted to its bearings. Crossed lines or a star indicates the front of the tool so that the figures may be held right side up without any trouble. By combining the usual ten dies upon one wheel in this manner, a lot of useless handling is done away with and the work of numbering parts is greatly facilitated.

L. H. Georger

Buffalo, N. Y.

LAPPING OF SMALL HOLES

Mr. Crosby's article on lapping in the February number of Machinery reminded me of a personal experience in that line about three years ago. I was then a college student and spending my vacation in a small shop manufacturing a special kind of sewing machine. The shop was not equipped as well as it might have been, and as a result the only manner of finishing the holes in the positive-motion cam-rollers *A*, Fig. 1, was by lapping. Hundreds of small shops all over the country finish work in this way.

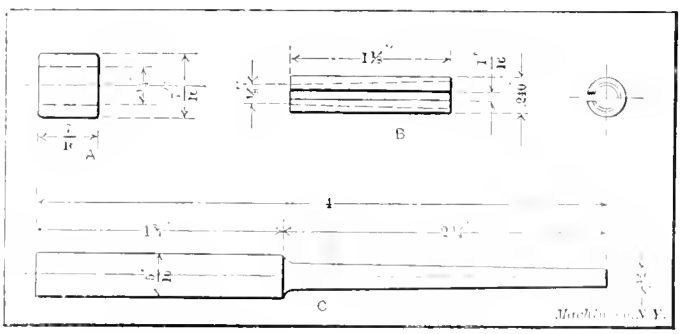


Fig. 1. Lap and Lap-arbor for Lapping Cam-roller shown at A

The rollers were made in a screw machine and casehardened. An exact size for the lapped holes was not necessary;

what was wanted was a straight hole, entirely free from "bell-mouths." The amount of metal to be abraded in this manner was rather abnormal, ranging anywhere from 0.005 to 0.010 inch.

The lapping was done in an ordinary speed lathe, and the rollers were held by the three most useful fingers of the right hand. This latter circumstance, although inconvenient, was the only practical method that gave very satisfactory results.

A taper arbor *C* was chucked true in the lathe and was not removed while the lathe was being used for lapping. This arbor had a taper of ¼ inch per foot, the same as a standard taper pin. The laps, one of which is shown at *B*, were made out of solid brass rod. The arbor holes were drilled and reamed with an ordinary taper pin-reamer. The

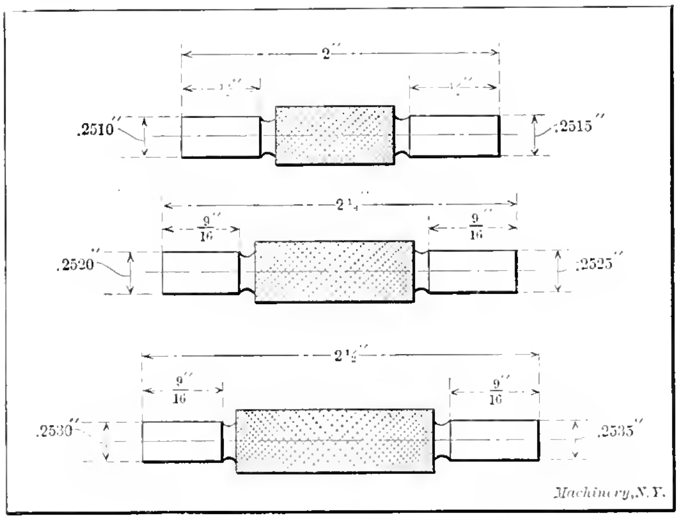

Fig. 2. Gages for Testing Lapped Holes

laps were then split while on the taper arbor, by means of a small square-nosed tool fixed in the tool-post and fed by hand, with the lathe spindle locked in place.

Three hardened and ground limit gages (Fig. 2) each end of which varied by 0.0005 inch, were constantly used during the process of lapping. Fine emery and oil served as an abrasive.

From time to time the laps had to be dressed with a file and tested with a pair of micrometers, as everything else being equal, "bell-mouths" were invariably the result of unevenly-worn laps.

The gages shown were made by the author from broken taps and milling cutter shanks, and they were machined and ground to size on a bench lathe. Not being very elaborate, they were made of varying lengths to prevent confusion.

Flint, Mich. M. Terry

CLEARANCE FOR BROACHES

There is one point in the article published in the January number of Machinery, engineering edition, on "Cutting Square Holes on a Keyseating Machine," upon which I cannot agree with the writer, *viz.*, giving no outside clearance to the teeth of a broach. The advantage gained by the support obtained with no clearance would be counteracted by the scoring of the work which would be caused by this type of broach, for immediately back of the cutting edge on each tooth, while cutting, the surface of the work is perfectly dry, and owing to this kind of broach never cutting to its full size the first time through the work, the friction caused by the hole being smaller than the back of each successive tooth and the dry surface of the work, prevents a good finish from being obtained.

Under the most favorable conditions, lubricating the cutting edges of these broaches is difficult, as each tooth of the broach is lubricated by the amount of lubricant carried in the flute cut to form the tooth; therefore the longer the hole to be broached of a given size, the less satisfactory the result will be, as the lubricant is used up before reaching the bottom of the hole, and if the tooth space is not of sufficient area to hold the chips accumulated, there is a tendency for the broach to seize.

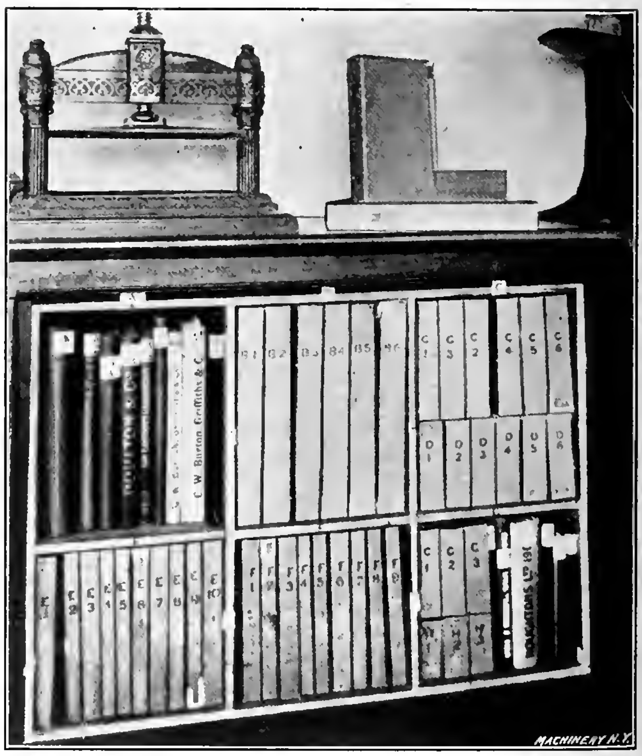
The style of broach that I have found most satisfactory in actual practice is made with a pilot 2 inches long, the diameter of which should be equal to the largest size of cutting edge on the broach. Each tooth should be relieved on the outside and undercut to form front rake; each tooth should increase in size 0.002 inch, except the last three teeth, which should be parallel and equal to the finished size of the hole. The area of each flute for each tooth should be as large as possible without making the tooth too weak to stand the strain of cutting. The diameter of the shank should be equal to the width across the bottom of the flute, of the largest tooth, and the length equal to the length of the hole in the work plus the depth of the guide hole in the ram of the broaching machine. W. C.

CATALOGUE FILING SYSTEM

I was greatly interested in the editorial in the November number of Machinery, describing a system of filing catalogues. At our works, for many years no attempt was made at systematic filing, and when a particular catalogue was called for, it was rarely forthcoming until a long search had been made for it. At last it became absolutely essential that some system of filing should be adopted.

First all dead and duplicate matter was removed, thus considerably reducing the number of catalogues to be handled. A number of cardboard boxes were then made, each measuring about 12 by 9 inches, with a width of 1 inch. The boxes were numbered and lettered at the back, and then placed in suitable pigeon-holes in a vertical position, as shown in the accompanying engraving. The letters corresponded with the pigeon-hole letters, and the numbers were run consecutively under each letter. Each box was then filled with as many books or leaflets as it would conveniently hold, each book being numbered and lettered the same as the box, in which it was placed. Large books were not put into the boxes, but simply placed on the shelves, library fashion, as shown.

As the boxes of the size given were found to be too deep



Cabinet in which Catalogues are filed

for small books, we had some made L-shaped. This allows easy extraction of the books, and at the same time keeps the backs of the boxes in line, thus preserving the neatness of the arrangement.

The catalogues were indexed in a card index under the firm names, and another index of subjects is being arranged as required. This latter index should be very valuable when more fully developed. The system is really very simple, costs little to install, and can be gradually introduced. The file is neat in appearance, and we have found it to answer its requirements admirably. C. J. Robertson

West Bromwich, England.

DANGEROUS OXY-ACETYLENE APPARATUS

Believing that you are desirous of informing your readers correctly, concerning the bad practices which are resulting disastrously to the oxy-acetylene industry, you are requested to publish the following communication. Realizing that some of your readers may possibly consider that the statements were inspired by a selfish interest, we invite a most searching investigation as to their correctness:

If the union of oxygen and acetylene did not produce an unusually powerful agent, the oxy-acetylene process would not have its present value. Acetylene is by far the richest of all gases in carbon, and combined with oxygen, produces much the hottest flame that has yet been created. It is generated from calcium carbide, which is nothing more than coke and lime combined at a very high temperature, but the finished product is as inert, and as little dangerous, as crushed stone, unless put in contact with water, and it can be subjected to any kind of rough usage without the least danger. Acetylene itself, can not be ignited without a mixture of air, or oxygen, unless it is compressed to more than thirty pounds pressure.

Chemically, oxygen is made from chlorate of potash, and similar materials, which are not dangerous unless placed in contact with carbonaceous matter, so that neither carbide, acetylene, nor the chemicals, are at all dangerous if they are properly handled; improperly treated, they can be made exceedingly dangerous, just as can ordinary coal, or water gas, or any of the hydro-carbons, such as gasoline, or oil.

The present acetylene generator is the evolution of various types that have been tested by years of use, and most of the earliest processes have been discarded by responsible manufacturers. Hundreds of thousands of acetylene generators are in use in the United States, and have become so important in the lighting industry, that they are the subject of yearly inspection by a body of engineers, in a laboratory which has been established by the National Board of Fire Underwriters. These engineers have become experts in the generation of acetylene, and have prescribed rules for the construction of such generators, which are the outcome of years of constant examination of apparatus of this character. Generators built in accordance with these rules, can be accepted by the public as desirable types.

These engineers, and the experience of a number of reputable manufacturers, have demonstrated beyond question, that what is known as the carbide-to-water types, are most desirable for the generation of acetylene. Carbide has what is termed "endothermic heat", which is similar to the heat of lime, when slaking, only the heat is much greater. One pound of carbide will boil six pounds of water; consequently the engineers for the insurance underwriters have a rule, requiring one gallon of water for each pound of carbide, which, it will be apparent, is sufficient to insure cool generation.

The types generally discarded are known as the water-to-carbide generators. The methods employed in this type were to sprinkle water on the carbide, or to flood compartments, or were of the recession type, where the water rose to the carbide and was forced back by the gas generated when the water came into contact with the carbide. All of these types are objectionable, because there is not a sufficient supply of water present for proper chemical reaction, and it is entirely absent so far as cooling is concerned. The result is that more or less gas is polymerized, or turned into tar vapors, by the excessive heat evolved locally, making a poor gas; and with rapid generation, there is danger of the heat becoming so great as to melt the portions of the generator in contact with the carbide, and to create danger of explosion should the generator be opened when the carbide is in this heated condition. Generally, the carbide is in the interior of the generator, surrounded by water, so that the heat is not perceptible from the outside of the generator, but it exists nevertheless.

Attracted by the supposed profits in the sale of oxy-acetylene apparatus, a new crop of generator makers, who are either unfamiliar with the established methods of generation, or unscrupulous, are springing into existence, and are placing these undesirable types on the market. They are doing exactly what was done with lighting generators, in the earlier part of of their history, until there became a great class of what was known as "tin can" machines, the poor results from which it took years of strenuous efforts by the better class of makers to overcome. These types of generators are even more objectionable for oxy-acetylene welding, than they were for lighting purposes, because the gas consumption is much more rapid, multiplying the bad effects from this improper generation. Should such generators be subjected to the inspection of the insurance engineers, they would unquestionably be promptly rejected.

Bad as is this method of gas generation, a still worse condition exists. It is known to those who are at all familiar with acetylene, that when it is compressed to from 30 to 45 pounds, or more, there is a kind of disintegration of the molecules, causing the gas to be explosive in the presence of a spark. In the early history of the art, some terrific explosions occurred from compressing acetylene in this form, and for a time its use under compression was entirely abandoned. Through a French discovery it was learned that if cylinders were completely filled with a porous material, and this material was then saturated with acetone, the acetone would dissolve the gas to twenty-five times its own volume for each atmosphere of pressure, and that when the pressure was relieved the acetone would give off the acetylene, and that this method not only gave the cylinders a marvelous capacity, but made it entirely safe to use acetylene in this form. The "Presto-o-lite" cylinders, which can be found on almost any automobile, are examples of what has been done in this line, and many railroad cars are lighted by this system. It is also employed quite extensively in oxy-acetylene welding for portable uses.

In the face of past disastrous experience, there are persons who are manufacturing acetylene by compressing it direct from carbide, without purification, and during the past year there have been several fatal accidents from this cause. In one case nine people were killed, and the directors of the International Acetylene Association held a special meeting, and passed resolutions condemning this process, which is nothing less than criminal to employ.

A method is being used to make apparatus portable, which is nothing more or less than to place an acetylene generator on an ordinary truck, and wheel it about. A generator in this position is not only likely to be accidentally tipped from the truck, but it may be placed in close proximity to red-hot furnaces, or struck by swinging cranes, or injured in many other ways, and it does seem as though any careful, thoughtful person could immediately realize the danger of such an arrangement. If the generator should be tipped over, it would immediately bring the whole body of water and carbide into contact, which would certainly burst the generator, and the volume of gas released might come into contact with fire, and an explosion follow. Obvious as is this danger, there are men in important mechanical positions to whom it did not occur until their attention was called to the possibilities. Certainly, no intelligent insurance representative would approve of such apparatus.

So far from acetylene being considered dangerous, when properly manipulated, the highest insurance authorities have concluded that it is much safer than movable units, such as lamps; and there is no reason why it should not be equally safe for oxy-acetylene purposes.

The conditions with regard to the generation of oxygen, are not much better. The desire of many persons, who can use the oxy-acetylene welding process to advantage, to obtain apparatus at very low cost, has proved to be a great incentive to constructing the apparatus cheaply.

Oxygen has been produced in this country for many years from chlorate of potash, and similar chemicals, but in such cases it has been the practice of the most prominent manufacturers to generate this gas under only sufficient pressure to wash it thoroughly, and force it into a gasometer, from which it is compressed by a compressor into tanks for portable use. It does not require much thought to realize that it would be much cheaper to generate the oxygen in the retorts, under sufficient pressure to force it into the tanks ready for use. This would cut out large washers, the gasometer, and the most expensive part of the plant, the compressor; such a plant could be built at small cost, and at considerable profit. That this is

being done, and advertised quite extensively, requires only the examination of the advertising columns of a number of trade papers to show.

The most approved types of plants generating oxygen from chemicals, have the compressors built with two stages of compression, with an intercooling coil between the cylinders, and with the cylinders totally submerged in water, so that even though there are impurities in the gas, there is not sufficient heat generated to ignite the mixture. It is also required that the parts of these compressors subjected to oxygen, must be of non-corrosive metal, which adds still further to their cost. It will be evident that plants not having these necessary requisites, can be, and are sold, for much less than properly constructed apparatus.

Defective and dangerous types of oxy-acetylene apparatus have not, as a rule, given satisfactory results and tend to discredit the process. Such apparatus has injured the art not only in this country, but in Europe as well. Solicitations have been received by the company which the writer represents, to sell its apparatus in Austria, by a very prominent firm, whose letter states that that country has numerous cheap and ineffective plants, which have brought the process into disrepute.

AUGUSTINE DAVIS,
New York. President Davis-Bournonville Co.

THE DIFFERENTIAL SCREW FALLACY

I notice an article in your April number (page 647, engineering edition) on the Derihon testing machine, and without criticising the principle upon which it is based as giving more or less reliable indications of hardness, I am very much surprised to see, in this age of enlightened mechanics, the old-fashioned device of a differential screw adopted as a means for increasing power. The earlier text-books on mechanics estimated the force exerted by a screw from a comparison of the distance traversed by the hand lever and the corresponding advance in the screw, and, by the same method, the differential screw was shown to have wonderful possibilities. But no allowance was then made for friction, which has since been shown to eat up about 90 per cent of the power applied to standard bolts and nuts, and, as a matter of fact, it has been demonstrated practically as well as theoretically that the pitch of a screw has very little effect upon the pressure exerted by a given force at a given distance from its axis.

It is high time, therefore, for the differential screw fallacy to be exploded, and without knowing the exact details of construction, I feel very safe in asserting that the pressure exerted by the differential screw in this case is no greater than the pressure that could be exerted by the screw *C* alone if attached directly to the handle bar *M*.

I came to the conclusion about thirty years ago that differential screws never accomplished any useful purpose, and established this fact by experiments as well as by analysis. Later in 1891, "Some Experiments with a Screw Bolt" was reported to the American Society of Mechanical Engineers, which confirmed my own experience, and in discussing this paper, I gave a general analysis of the power of screws as affected by friction.

Experiments on the friction of screws were again reported to the same society in 1895, and it should be more generally understood how little the pitch of a screw really has to do with its power. This really depends more upon the relation between the diameter of the screw and the length of the lever arm to which it is attached than it does upon the pitch of the screw, and it makes little difference whether the advance of the screw comes from a single thread or from the difference in the pitches of two threads combined.

There may be instances in which differential screws can be used to advantage for the purpose of reducing velocity ratios, but when used for the purpose of increasing power they are, and always have been, a mechanical absurdity.

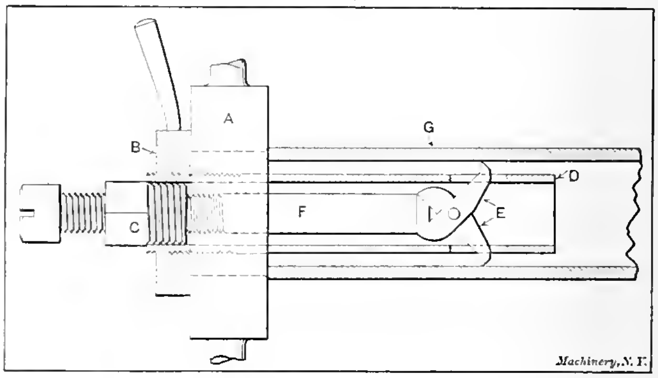
WILFRED LEWIS,
Philadelphia, Pa. President Tabor Mfg. Co.

[The use of the differential screw principle in the Derihon apparatus enabled the designer to provide a thrust bearing of comparatively large area and small pitch diameter. A swivel and suitable thrust bearing would have been necessary if *M* were mounted on *C*, in order that the steel ball *B* may not rotate when in contact with the piece being tested. The efficiency of a screw thrust bearing designed like this in the Derihon apparatus is undoubtedly much higher than that of a plain thrust bearing of equal diameter. We agree with Mr. Lewis that the efficiency of differential screws in general, is very low.—EDITOR.]

PIPE FITTER'S KINK FOR STARTING DIES

While in a pipe fitter's shop recently, the subject of threading pipe came up, and the man of the shop showed me the device shown in the sketch which he said had helped him in threading pipe that was hard to start the thread on.

In this case the part *D* is a piece of ½-inch pipe about six inches long with a thread cut on the outer end about two or three inches; *C* is an ordinary plug with a hole through the center, through which a 5/16-inch rod is screwed, the plug



Device for Starting Dies on Pipe

being screwed in the end of the ½-inch pipe; *E* are steel jaws pivoted, as shown, and forced outward through holes cut in the sides of the ½-inch pipe; *B* is a plate with a handle, which is screwed on the outer end of the ½-inch pipe, and *A* represents the die used in threading the pipe *G*. By screwing the rod *F* either with a wrench or screw-driver, the jaws are forced outward against the inside of *G*; then by screwing the die and the plate *B* at same time, the die will start the thread in a very satisfactory manner. The device is easily removed by unscrewing the rod *F*.

LOOSE CORRESPONDENCE METHODS

Americans would sell more machinery abroad if they were less "slap-dash." I write, say, to the Robinson Lathe Co. asking who is its German representative; in the meantime the company changes to the United States Machinery & Mfg. Co., or some such name, and answers under that head simply: "Our German agents are Blank & Bros." I have no letter copy with the U. S. M. & M. Co. so their statement does not interest me a little bit. Later I write a second letter to the R. L. Co. and get a second reply from the U. S. M. & M. Co. again without any reference to the R. L. Co. This is a common experience. Also, young firms with high-sounding names advertise or their products are described, without any street address; and inquiries come back stamped "Unknown." The Niles-Bement-Pond Co. needs no street address; but the Universal Machine Tool Co. and the General Mfg. Co. do.

ROBERT GRIMSHAW
Dresden, Germany.

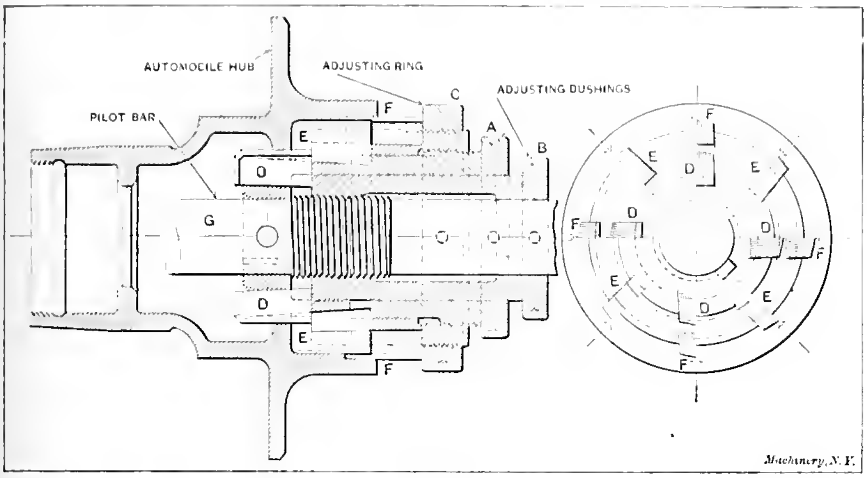
POINT IN GAS ENGINE PISTON MANUFACTURE

The article in the April number of MACHINERY about machining gas engine pistons, does not bear out my experience in such matters. In my experience the boss cast on the closed end of the piston to hold it by when turning, would have a mushy center where cut off. This would be the worst possible thing to have on a gas-engine piston, making a weak end, and giving a ragged surface, causing premature ignition. There would also be a chance of loss in work and material, as cutting off this boss is the last of a series of operations. Our company does not permit a piston to pass, having a rough or porous end; we also chill all pistons over the ring grooves.

Oil City, Pa. JOHN REID

AN ADJUSTABLE BORING-HEAD

A design of adjustable boring-head which can be used for boring three different sizes at once is shown in the engraving. The particular tool illustrated is intended for boring out the axle hubs of automobiles. The body of the boring-head is of cast iron, and it contains, as shown more plainly in the end view, three different sets of blades for reaming a corresponding number of diameters in the hub. The blades fit into slots which should be dove-tailed to an angle of from 3 to 5 degrees to prevent the blades from lifting out of the head. The bottoms of these slots are also tapered, as



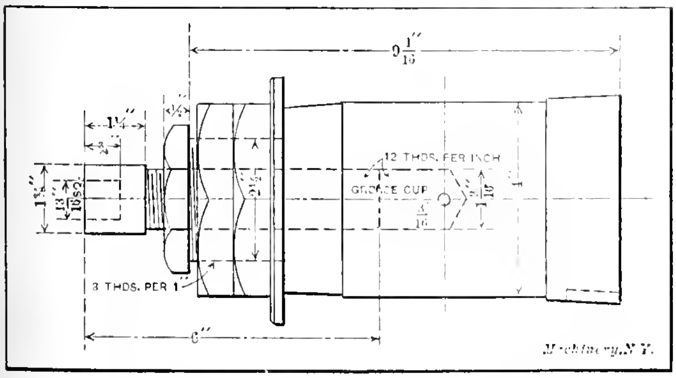
Adjustable Boring-head for Machining Three Different Diameters Simultaneously

shown in the sectional view. The blades, of course, have a corresponding taper so that by changing their longitudinal position they may be set to different diameters. The body of the reamer is attached to a pilot bar *G* by a taper pin or key. This bar is threaded (16 threads per inch), as shown. Adjusting bushing *B* is an accurate fit over the bar on one end, and is threaded to it on the other. The recess which is cut into this bushing is to do away with the long bearing and to lessen the length of the threaded part. A second adjusting bushing *A* is accurately fitted over *B*. The outside of this second bushing is threaded into the reamer body, and it is also a close running fit on the end. The last adjusting bushing is threaded to the outside of the reamer body. As will be seen, any one of the three sets of blades may be adjusted independently. For example, by screwing in bushing *B*, the four blades *D* could be adjusted out to any dimension within the limits of adjustment. Similarly, by turning bushing *A* or *C*, the blades *E* or *F* may be adjusted, respectively. These blades are made of the best tool steel and they should be a snug fit in the head. They can be ground to take an end cut when this is necessary.

Pawtucket, R. I. HAROLD E. MURPHEY

GREASE CUP IN THE WRIST-PIN

A grease cup that is made by boring a hole in the center of the wrist-pin and screwing in a plug which has a square recess



Locomotive Wrist-pin with Self-contained Grease Cup

which will take the regular grease cup wrench is shown in the engraving. A lock-nut is provided to prevent the plug from working loose. Regular hard grease is used. Two holes are drilled in the wrist-pin, one in the front and one in the back, and oil grooves are cut in the connecting-rod brasses. This plug is the design of Mr. Charles Cotter, traveling engineer for the Duluth and Iron Range R. R., and it has been used on the engines of this road for a number of years, giving great satisfaction. AUSTIN G. JOHNSON

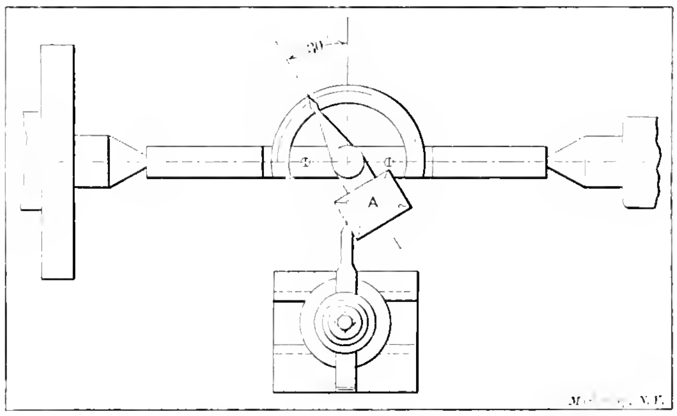
Two Harbors, Minn.

TINNING STEEL PANS

In answer to the question by G. S. on the How and Why page of the February number of MACHINERY relative to the tinning of steel pans, I would suggest the following, which I tried with good results: In tinning sheet metal, if the parts are scaly, they should first be sand-blasted or pickled so that the tin will adhere properly. Before tinning, they should also be put into a muriatic acid bath. The parts are then dipped into melted tin, removed and plunged into oil while still hot (we use melted tallow). They are then re-dipped into the tin; this second dipping gives a thicker and heavier plate. The oil acts as a flux which gives the tin plating a brighter and smoother finish. After the pieces have been dipped a second time, they are put onto racks to drip until cold. The cast-iron pot or vat in which the tin is melted, should be about 12 inches deep and several inches wider and longer than the pans. Wire hooks are used when dipping the parts to be tinned; the pieces should be perfectly dry before they are placed in the molten metal. J. S. S.

COMBINATION TEST BAR AND PROTRACTOR FOR THE LATHE

A combination test bar and protractor intended for use in the lathe is illustrated herewith. It is quite difficult when the cutting edge of a tool is to be set to a certain angle, to



Protractor for Setting Lathe Tools, which is mounted on Hardened and Ground Test Bar

hold an ordinary protractor with one hand, and adjust the tool with the other. With this device the protractor is set to the required angle and then the tool is adjusted to one of the hardened edges on the rectangular piece *A*. The edges of this rectangular piece are ground after the tool is assembled, thus insuring their accuracy. The cylindrical part on which the protractor is mounted is hardened and ground so that it may be used as a test gage. When the protractor is being set, the lathe centers are tightened just enough to hold it in position so that the workman has both hands free for setting the tool. The small slots in the corner of the piece *A* were cut in to prevent it from cracking during the hardening operation.

This protractor may be used to advantage for setting lathe tools when making angular cutters for the milling or screw machine or when making bevel or miter gear blanks, and for setting threading tools for either internal or external threading. E. E. MARTIN

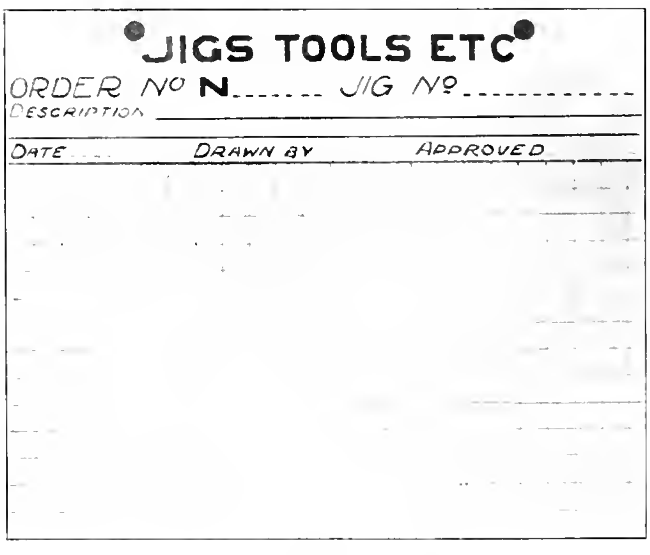
Providence, R. I.

SIMPLE METHOD OF MAKING BLUE-LINE PRINTS

Some time ago the writer found that it would be a great convenience to have a number of forms, but as these were to be used in small quantities it was hardly advisable to have them printed. Blueprints with blue lines upon a white field was just the thing, and a very simple method of making them was found, which will possibly be of interest to other draftsmen.

A negative was prepared as follows: A piece of tracing cloth somewhat larger than the desired size was placed upon a smooth board with the dull side of the cloth exposed, and the edges tacked securely. Two thin coats of black shellac varnish, such as is commonly used by pattern-makers, were applied to the cloth, so as to make it perfectly opaque. The shellac was allowed to set for about an hour, so that it was thoroughly dry, but not long enough to become brittle, and then the tracing cloth was removed and placed upon the drawing board with the varnished side up. The desired lines were then laid out upon the tracing cloth by rubbing it thoroughly with soft white chalk, and then drawing the lines upon it with a lead pencil, the pencil point leaving a black line where it removed the chalk from the black surface. The letters and figures desired were laid out in the same way. The ends of a piece of wire about six inches long were then ground down to a sharp point, one end being flatted slightly on an oilstone. The lines in the chalk were then traced over with the sharp point of this wire so as to scratch them evenly through the shellac. The letters were also outlined with the sharp point of the wire, and then the shellac inside these outlines was scraped off with the flat end of the wire. The shellac was found to come loose very readily, so that with a few minutes' practice letters could be formed that looked fairly presentable, almost if not quite as easily as they could be made with an ordinary pen upon tracing cloth. The chalk was then removed, and after trimming, the negative was ready to make blueprints from.

The accompanying illustration shows a blueprint that was



Print with Blue Lines on a White Sheet

made from a negative which was the writer's first attempt along this line. This negative has been in use for quite a long time, possibly two hundred prints having been made from it, and it shows no signs of wear. By referring to the engraving it will be noticed that the cross lines in the body of the print are lighter in color than the heading, so as not to obscure the writing and sketches made upon it. This was accomplished by placing a piece of thin bond paper in front of the negative when printing.

This method has been used by the writer in preparing forms for monthly labor records, monthly reports, shop sketches, etc. Of course it is hardly applicable to the preparation of complicated drawings, and possibly could not be recommended for forms having a great deal of small lettering or figuring upon them, but for plain ruled forms with fair-sized letters, it does very well.

It was mentioned previously that the shellac should not be allowed to set long enough to become brittle before finishing. The reason for this is that when the shellac becomes brittle it will chip away when scratched, making it impossible to get satisfactory results. BRUCE C. MCALPINE

Jackson, Mich.

DIVIDING A CIRCLE INTO EQUAL PARTS

A simple method of dividing a circle into any number of equal parts is shown in the accompanying illustration. To divide any circle, draw a line *A-B* from *S* at any convenient angle with *L-S*; then divide *A-B* into the number of parts that the circle is to be divided into. Draw from the last point *G* a line *D-C* through *L*. Count down two divisions from *G* on *A-B* to *E*, and draw *E-F* parallel to *C-D*. Strike two arcs at *H* from points *L* and *S* and with *L-S* as a radius. Then draw the line *N-K* through point *P;* the point of intersection *M* will then be the first point on the circle; in other words, arc

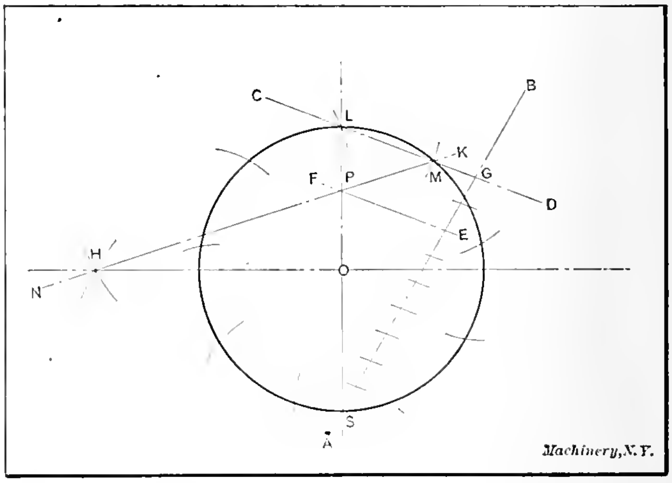


Diagram for Dividing a Circle into Equal Parts

L-M is one division of the circle. Of coure I do not claim to be the originator of this method of dividing a circle; it is, however, so simple that it will doubtless be appreciated by those who have not been familiar with it. ROBERT WILKINSON

Buffalo, N. Y.

[We will be glad to receive from any of our readers the geometric proof of this method of dividing a circle, which will doubtless be of general interest.—EDITOR.]

FINISH ON IRON CASTINGS

In the February number, E. S. S. asks through the How and Why page for a good method of securing a glossy enameled finish on iron castings. Two methods are given in the following, which I have used with good results, after a long search for suitable preparations:

For a fine, rich, black gloss, I use Minett's air-drying black varnish, which can be obtained from almost any wholesale paint and oil store. Two or three coats of this varnish should be applied; it dries quickly and when dry becomes hard. It will weather longer than any preparation that I know of, and it also fills the pores and will not break out in streaks. This varnish is cheap, and it gives a rich, bright gloss to the work.

When castings are very porons, the following preparation may be used as a filler to obtain a smooth surface: For one quart of this filler mix one-half pound of white lead, one pound of whiting and one gill of varnish, with enough turpentine to properly thin the filler. The white lead is to bind or hold the mixture together, the whiting is for filling the pores, and the varnish is to give a glossy finish. After putting on one coat of the filler, a coat of ivory black should be applied, and then a coat of varnish. This finish is not as cheap as when the black varnish is used, but it is a good one and lasting.

The gray or streaked spots, referred to by E. S. S., which appear on malleable castings are very common, especially after certain metals have been plated. Some experts claim that it is the pickling acid working out of the pores, and I am inclined to believe that this is the trouble. The Platers' Organization of America has, I understand, this same question under dis-

cussion at the present time, but as yet no one has explained how to prevent these streaks from showing. Poor oxidization will also aid in causing the streaks to appear on account of the rough porous surface which contains so many small cavities that secrete the acid. J. S. S.

IRREGULAR SPACING FOR REAMERS

The accompanying table will be found useful in fluting reamers with irregularly spaced cutting edges. All even numbers of flutes from 4 to 24 are given in the column to the left, and the number of turns of the dividing head crank to be made when indexing for each flute are stated in the body of the table. For four flutes, two sets of figures are given, one when the diameter of the reamer is under two inches, and one when the diameter is over two inches. The table gives the movements for the spacing of half the reamer only; then the same movements are repeated for the other half.

IRREGULAR SPACING FOR REAMERS

Table is for one-half the reamer; repeat the same movements for other half

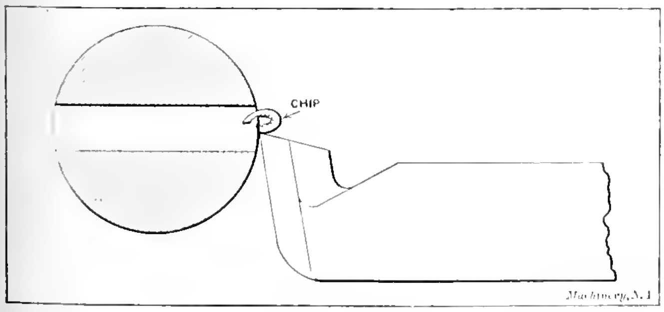
No. of Flutes	Turns for Dividing Head											
4	$9\frac{3}{4}$	$10\frac{1}{4}$	Under 2 inches diameter									
4	$9\frac{1}{2}$	$10\frac{1}{2}$	Over 2 inches diameter									
6	$6\frac{1}{3}$	$6\frac{2}{3}$	7									
8	$4\frac{1}{4}$	$4\frac{3}{4}$	$5\frac{1}{4}$	$5\frac{3}{4}$								
10	3	$3\frac{1}{2}$	4	$4\frac{1}{2}$	5							
12	$2\frac{4}{5}$	3	$3\frac{1}{5}$	$3\frac{2}{5}$	$3\frac{3}{5}$	5						
14	$2\frac{3}{7}$	$2\frac{4}{7}$	$2\frac{5}{7}$	$2\frac{6}{7}$	3	$3\frac{1}{7}$	$3\frac{2}{7}$					
16	2	$2\frac{1}{7}$	$2\frac{2}{7}$	$2\frac{3}{7}$	$2\frac{4}{7}$	$2\frac{5}{7}$	$2\frac{6}{7}$	3				
18	$1\frac{7}{9}$	$1\frac{8}{9}$	2	$2\frac{1}{9}$	$2\frac{2}{9}$	$2\frac{3}{9}$	$2\frac{4}{9}$	$2\frac{5}{9}$	$2\frac{6}{9}$			
20	$1\frac{11}{20}$	$1\frac{13}{20}$	$1\frac{15}{20}$	$1\frac{17}{20}$	$1\frac{19}{20}$	$2\frac{1}{20}$	$2\frac{3}{20}$	$2\frac{5}{20}$	$2\frac{7}{20}$	$2\frac{9}{20}$		
22	$1\frac{4}{11}$	$1\frac{5}{11}$	$1\frac{6}{11}$	$1\frac{7}{11}$	$1\frac{8}{11}$	$1\frac{9}{11}$	$1\frac{10}{11}$	2	$2\frac{1}{11}$	$2\frac{2}{11}$	$2\frac{3}{11}$	
24	$1\frac{5}{24}$	$1\frac{7}{24}$	$1\frac{9}{24}$	$1\frac{11}{24}$	$1\frac{13}{24}$	$1\frac{15}{24}$	$1\frac{17}{24}$	$1\frac{19}{24}$	$1\frac{21}{24}$	$1\frac{23}{24}$	$2\frac{1}{24}$	$2\frac{3}{24}$

Freeport, Ill. D. O. BARRETT

[This method of indexing, it will be noted, makes the two halves of the reamer exactly alike, and opposite cutting edges are exactly in line, that is, they are not off-set or "broken up." An article is published in another part of the paper regarding the practice of irregular spacing for reamers, where the subject of "breaking up the flutes" is more thoroughly treated. —EDITOR.]

FINISHING SLOTTED COLLETS IN THE LATHE

A small shop received an order for a number of Brown & Sharpe collets (No. 7 inside taper and No. 9 outside taper). There being no grinder to finish the outside diameter, it meant that the collets must be rough- and finish-turned in the lathe. As the work had to be accurately done, it occurred to me that if the collets were finished and polished before the drift slot was cut, they would be bruised while this was being done, which would make it necessary to go over them again; therefore, I concluded when turning them to allow 1/32 inch above the largest size for finishing after the slots were cut, and to make them straight. When turning these collets after the drift slots had been finished, I noticed that when my turning tool reached the slot, a deep groove was left on one side of it, but when the tool had passed the slot, it cut smoothly. The cause of this trouble was as follows: When the tool reached the drift slot, and as the point left it on one side, a chip was balancing itself on the point so that when the opposite side of the slot reached the tool the chip was between the tool and collet which caused the groove. The relation between the chip, the tool, and the work will be understood by referring to the illustration. Invariably on each succeeding turn of the collet this groove was formed on one side. By driving a piece of hardwood in the slot the trouble was overcome. The wood should not be driven in too tightly, as it may spread the metal on either side of the slot. This wood was also an advantage in filing, as the file did not leave a flat on either side of the slot, as is usually the case.

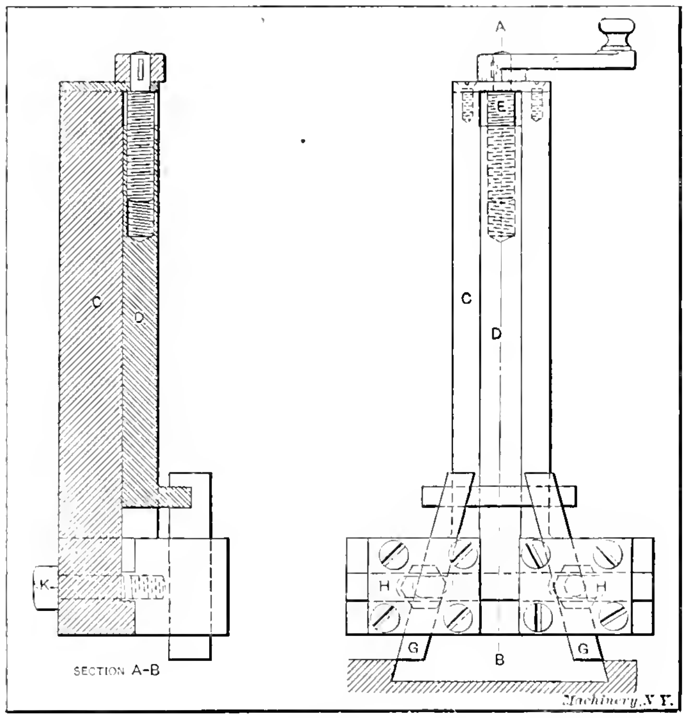


Sectional View of Slotted Work showing Chip Interference when Tool is crossing Slot

Covington, Ky. ROBERT LANG

TOOL FOR PLANING DOVETAILS

A tool for planing dovetails is illustrated herewith. This tool was designed by Mr. C. H. Marsh, foreman of the planing department in the works of Fay & Scott, Dexter, Me. It is used principally to plane the dovetail ways in lathe aprons, in which the lead-screw nut slides. When the tool is in use, the shank *C* is held in the clapper-box of the planer. When the cutters are to be set for planing a dovetail of a given size, the lever *F* is turned, thus moving slide *D*, which, in turn, moves the cutters *G* up or down until they are set to the required width at the top of the dovetail. The head is then raised or lowered until the tools just brush the work; they are then fed into the dovetail by turning lever *F*, the movement of each tool being, of course, on an angle corresponding to its angular position in the blocks *H*. Perhaps a better adjustment of the cutters is secured by loosening bolts *K* and moving the blocks *H* in or out, thus keeping the cutters closer to the tool body. J. GRAY CARD



Tool for Planing Dovetails

Dexter, Me.

* * *

CORRECTION

An error occurred in the wiring diagram No. 7 for shunt reversing motors, MACHINERY'S data sheet for March. The connections for the fields are tapped in on the same side of the line, so of course, there could be no field. One connection for the field should be shown transposed to the opposite side of the line.

HOW AND WHY

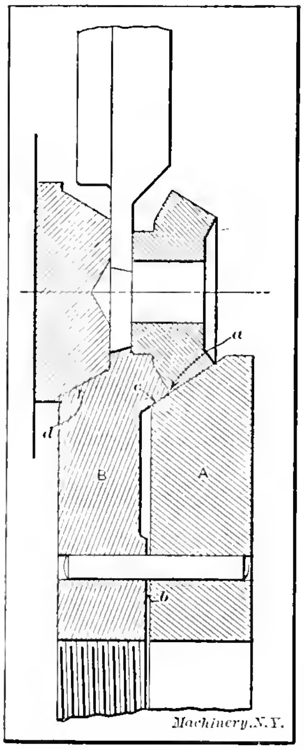
A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details and name and address. The latter are for our own convenience and will not be published

FORMING TOOL FOR BEVEL GEAR BLANKS

H. M.—Kindly give me through the columns of MACHINERY some information relating to the designing of a tool for forming the outside angular surfaces of small bevel gears on automatic screw machines.

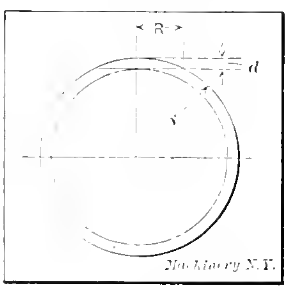
A.—The forming tool for forming the outside angular surfaces of a bevel gear can best be made as shown by the accompanying illustration. The forming tool consists of two sections A and B, doweled together. Two fillister head screws, not shown in the illustration, are also used for clamping the sections together. When grinding the two sections, allowance should be made so that a slight clearance of about 0.002 inch is allowed between the parallel faces at b; then, when the tool is fastened in the tool-holder, the clamping screw will entirely close any space at point a. When grinding the inside face c of section B, the angle should be somewhat less than the corresponding angle on the part A, so that the sections will fit very tightly at a. The angular surface at d takes a roughing cut on the next piece. The calculations necessary for forming tools of this class were quite fully treated in an article on circular form and cut-off tools in the April issue of MACHINERY, so that it will not be necessary to deal with this question here. It may be mentioned, however, that the face of the section A when cut down below the center, would theoretically be slightly concave, but the amount would be so slight that it would be imperceptible, and of no account in practice. When an absolutely true taper is required, a circular forming tool cut down below the center should not be used, but instead a taper turning box tool or a taper turning attachment, operated from the cross-slide. A so-called dove-tail forming tool is also sometimes found convenient. All of these methods have been used to good advantage.



THREAD ROLLING IN AUTOMATIC SCREW MACHINES

J. G. S.—I would like some information relating to thread rolling on automatic screw machines; in particular, I would like to know about methods used for making the rolls for thread rolling on this class of machines.

A.—The Brown & Sharpe Mfg. Co., Providence, R. I., states regarding the method of determining the pitch diameter for rolls for thread rolling in the automatic screw machine, that it is the practice of this company to first determine the pitch diameter of the piece to be rolled and then to deduct from it 1/6 of the double depth of the thread, and to use the constant thus obtained as a multiple for determining the pitch diameter of the thread roll. In general, a thread roll is made of a diameter about three or four times the diameter of the piece to be rolled. In such cases it is, of course, necessary to provide the roll with a triple or quadruple thread, as the case may be, in order that the angle of the thread on the roll shall be the same as the angle of the thread on the piece to be rolled.



The hand of the thread on the roll must be opposite to that of the thread to be rolled. A little consideration will easily make this clear. The calculation of the diameter of the roll should be based upon the pitch diameter of the thread to be rolled, and not upon the root diameter as has sometimes been done and which gives unsatisfactory results. The angle of the thread of the roll must equal the angle on the piece to be threaded, and when the diameter of the roll is a certain multiple of the diameter of the piece being threaded the roll must be provided with a multiple thread corresponding to the rate of increase. The diameter of the thread roll is found from the formula:

$$d = N\left(D - \frac{C}{6}\right)$$

in which d = pitch diameter of thread roll,

N = approximate ratio between pitch diameter of roll and pitch diameter of piece to be threaded,

D = pitch diameter of piece to be threaded,

C = double depth of thread.

As an example, assume that we wish to roll a piece 0.372 inch in diameter with 16 threads per inch, this being a No. 24 A. S. M. E. standard screw. The pitch diameter of this screw is 0.3314, and the double depth of thread equals the outside diameter minus the root diameter, or $0.372 - 0.2908 = 0.0812$ inch. Assume that the diameter of the roll will be made approximately twice the diameter of the screw. Then:

$$d = 2\left(0.3314 - \frac{0.0812}{6}\right) = 0.6357 \text{ inch.}$$

The roll will also have a double thread of 1/8 inch lead, and the outside diameter will equal:

$$0.6357 + \frac{0.0812}{2} = 0.6763$$

and the root diameter:

$$0.6357 - \frac{0.0812}{2} = 0.5951$$

Rolls made according to this formula have given good satisfaction. When rolling a thread on the Brown & Sharpe automatic screw machines, the following points should be taken into consideration: 1. The thread rolling tool-holder should be fastened to the cross-slide which carries the cut-off tool so that the piece will be severed from the bar before the roll returns. 2. The roll should be fed to the work in the same manner as a knurl. 3. The roll should be brought to within 0.010 inch from the piece on the quick rise of the cam, then fed the distance R in the accompanying engraving at a certain number of thousandths inch per revolution, and then released from the work by a quick rise of the cam, at the same time bringing the cut-off tool in position. 4. The feed per revolution for thread rolling is practically the same as for knurling, a table for which was given in MACHINERY, July, 1909, engineering edition. The formula for calculating the rise on the cam for thread rolling is given below; in the accompanying engraving, let

r = radius of piece to be threaded,

d = depth of thread,

R = rise on cam.

Then

$$R = \sqrt{r^2 - (r - d)^2} + 0.010.$$

* * *

In a paper by Mr. W. L. R. Emmett on the application of electricity to the propulsion of naval vessels, read before the American Association of Naval Architects and Marine Engineers, the author states that the efficiency of a turbo-electric installation on board ship can be brought up to 92 per cent, and he also expressed his opinion that no other form of speed-reducing gear between the turbine and propeller could be made to show as high an efficiency. Recent tests, however, on the Mellville-MacAlpine turbine reducing gear, illustrated in the February issue of MACHINERY, engineering edition, shows an efficiency of 98½ per cent.

NEW MACHINERY AND TOOLS

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP

Comprising the description and illustration of new designs and improvements in American metal-working machinery and tools, published without expense to the manufacturer, and forming the most complete record of new tool developments for the current month.

LANDIS HEAVY-DUTY PLAIN GRINDING MACHINE

The accompanying illustrations show a new self-contained **plain** grinding machine of large capacity (16 inches by 72 **inches)** built by the Landis Tool Co., of Waynesboro, Pa. As will be explained later, it is designed to be fitted with special appliances for chilled roll grinding; it will also be furnished with provisions for taking work such as pistons or rods, and similar parts met with in railroad shops. It is essentially,

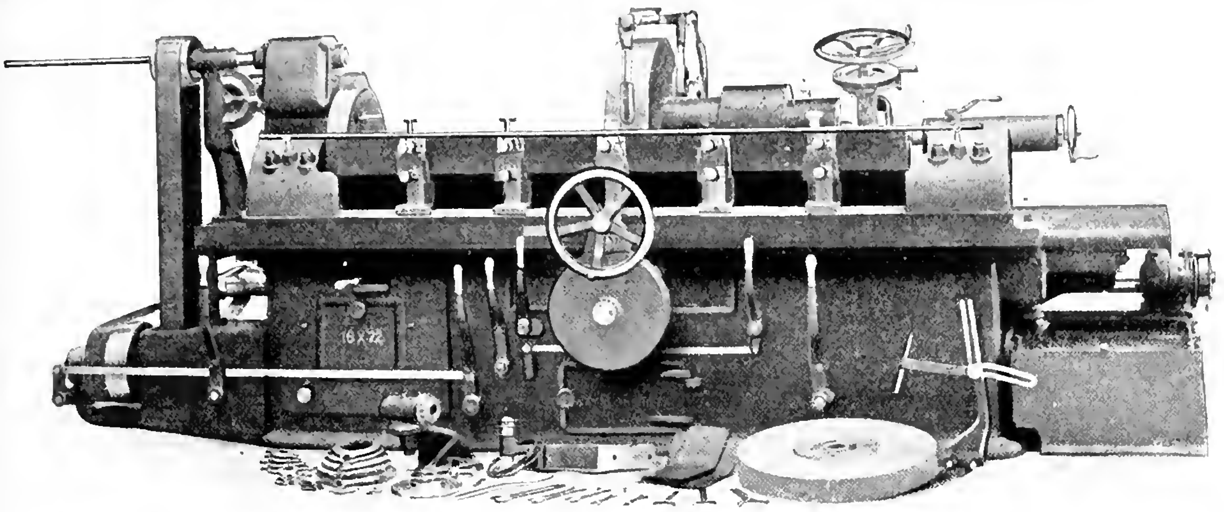


Fig. 1. Landis 16- x 72-inch Plain Grinding Machine for Heavy Duty

however, a plain grinding machine, of high power for heavy-duty operation, fitted for hard service in manufacturing work.

All the conveniences of the older design have been retained. The machine is of the traveling wheel type, with headstock and footstock mounted solidly on the stationary base of the machine. Quick-change, geared speeds for the work, and

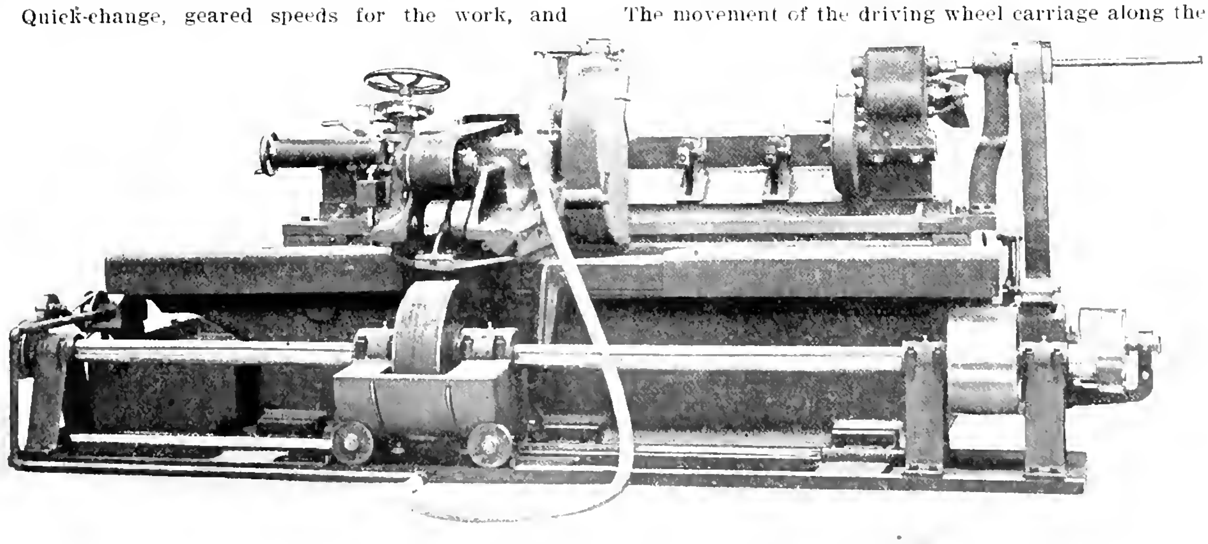

Fig. 2. Rear View of Landis Grinding Machine, showing Self-contained Drive

feeds for the wheel traverse, are provided. The geared feed can be operated automatically, and is provided with an automatic stop. The controlling handles are all reached from the front of the machine. The work speed and wheel feed are started and stopped together by a clutch in the pulley at the end of the feed box at the left of Fig. 1. These drives can also be operated separately, and their speeds are varied entirely independently of each other.

A new and interesting feature of the design is the drive for the wheel spindle. This is best seen in the rear view of the machine in Fig. 2. The power is applied to the large driving pulley at the right, mounted on the heavy main driving shaft, running the length of the machine. This shaft has keyed to it a pulley, mounted in a carriage on rollers as shown, which is connected with the driving wheel slide by an arm so as to always keep in alignment with it. A belt runs from this pulley over a series of idlers and over the pulley on the grinding wheel spindle. These intermediate pulleys are so arranged as to automatically take up any change in the belt length, and at the same time keep it under uniform tension. Almost two hundred degrees of contact are provided on both the driving and driven pulleys. The six-inch belt can stretch about eight inches in length before it is necessary to remove a section to shorten it.

The movement of the driving wheel carriage along the main shaft in unison with the wheel slide is made easier by the method of keying the driving pulley to the shaft. This "key" is in the form of rollers in the hub of the pulley, engaging stepped grooves on the driving shaft as seen in Fig. 4. This does away with the heavy frictional resistance to sliding motion which would be felt if the pulley were keyed to the shaft as usual, especially when driving under a heavy strain. The mounting of the pulley carriage on rollers, in addition to this, gives perfect freedom of movement.

Great care has been taken to give the grinding wheel head the massiveness and rigidity required for the rapid production of accurate work. The spindle is of very large diameter, and is made of hardened steel. The bearings are phosphor-bronze; they are self-aligning and are adjusted in taper bearings to take up the wear. Self-oiling boxes are furnished. The very important feature of protecting these bearings from grit and emery has been attended to, positive dirt-

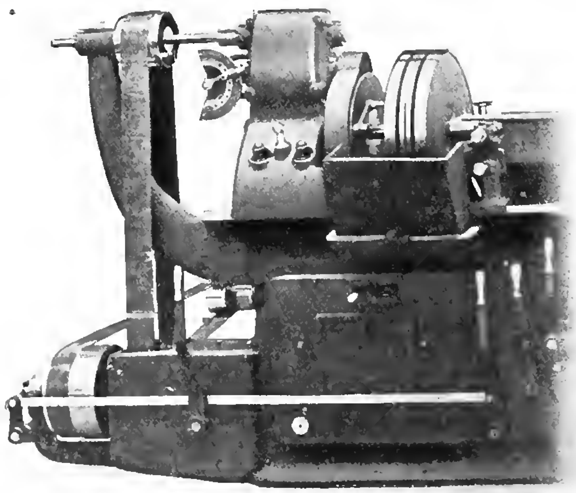

Fig. 3 Heavy-duty Grinder with Gap in Bed, for Railroad Work, etc.

proof covers being used for the purpose. The wheel collar is provided with an angular groove on its face, in which two weights are adjustably mounted. By this means the grinding wheel may be balanced so as to run quietly at the highest speeds. This also is an important feature in the production of good work. Wheels up to 24 inches diameter and 4 inches face can be used on work up to the full capacity of the machine.

Besides driving the wheel spindle, the main driving shaft has also connections with the pump and with the feed and work spindle mechanism. The feed and speed connections are taken off from the pulley at the extreme right in Fig. 2, and at the left in Fig. 1, being belted to a gear box at the end of the machine in front. From this gear box a belt connection with the headstock, which is strongly geared, giving ample power for the largest piece of work that can be placed in the machine, is provided. It gives five rates of speed for each of the two positions of the back gear in the driving box, or ten rates of speed in all, indicated plainly on a dial. All the clutch mechanisms are of hardened tool steel, and all the gears have planed teeth.

For roll grinding, the machine is fitted with special supports for the necks or journals of the work. Previous to the operation of finishing the body of the roll, these journals or necks are themselves ground, with the roll carried on centers the same way as for regular plain grinding, but in grinding the roll face, the work is supported by its own bearings. The importance of having the roll face true and concentric with the journals is, of course, vital. This method of supporting the roll while finishing it has been found the only practical and reliable one for general use.

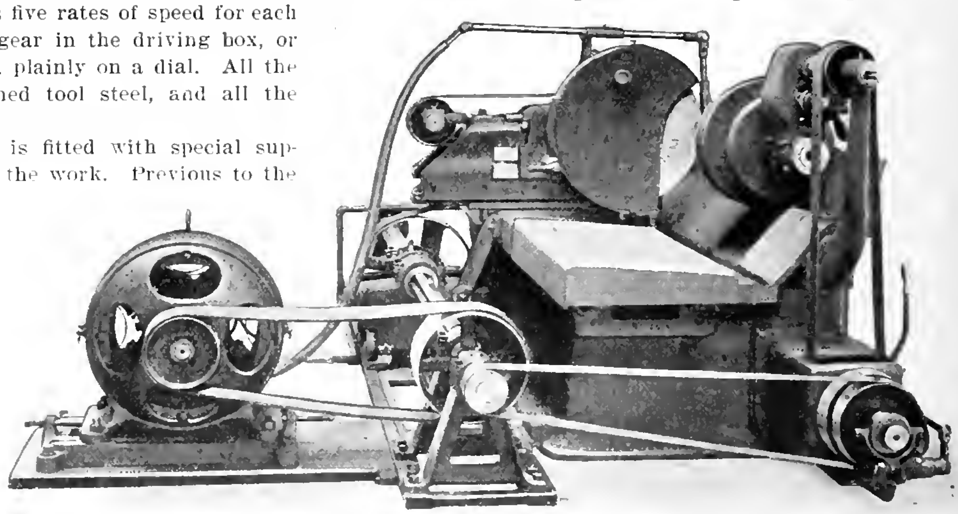

Fig. 4. End View of Gap Grinder, showing also Details of Self-contained Electric Drive

To compensate for any slight error in the alignment of the headstock and center line of the rolls, and to avoid any tendency of the drive to shift the roll from its true position parallel with the bearings, an equalizing fixture is adjusted to the face of the headstock. This drives the roll with equal force from opposite points. Neither the neck bearings nor the equalizing fixture are here shown.

As explained, this machine is also made in a form which is adapted more particularly for railroad work. For this work a gap in the bed is provided, as shown in Figs. 3 and 4. When the gap is provided, the grinder is adapted to handle locomotive pistons, piston valves, valve stems, cranks, links and knuckles, pins, axles, etc., it being possible to grind piston rods with the pistons in place and to swing valve yokes when grinding the stem. The gap can be located at the time the machine is being built in any desired position to suit special work.

STURTEVANT ELECTRIC FORGE BLOWER

The accompanying illustration shows a motor-driven forge blower made by the B. F. Sturtevant Co., Hyde Park, Mass., applied to a pair of Sturtevant forges. The blower is composed of a pressure fan of the multi-vane type, enclosed in a pressed steel plate casing, driven by a direct-connected electric motor, operating from the electric lighting circuit if necessary. The multi-vane type of fan wheel is highly efficient and gives a greater pressure and volume of air than can be obtained from fans of the ordinary type.

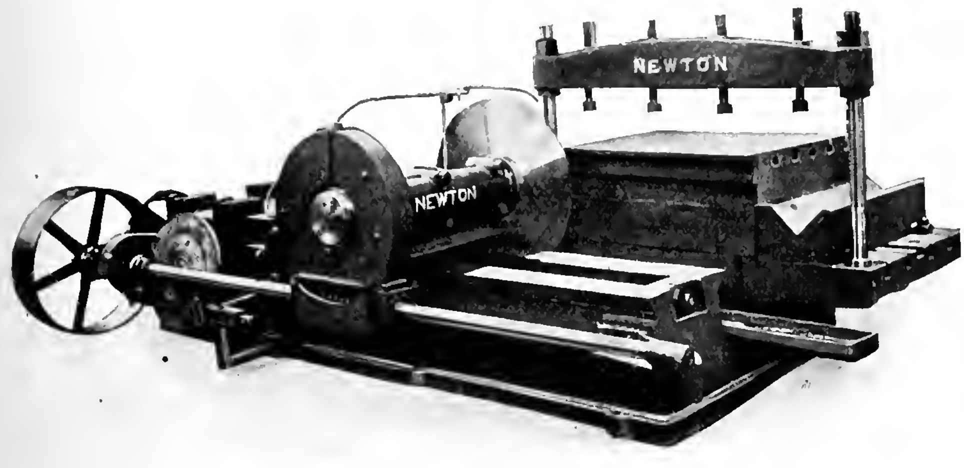
It may be of interest to mention that with this blower con-

Motor-driven Forge Fan made by the B. F. Sturtevant Co., Hyde Park, Mass., applied to a Double Forge

nected to a forge with a tuyere area of 1.5 square inch, two-inch round soft steel stock may be heated to a welding heat in four minutes, and one-inch round soft steel stock in $2\frac{1}{2}$ minutes. The blower can be set on a bench, shelf or box, or on the floor near the forge. The casing is arranged so that it can easily be revolved to discharge in any desired direction. The weight of the complete outfit is 35 pounds; the total height is $14\frac{1}{2}$ inches, and the width from the inlet of the fan to the outside end of the motor-shaft 10 inches. The base is provided with four holes for screwing the blower to the floor or shelf. In addition to its use as a forge blower it will be found convenient for blow pipes, soldering tubes, etc.

NEWTON COLD SAW CUTTING-OFF MACHINE

A modification of the combination type of cold saw cutting-off machine manufactured by the Newton Machine Tool Works, Inc., 24th and Vine Sts., Philadelphia, Pa., is illustrated herewith. This machine is designed to give a maximum output on work comparatively short in length and of large diameter. The drive for the spindle is direct through a triple-threaded steel worm which is fitted with roller thrust bearings and a large wormwheel having a bronze ring. By having a wheel of large diameter, the length of the stock that can be cut is limited, but the life of the gearing is prolonged and chatter at the saw reduced to a minimum. In this connection it might be mentioned that on all types of machines, the saddle feed screw has a bearing at each end permitting of its being always maintained in tension for the purpose of eliminating chatter.



Newton Cutting-off Machine with Powerful Direct Worm Drive

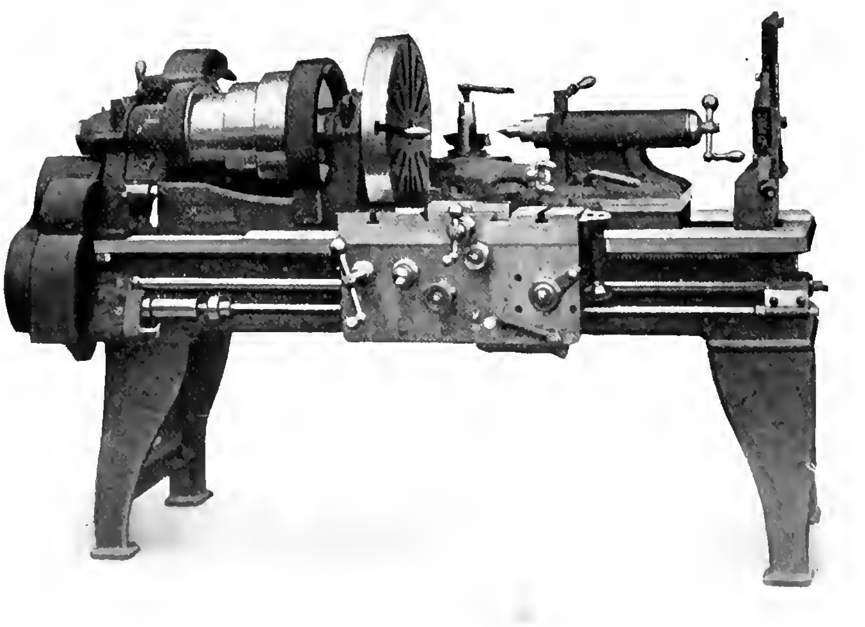
Both worm and wheel are encased, as shown, for continued lubrication. On this particular machine the spindle has a continuous capped bearing which is equal in length to the over-all diameter of the saw blade. The spindle saddle has a square locked gibbed bearing cast solid with the taper shoes to compensate for wear. The feed of the saddle is continuous and has a variation ranging from ¼ to 1½ inch per minute. An adjustable, automatic and positive safety release is provided and also a power quick return. As the motor is fitted with a double throw switch, the quick return is, of course, available in both directions.

This machine is furnished with a bottom table having an in-and-out adjustment for setting work to the required position for obtaining the desired length. In addition, there is furnished an auxiliary top table for handling flats or multiple pieces, and a V-block for holding angles or round stock. The clamping yoke just above the table is rigidly supported by two vertical screws to which are fitted nuts for obtaining the necessary vertical adjustment. Ordinarily, for clamping work it is desirable to operate the independent hand jacks. All the operating levers of this machine are located within convenient reach of the operator, and it is furnished with a pump, piping and attachments for cutter lubrication. All parts are of the very best material and all the high speed shaft bearings are bushed. The gears, where necessary, are made of steel, and the machine is rigidly designed throughout.

BRADFORD HEAVY PATTERN LATHES

A new design of heavy pattern engine lathes has recently been brought out by the Bradford Machine Tool Co., Cincinnati, Ohio. These machines are built in 18- and 22-inch sizes, the accompanying illustration showing what is known as the 18-inch heavy pattern Bradford standard lathe. In the design of these machines special efforts have been made to correctly distribute the metal in order to provide sufficient strength for the most severe duty. The machines are double back-geared, and are provided with a three-step cone pulley for a 3½-inch belt on the 18-inch size, and for a 4-inch belt on the 22-inch size. The spindles are made of high carbon crucible steel, bored from the solid, ground and mounted in adjustable bronze bearings. The hole through the spindle in the 18-inch size is 1 11/16 inch, and in the 22-inch size is 2 inches. The spindles extend clear through the head so that draw bars and tubes for draw-in attachments can be conveniently used; the draw-in attachments can be furnished and attached to the lathe at any time.

The carriage has a full bearing on the V's for its entire length, and is gibbed in front and back and designed with an extra amount of metal in the cross bridge. The apron is of the double-plate pattern, with a non-interfering safety device, so that the feed-rod and the lead-screw cannot be engaged simultaneously. The lead-screw is cut from a master screw, and the nut is of the split pattern made of phosphor-bronze. A chasing dial is provided for catching the threads, so that threads can be cut without stopping the lathe or reversing the lead-screw. The range of threads that can be cut on either of the sizes of lathes is from 2 to 40 per inch including 11½ threads. The feeds cover a range of from 8 to 90 per inch for the 18-inch size, and from 5.7 to 64 per inch for the 22-inch size. The feed gear train is at all times independent of the screw cutting train, which provides for a simple and direct drive for each. The idea of using a separate train of gears for feed purposes will appeal to all mechanics as a feature of great merit. The lathe is provided with a friction cross-feed graduated to read in thousandths of an inch, and with a friction traverse feed in the apron, and automatic stop for the carriage.



Eighteen-inch Heavy Pattern Engine Lathe made by the Bradford Machine Tool Co., Cincinnati, Ohio

An improved taper attachment, turning tapers up to 4½ inches per foot, 16 inches in length, and available the full distance between the centers, can be provided. If required, quick-change gear device, coarse screw-cutting mechanism, relieving attachment, draw-in attachment, etc., will be provided.

The general dimensions of the 18-inch size are as follows: Swing over ways 20¼ inches; maximum distance between centers of six-foot lathe, 2 feet 2½ inches; back-gear ratios

10.95 to 1, and 3.31 to 1; spindle speed range, 12 to 349 revolutions per minute; weight of lathe with six-foot bed, 2950 pounds; and weight of bed per additional foot, 140 pounds.

The 22-inch size swings 22½ inches over the ways and takes 3 feet 7½ inches between the centers on an 8-foot bed. The spindle speed range is from 11 to 346 revolutions per minute; the back-gear ratios are 10.04 to 1 and 2.82 to 1. The weight of a lathe with 8-foot bed is 4400 pounds, and the weight of the bed per additional foot, 175 pounds.

A noteworthy feature is the complete manner in which all gearing has been covered. Not only does this provide for added safety in operating the machine, but the gear guards have been designed so that they give to the machine a finished and pleasing appearance, as well.

WOOD TILTED-TURRET SCREW MACHINE

A tilted-turret type of screw machine, with a friction geared head and geared automatic feed for the turret slide, has recently been brought out by the Wood Turret Machine Co., Brazil, Ind. This machine embodies in its design many improvements and new features which adapt it to the rapid and accurate production of duplicate parts.

It will be noted, by referring to the engraving Fig. 1, that the head and lower half of the gear guards are cast integrally, thus assuring great strength and rigidity. In addition to the friction geared head, a three-step cone of large diameter and wide face is provided, giving a powerful drive to the machine. Two spindle speeds for each speed of the cone are obtained by the friction geared head, thus enabling the operator to use two speeds without stopping the machine to throw in the back-gears. By moving the handle shown at the side of the cone to the right or left, the back-gears are thrown in or out while the machine is in motion, thus securing the necessary speeds for changing from boring to tapping, or for turning different diameters on the same piece, without stopping the machine.

The headstock end of the machine with the protective casing removed, is shown in Fig. 2. This view shows clearly the arrangement and construction of the friction geared head, and

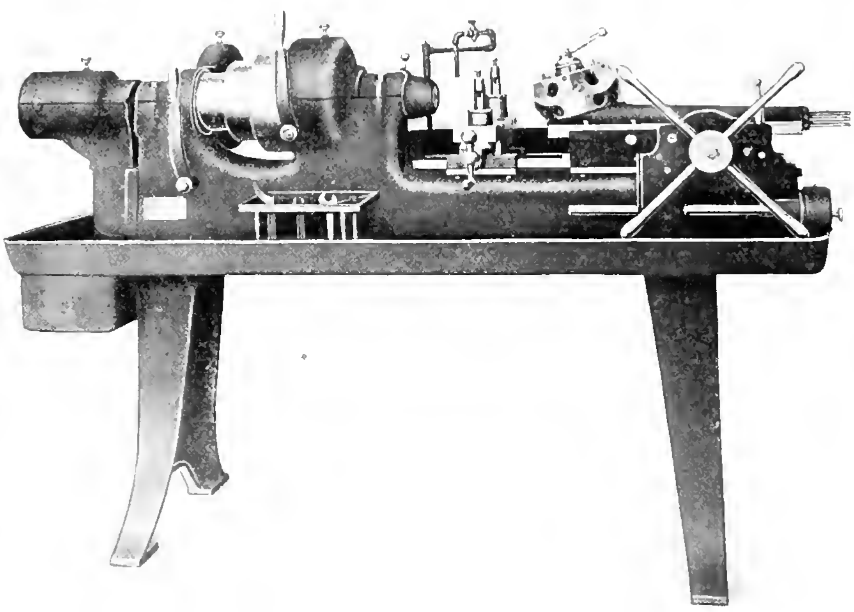


Fig. 1. Wood Tilted-turret Screw Machine with Friction Geared Head and Geared Automatic Feed to the Turret Slide

also the chain drive for the geared automatic feed to the turret slide. As will be noted, there is a sprocket screwed to the spindle of the machine which transmits the motion through a roller-chain to a shaft located in the bed. This shaft extends to the rear of the bed and transmits the feed motion to the gear-box of the turret slide. The details of the geared automatic feed are shown in Figs. 3 and 4. The necessary reduction in the speed of shaft *A* (which is the one that is connected by chain to the spindle) is obtained by means of four gears *B*, *C*, *D* and *E*. Gear *B* is keyed to shaft *A*, while gear *C* and the three gears adjacent to it, are solid and run free on their shaft. Gears *D* and *E* are also solid and are free to turn on their shaft. The power is therefore transmitted from *B* to *D* and from *E* back to *C*. The pull-pin *F* operates a sliding key which engages any one of the three gears mounted on the shaft with *D* and *E*. As these gears are always in mesh with the three which are adjacent to gear *C*, three different rates of feed may be obtained.

By referring to Fig. 4, the position of the gears which are interchanged to double up the number of feeds, making six in all, may be seen. This view also shows the automatic trip mechanism for disengaging the feed. This trip operates in

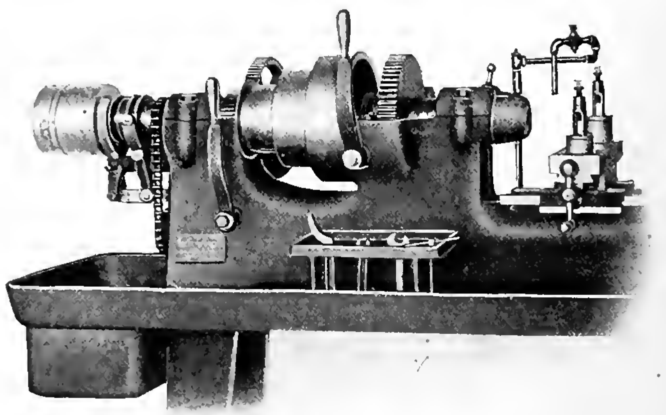

Fig. 2 View of Headstock End showing Construction of Friction Geared Head

conjunction with independent adjustable stops for each hole of the turret. The feed is transmitted from the spur gear on the pull-pin shaft *F* through two gears and the shaft *G* to the gears *H* and *I*. These latter gears are so arranged that they can be instantly interchanged, as stated, thus doubling the number of available feeds. On the same shaft with gear *I*, there is a worm meshing with a worm gear. This worm is held in a rocker arm, which throws it in and out of mesh with the worm gear by the operation of the hand lever. The worm gear is keyed to the same shaft that carries the turnstile. The turnstile shaft has mounted on its other end a spur pinion meshing with a rack secured to the under side of the turret slide, resulting in the automatic movement of the turret slide. The small forked lever *J* passes up through the under side of the turret saddle, and automatically trips out or disengages the feed in connection with the independent adjustable stops for each hole of the turret.

Among the special advantages of this machine might be mentioned the tilting of the turret which makes possible the use of extra large box tools and die-heads on this machine. When the turret is swung around to the rear position, the tools are thrown up at an angle of approximately 30 degrees, entirely clear of the turret slide. The tilt of the turret also minimizes the strain on the center-bolt of the turret head, and applies part of the thrust directly to the inclined surface of the slide. This feature also causes a full bearing on the slide, and eliminates the tipping which is likely to occur with the high turret. Stock may be passed into or directly through the tilted turret, since the center-bolt has a hole directly through it; this feature allows the use of a short, stiff box tool and eliminates the necessity of the box tool rest guide. Thus with this machine it is possible to obtain the benefit of the long effective motion to the slide. The turret also being hexagonal allows the box tool to be bolted to the face, leaving the turret hole open to let the work pass through. Work, when machined, is passed into or directly through the turret, coming out at the rear through one of the auxiliary holes in the lower half of the turret without interfering with a tool in the rear position.

In regard to the general construction it may be mentioned that the machine is equipped with bar feed for automatically

feeding stock through the spindle. There are four gears and a scroll which gives the power to two rollers, while a second scroll is used to fit the adjusting jaws to the stock. Provision is made on the stock adjusting jaws to take round, square, hexagon, or any other shaped stock that one may desire to use. The same lever (located on the left-hand end of the machine) which operates the automatic bar, operates the automatic chuck, opening it before the feed is thrown into action when the lever is thrown to the left, and closing it after stopping when the lever is thrown to the right. Thus one lever controls two operations, and at the same time eliminates

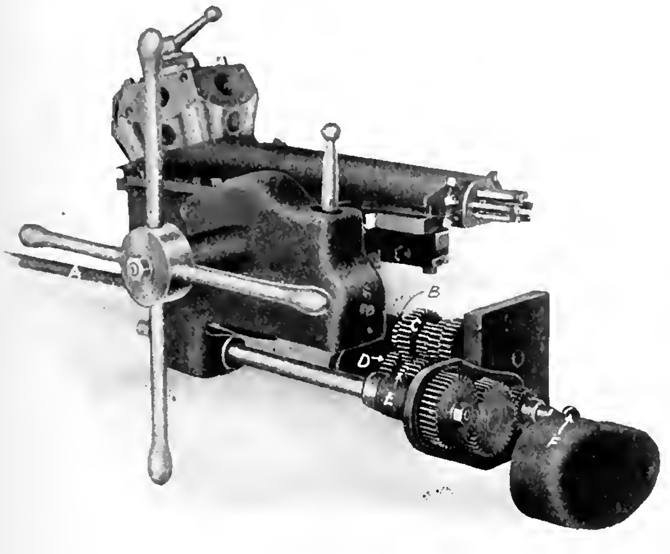

Fig. 3. Detail View of the Geared Automatic Turret Feed

the danger of trying to roll stock into the machine when it is gripped by the collet.

The turret slide, which rests and moves in the saddle, is furnished with a taper gib fitted the whole length of the saddle on either side, providing a means of adjusting the slide sideways. The saddle is gibbed to the outer edges of the bed by flat gibs throughout its entire length. There is a supplementary taper base to the saddle by means of which the turret holes can be adjusted to the exact height of the center of

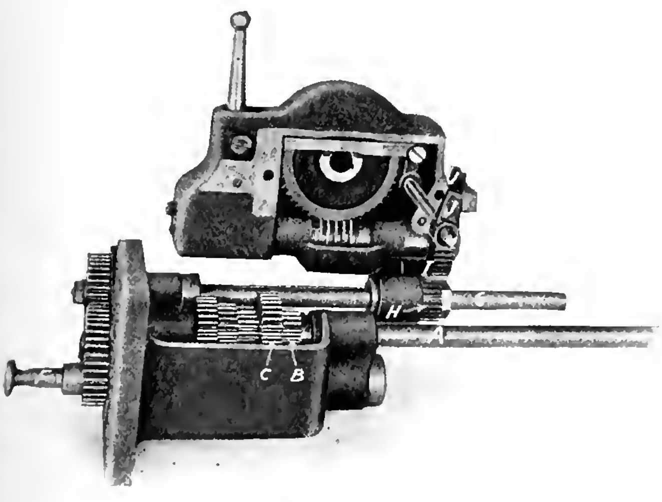

Fig. 4. Another View of Turret Feed Mechanism showing Automatic Trip

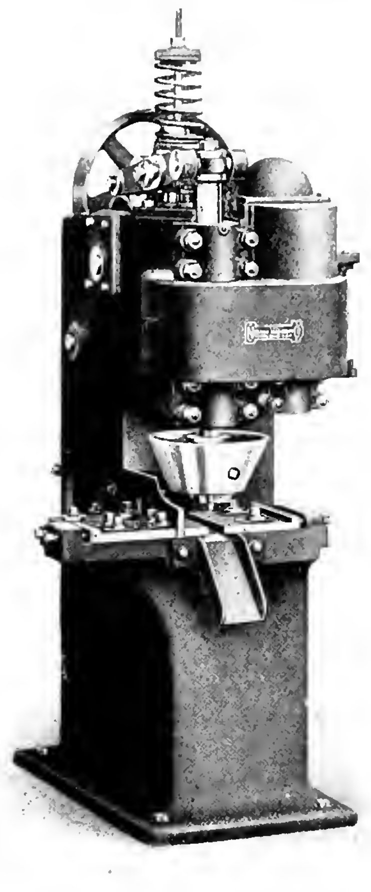
the spindle. This provision makes it unnecessary to rebore the turret holes. Automatic stops for each hole in the turret are furnished with the machine and are instantly adjustable to different lengths.

Hill, Clarke & Co., Inc., of Boston and Chicago, are the sales agents for this machine. This firm also has branch offices at New York, Philadelphia and Cleveland.

NATIONAL NUT BURRING OR SHAVING MACHINE

The accompanying illustration shows a new design of nut burring or shaving machine for hot pressed nuts, recently brought out by the National Machinery Co., Tiffin, Ohio, manufacturer of bolt, nut and rivet machinery. The machine is of the semi-automatic type, of simple design, its specific features being high productive capacity accompanied by perfect safety to the operator.

The machine will easily handle the output of a hot pressed nut machine, and a production of from two to four times that of the ordinary hand-feed burring machine is possible. When in operation, it is only necessary for the operator to place the nuts in a slot at the side of the machine and move them forward. The raising and lowering of the burring spindle, and the feeding of the nuts under the revolving cutter is entirely automatic. This, it will be seen, insures a maximum production, as the machine sets the pace for the operator. At the same time it eliminates all chance of accident to the operator incident to the feeding of the nuts under the rapidly revolving cutter, as this feature is eliminated and taken care of by the automatic feed. The finished nuts are ejected from the machine automatically, passing through a chute shown in the illustration in the front of the machine.



Nut Burring Machine, made by the National Machinery Co., Tiffin, Ohio

The finish on the nuts is uniform. All burr is effectually removed, and as the cutters are lowered gradually by a cam movement, there is no tendency of the burr to turn over the edge instead of being cut off. A compensating spring is provided which takes care of variations in nut thicknesses, and safety arrangements are provided both on the burring spindle and feed mechanism to prevent breakage. Changes for various sized nuts can quickly be made. The machine is built in two sizes, the capacities being 1¼ and 2 inches, respectively.

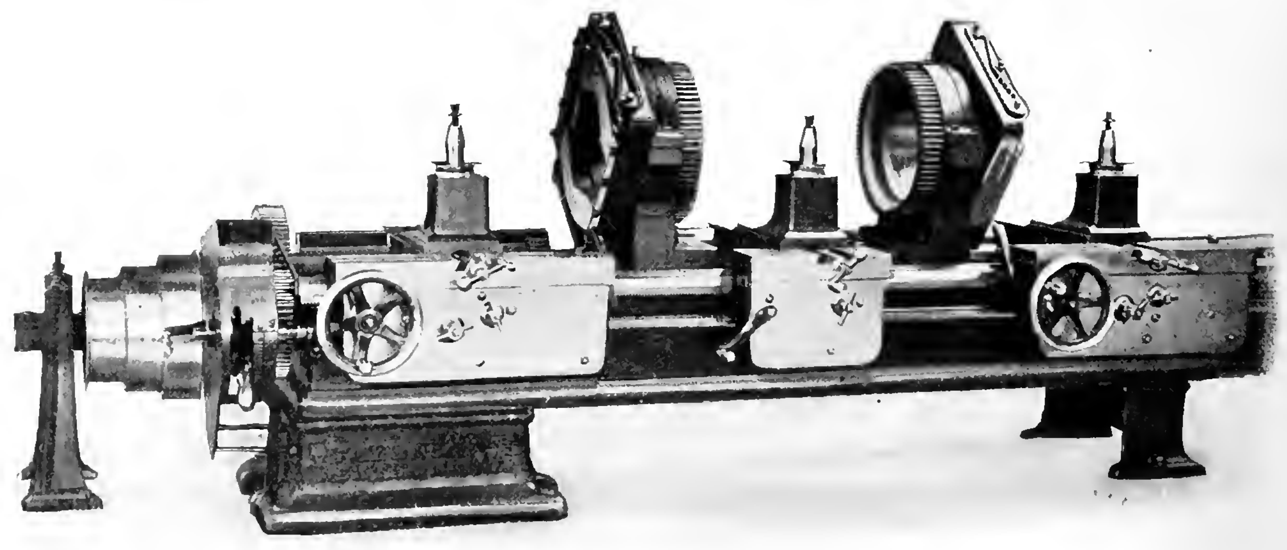
FAY & SCOTT DOUBLE-END TURNING AND FACING LATHE

A double-end turning and facing lathe, which was designed and built by Fay & Scott, Dexter, Me., for the Merrimac Iron Foundry Co., of Lawrence, Mass., is illustrated herewith. This lathe is specially built for facing the ends and turning the flanges of heavy cast iron columns. The work is gripped on the outside by two large hollow chucks, which are mounted in massive bearings or brackets. These brackets may, of course, be adjusted along the bed to accommodate columns of different lengths. The machine will handle a maximum length of 22½ feet, while the chucks will take a maximum diameter of 13 inches. Flanges as large as 32 inches in diameter will swing over the lathe carriages.

As the engraving shows, this machine is equipped with three carriages. Those at the ends make it possible to perform the turning and facing operations on the flanges of columns simultaneously, thus greatly facilitating work of this kind. The carriage in the center may also be used when necessary on special work thus making the tool more universal. The two

end carriages both have power, longitudinal and cross feeds, while the middle carriage has a power cross feed only.

The drive is by belt onto a four-step cone pulley, which is supported by an outboard bearing as shown. The power is transmitted from this pulley through gears to a splined shaft which runs through the center of the bed. This shaft, in turn, is connected to the chucks or work holders through gearing, the arrangement of which is as follows: On the splined shaft and just beneath each chuck is mounted a sliding pinion



Double-end Turning and Facing Lathe built by Fay & Scott

which drives through an intermediate gear to the hollow gear which forms a part of the chuck. One of these intermediate gears is shown in the engraving in mesh with the right-hand chuck gear. These chucks are equipped with hardened cast steel, V-shaped jaws, which are operated by two right- and left-hand threaded screws. These screws, by means of a connecting chain, are turned simultaneously. The chains, as well as the sprockets on which they run, are plainly shown in the engraving. This arrangement makes it possible to obtain a powerful grip on the work, which will withstand the heaviest cutting strains.

The changes of carriage feed are obtained by means of a quick-change sliding tumbler gear at the head end of the lathe. As the engraving shows, the bed of the machine is deep in section, and all parts are heavily built to withstand the strains incident to the class of work which the lathe is designed to handle. The weight of this machine, with a 26-foot bed, is 12,000 pounds.

ROCKFORD SENSITIVE BENCH DRILLS

The sensitive bench drills illustrated in Figs. 1 and 2, are the product of the Rockford Lathe & Drill Co., Rockford, Ill. These machines, while designed along the same lines as the Rockford tools previously illustrated and described, contain one or two important changes in their construction. The machine shown in Fig. 1 is of the 10-inch size and is electrically driven. The motor and speed controller are mounted on an extension cast to the base. The motor can be furnished with either direct or alternating current, and by means of the controller a wide range in speed can be obtained. The driving belt passes from the pulley on the armature shaft over two idlers at the rear which are mounted on an adjustable bracket actuated by the rack and pinion movement shown at the top of the column. This arrangement provides a very quick means of giving the belt the necessary tension. The spindle is counterbalanced by means of a taper plunger that fits in the spline of the quill. The necessary thrust on the spindle is obtained by an adjusting screw which acts on a spring back of the plunger. A stop collar is placed on the outside of the quill above its bearing, as shown, which gives a positive stop and makes it possible to drill different holes to the same depth with accuracy. The machine is equipped with a tilting table which adapts it to drilling holes at an angle and for other irregular work. The size of the table is 8 by 8 inches and its vertical adjustment, 9 inches. The maximum distance from the spindle to the table is 12 inches, and the spindle has a lever feed or 3 inches.

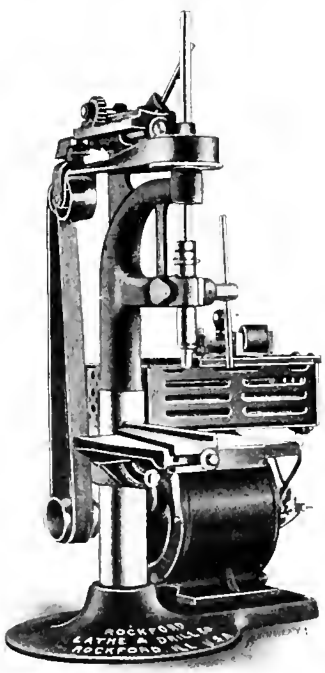


Fig. 1. Electrically-driven Sensitive Bench Drill

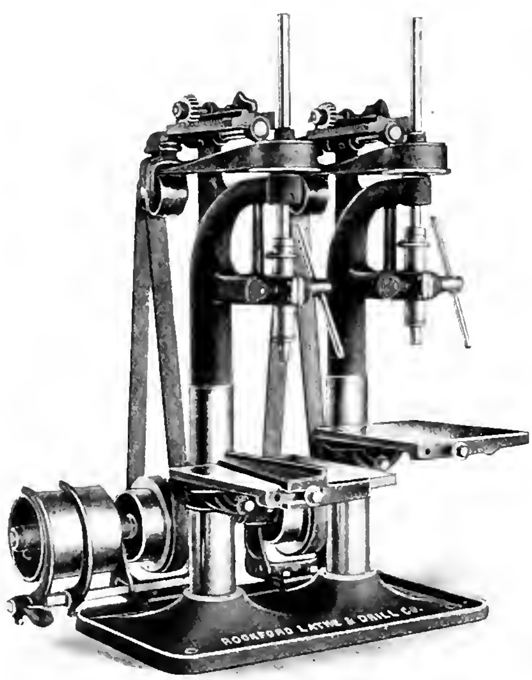

Fig. 2. Two-spindle Bench Drill with Self-contained Countershaft

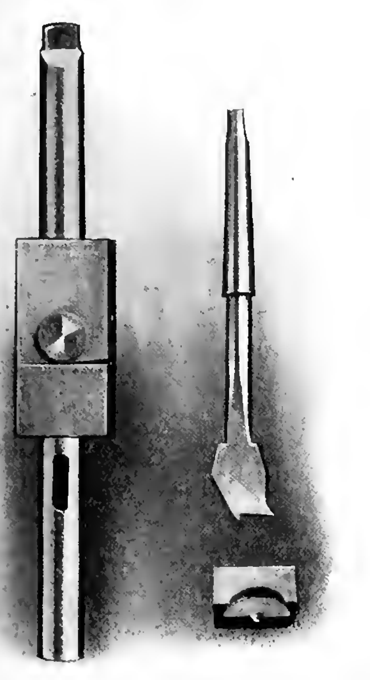
The machine illustrated in Fig. 2 is of the same size as the one just described, but of the two-spindle type. As the illustration shows, this drill is arranged with a self-contained countershaft which is mounted on brackets attached to the base. It will also be noted that two-step cones are mounted on this countershaft to give the necessary speed variations.

When the belt is to be shifted from one step to the other, the cone is moved over to a stop where a ball plunger engages a hole in the shaft. The belt-tightening arrangement is the same as the one previously referred to, and is especially useful on this particular tool for quickly taking up the slack in the belt when the latter has been adjusted to the smallest cone step. The spindles are also equipped with a spring-actuated counterbalancing device and the tables are of the tilting type. The size of these tables, their vertical adjustment and the maximum distance to the spindle is the same as given for the single-spindle machine.

THE PHILLIPS BABBITT METAL LOCK DRILL

The accompanying illustration shows an interesting tool used for boring undercut holes in bearing boxes, or other surfaces to be lined with babbitt metal, for locking the metal securely and permanently in place. The tool is the invention of Mr. C. H. Phillips, 689 Massachusetts Ave., Cambridge, Mass. Before this drill is used, the hole is first started by using a twist drill ground to an angle of 72 degrees, and a hole is drilled to a depth of 3-16 inch. After that the drill shown to the right in the illustration is used, it being held in the special jointed socket shown to the left. This socket permits the drill to wabble so as to cut or bore a hole having a dovetail section as shown in the view at the bottom of the drill, the point of the drill being guided by the hole already drilled as mentioned. These drills cannot be used in an ordinary drill chuck. They are made in ½, ⅝ and ¾-inch standard sizes, and special sizes can be made if required. High-speed steel drills of this type will bore a hole in a fraction of a minute. Among other uses, it may be mentioned that the tool is very convenient for providing locking means for the babbitt on the shoes on cross-heads of stationary and marine engines, and for thrust bearings on marine engines, as well as for securing the babbitt in locomotive bearings.



The Phillips Babbitt Metal Lock Drill, with Special Socket and Section of Hole Bored

BAIRD LARGE OBLIQUE TILTING TUMBLER

The accompanying illustration shows a large size oblique tilting tumbler brought out by the Baird Machine Co., Oakville, Conn. This tumbler is larger than those previously brought out by the same company, and is known as the No. 3 size. It is especially intended to meet the demand for a machine to tumble castings of medium size and weight, such as valves, stove trimmings, the larger sizes of chain, etc. The capacity of the tumbling barrel is about four bushels or 700 pounds of work. Tumbling barrels of from 28 to 48 inches diameter at the base can be mounted interchangeably in the machine, the barrels being made either of wood, cast iron, sheet steel or brass.

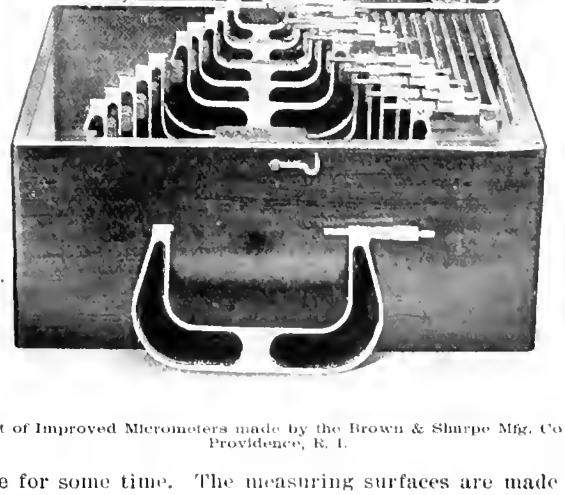
The No. 3 Baird tumbler has all the advantages of the regular line of oblique tilting tumblers built by this company, including convenient means for putting in the work, inspecting articles during the progress of operation, tilting, elevating or dumping the contents, which all can be accomplished without stopping the machine. In addition to the mechanism required for these operations, the No. 3 tumbler is fitted with a clutch pulley controlled by a lever placed conveniently for the operator, near the tilting crank. The tilting mechanism is well back-geared, and makes the operation of the barrel comparatively easy. The weight of the machine without barrel is 2000 pounds.

Large Size Tumbler made by the Baird Machine Co., Oakville, Conn.

NEW LINE OF BROWN & SHARPE MICROMETER CALIPERS

The accompanying illustration shows a complete set of a new line of micrometer calipers recently brought out by the Brown & Sharpe Mfg. Co. of Providence, R. I. The complete set comprises eleven micrometers ranging from 1 inch to 12 inches, and from 25 to 300 millimeters. These micrometers are intended for shops where accurate measurements must be taken on large work, and are made heavier than those of earlier designs. The frame of the micrometer is made of I-section, which provides great strength and rigidity, while at the same time the weight of the instrument is reduced to a minimum so as to make it convenient to handle.

Care is exercised in making to have the micrometers very accurate when they leave the makers, and every precaution is taken to have them retain their accuracy after they have been in use for some time. The measuring surfaces are made perfectly square, so that small projections on a plane surface for example, may be measured with accuracy. A standard gage is furnished with each micrometer for testing purposes



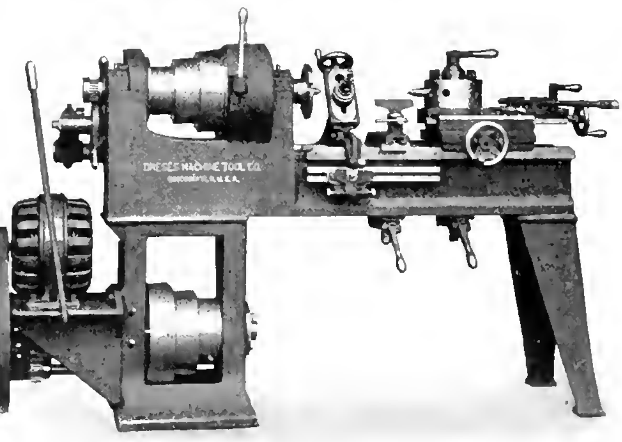
Set of Improved Micrometers made by the Brown & Sharpe Mfg. Co., Providence, R. I.

and means for adjustment to compensate for wear are provided. All points that are exposed to wear are hardened. These micrometers are furnished either singly or in sets of six or eleven, the set of six comprising the six largest sizes, with an inclusive capacity of from 6 to 12 inches.

DRESES ELECTRICALLY-DRIVEN 16-INCH UNIVERSAL MONITOR LATHE

Because of the high speed at which a brass lathe must run, it has been found impracticable to have a geared connection between the motor and spindle. It is also undesirable to mount the motor on top of the headstock as disturbing vibrations are likely to result. To overcome these objectionable features, the Dreses Machine Tool Co., of Cincinnati, Ohio, has equipped its brass lathes with a special form of motor drive. This drive, as applied to a 16-inch universal monitor lathe, is shown in the accompanying illustration. The motor-driven turret lathe described in the March, 1909, number was also equipped with this form of drive.

As the illustration shows, the countershaft with its cone is placed in the cabinet support under the head. The motor, which is mounted on a bracket, has a rawhide pinion on its



Dreses 16-inch Universal Monitor Lathe with Special Motor Drive

armature shaft, which meshes with a large gear on the lower cone shaft. As an electrically controlled device would be somewhat slow for brass and similar work, a frictional mechanical connection between the motor and countershaft is used. The long vertical lever shown operates this device and starts, stops or reverses the countershaft instantly without stopping the motor. It will be noticed that the cone pulley is placed as low as possible to obtain the maximum length of belt and to avoid vibration. The motor used is of the constant-speed, polyphase type and develops, in this particular installation, 2½ horsepower. When a variable speed motor is to be used, single pulleys are substituted for the cone pulleys. This drive arrangement is used on all the screw machines, turret and brass lathes manufactured by this company.

BROWN & SHARPE NEW TYPE FACE MILLING CUTTER

A new type of inserted tooth face milling cutter has recently been brought out by the Brown & Sharpe Mfg. Co., Providence, R. I. This cutter, as illustrated in the accompanying halftone and line engraving, Figs. 1 and 2, embodies some important changes from the ordinary type of inserted blade milling cutters, and presents a radical departure from the usual construction. The two main features of the cutter are the means provided for using the same cutter on different size spindles on different machines, this being accomplished by the employment of special sleeves, and the provision for a quick release from the nose of the spindle when the work is finished and the cutter is to be removed.

The cutter consists of four parts, as shown in Fig. 1: the cutter proper, the split sleeve shown to the left, the clamping plate shown to the right, and the drawing-in bolt. As shown in Fig. 2, the sleeve is screwed onto the spindle nose and the outside of the sleeve is provided with a taper fitting the hole of the cutter body. This taper is sufficient to cause the latter to release readily from the sleeve when not forced inward by the clamping plate. When in use, however, the cutter body is drawn onto the sleeve by the clamping plate by means of the drawing-in bolt as shown, and is keyed to the sleeve as indicated, as an extra precaution against turning or slipping. When the drawing-in bolt is tightened, the sleeve is contracted

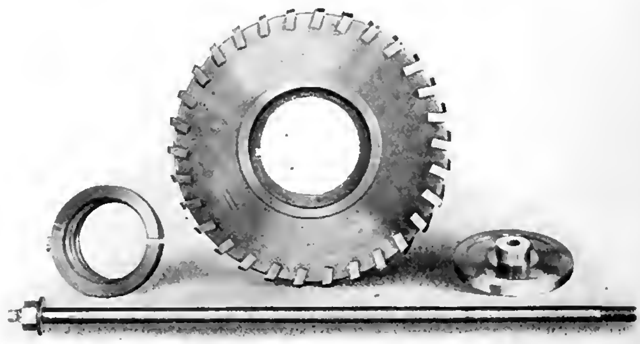


Fig. 1. New Type Brown & Sharpe Inserted Blade Milling Cutter, with Sleeve, Clamping Plate and Drawing-in Bolt

and closely grips the spindle, thus furnishing the full efficiency of the drive to the cutter at all times. The cutter can be quickly and easily removed simply by loosening the drawing-in bolt. As the cutter is made without a hub, it is held close to the spindle end and thus provides for the maximum of working space.

When it is desired to use the same cutter on several machines having different sizes of spindles, all that is necessary is to provide a sleeve for each size of spindle. The outside of these sleeves all fit the hole in the cutter body, while the holes in the sleeves, of course, are made to fit the spindles of the various machines.

The features of the new tool will be readily appreciated both by machine shop owners and machine operators. To the former the possibility of avoiding keeping a large number of cutters on hand, differing only as to the size of hole to fit different spindle noses, will appeal; to the latter the avoidance

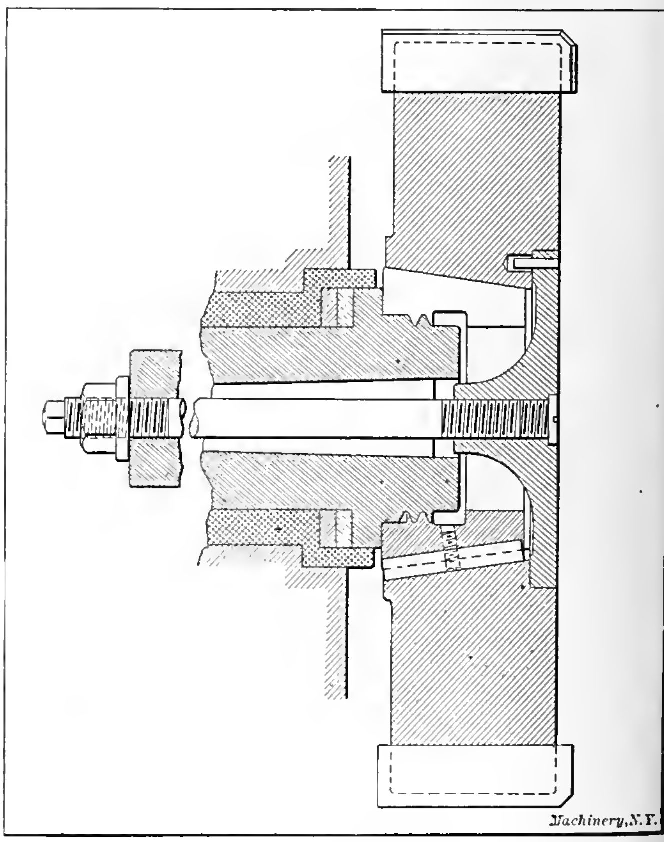

Fig. 2. Section through Milling Cutter Mounted in Place on Spindle Nose

of trouble oftentimes experienced in removing large cutters from the spindle nose after having taken heavy cuts will be of especial interest.

DAVENPORT CLOCK AND WATCH PINION MACHINERY

In Fig. 2 is shown a pinion and staff of the kind ordinarily used in clocks of various sizes and designs. It consists, as may be seen, of a shaft or "staff" on which are pressed three brass disks or "collets." In the two at the right are inserted wires or "needles" as they are called, forming a "lantern" pinion. The disk at the left is turned and shouldered to form a seat for the brass gear wheel, which is afterward pressed on it and staked in place.

Until very recently the thousands of these pinion shafts made every day, had been made in accordance with practices which were fifty years old or more. The first operation consisted in cutting the wire for the staff in lengths a little longer than the finished staff, pointing one end at the same time. This was done in an automatic straightening, cutting-off and pointing machine, and was the only automatic work in the making of the pinion. The brass disks or collets were then driven on in a sort of small arbor press, in which the wires were placed by one boy and the disks by another, and the wire driven through them.

The turning was done by a man in what was called a "clock lathe." This consisted practically of a speed lathe having a live spindle with a draw-in chuck, operated by the knee of the workman. The footstock was of the common type, and the turning was done by tools held in a long bar sliding in adjustable V-blocks on the head- or foot-stock. There were usually four tools in this bar, one on each of the four sides, for turning the different parts of the pinion. Each tool was set out to turn the desired diameter, and stops were provided for each tool, thus duplicating the lengths of the cuts. The pivots were finished by a highly polished steel burnisher, dipped in a soap solution, which was dexterously applied while the pivots were revolving at a high speed. An expert turner could finish from 700 to 1000 pinions in a day of ten hours.

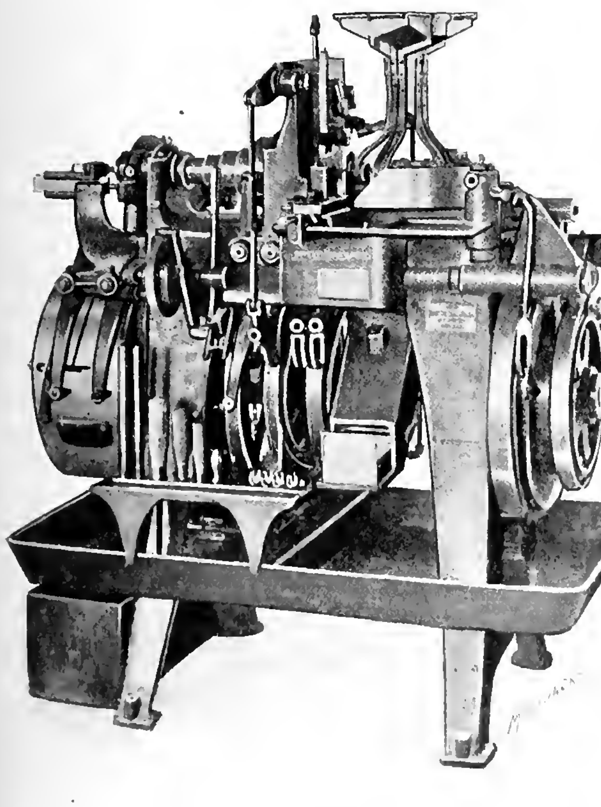

Fig. 1. Davenport Automatic Machine for Assembling and Turning "Lantern" Pinions

The holes in the collets for the needles of the lantern pinions were drilled by girls in a special jig of simple construction. These girls became very expert, pulling the lever which fed the drill with one hand, and indexing the head which held the pinion with the other. Afterward the needles were inserted and the holes staked over to keep the needles in place.

This method of making lantern pinions had been in vogue for so long that it was thought impracticable to perform the operations automatically. That this was not impossible, however, is shown by the line of machines which we herewith illustrate and describe. These consist of a staff turning machine for finishing the staff and pressing on the brass collets, and a lantern pinion drilling machine for automatically in-

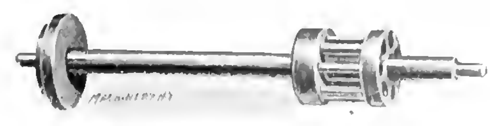

Fig. 2 A Completed Lantern Pinion as used in Clock Work

dexing the pinions and drilling the holes through the needles. These machines are the design of Mr. W. S. Davenport, and are built by the Davenport Machine Tool Co., New Bedford,

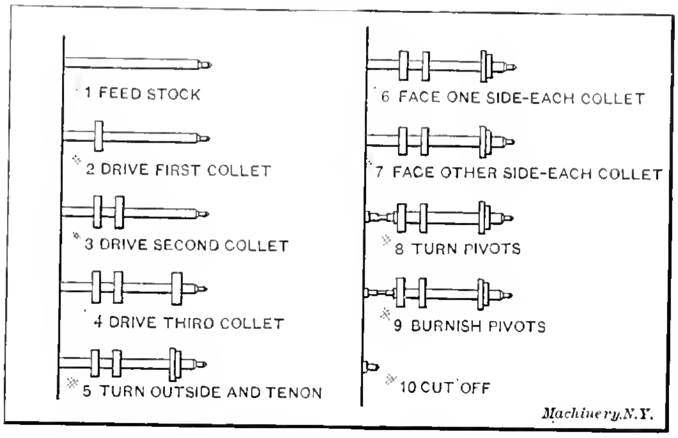

Fig. 3. Order of Operations followed in Machine shown in Fig. 1

Mass. In addition to these we show a universal automatic staff lathe for small clock pinions, which will be described later.

Lantern Pinion Turning Machine

The first machine, shown in Fig. 1, is the automatic turning machine. This performs the operations of finishing the staff over all, pressing on the collets, turning, facing and shouldering them, and delivering the whole completely assembled ready for drilling the needle holes. The machine is similar in many ways to the automatic screw machine of the "Hartford" type, but, in addition to the regular turret, it has another with its axis parallel with the spindle and sliding vertically above it. This turret carries five tools, making seven cross-slide tools available, as is required for finishing the pinions.

The first operation is feeding the stock out to a stop. The pivot on the front end of this stock has already been formed and burnished, as shown in Fig. 3. In the second, third and fourth operations, the collets are driven. These collets are placed loosely in the aluminum hoppers seen above the regular turret in Fig. 1, and by the motion of this turret they are shaken so as to come down an incline, and then to slide down the vertical chute into line with the spindle. Here they are in position to be driven on the wire held in the spindle, which is to form the shaft of the pinion, the spindle being stopped at the time. When two collets are of the same size, as is the case with the first two driven on in Fig. 3, they are both driven from the same magazine, the second magazine driving the third collet.

For the sixth operation the spindle is started and a swinging box-tool held in the regular turret turns off the outside diameters of the collets, and also turns the tenon of the larger collet where it is driven on. The tool-holder with three facing tools then comes down in the vertical turret, and faces one side of each of the three collets for the seventh operation. This vertical turret is again revolved and another holder comes down, facing the other sides of the same collets.

The pivots are now formed (eighth operation) by the regular cross-slide tools, one roughing and beveling the shoulder and the other finishing to size. The pivots are then burnished and polished by a pair of rollers in the vertical turret, in the

ninth operation. These rollers are hardened and highly polished, producing the same kind of a surface on the pivots themselves; they are rigidly held the right distance apart to burnish to the correct size for the pinion being made. Another tool in the vertical turret then necks both, and the last tool cuts off the pinion, for the tenth operation.

The machine will make from 1000 to 1800 complete pinions in a day of ten hours, depending on the size, number of collets, etc. One operator usually runs four machines, making the cost of the pinions so much less than by the old methods described, that the machine commonly pays for itself in about a year's use. The work is more accurate than by the old method, the pivots being finished to within 0.0005 inch above or below the standard size, with the length of the pinion correct to within about 0.002 inch limit above or below.

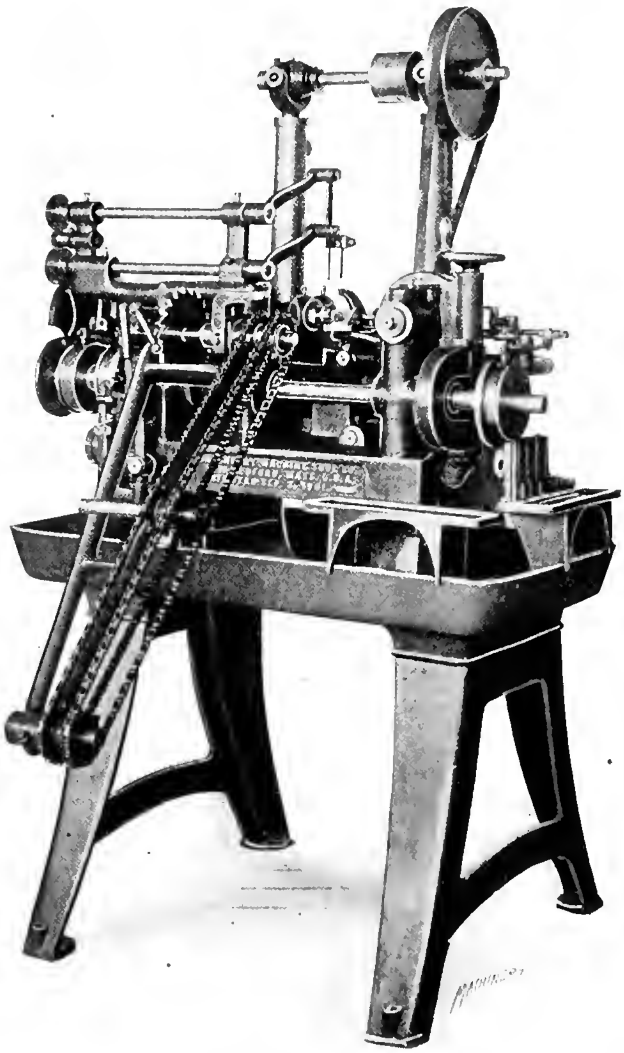

Fig. 4. Automatic Machine for Drilling Needle Holes for Lantern Pinions

In this machine the spindle speeds vary from 3600 to 1200 revolutions per minute, being suitable for wire from 0.075 inch diameter, used for alarm clocks, to 1/4 inch or greater diameter, used in ratchets, etc. Drilling attachments are sometimes placed in the cross-slide and are used for drilling holes through the shafts of ratchets for attaching springs and other parts. The hole through the spindle is 13/32 inch and the largest chuck used is for 3/8 inch stock. It feeds stock four inches long, and turns to two inches length. By making certain changes in the construction, however, it can be made to take cuts three inches long.

Many other kinds of work can be made in this machine besides clock pinions. Among these may be included the center pinions of steam and other pressure gages, pinions for mechanical toys, or other work requiring an unusual number of forming tools or requiring to be burnished. This operation of burnishing makes the best finish known for a staff bearing, being far superior to grinding or any other process.

It may be interesting to state that from the time the first lines were put on paper for this machine until the machine was turning out satisfactory work, was only about five months, which is an unusually good record in automatic machinery building.

Lantern Pinion Drilling Machine

The companion machine which performs the operation of drilling the small holes in the double collets for inserting the needles, is shown in Fig. 4. This has a magazine in the shape of a chain, with side plates having notches in which the pivots of the pinions are placed. The magazine shown holds about 50 pinions; they are taken from the chain by a pair of fingers mounted on the double arms seen about the spindle in the illustration. These place the pinion in line with the work-holding spindle, which then grasps it, the foot center coming up at the same time and holding and centering the outer end.

The spindle is now brought up and, under the action of suitable cams, the drill is fed slowly through the first collet, quickly through the space between the two, and again slowly nearly through the second one. It is then quickly withdrawn, the spindle holding the pinion is quickly indexed, and the drilling is repeated. The machine drills a hole in a second in both disks, or 60 holes a minute, besides feeding the pinions into the spindle, ejecting them, etc. The drill is often as small as 1/32 inch in diameter, and as the hole in each disk is about 1/16 inch long, it will be seen that the drill feeds through about 7½ inches per minute, making allowances for various stoppages during a day of ten hours. This amounts to about 300 feet, which is certainly a long hole for a 1/32-inch drill to make in a day. As one operator can feed four or five machines, the operation is performed at a very low cost. The drills are held in regular watchmakers' chucks, and run about 20,000 turns a minute. Both spindles are hardened, and a high grade of workmanship is supplied throughout the machine. Change gears and index mechanism are provided for drilling from six to twelve holes. The needles are inserted and staked in place by methods commonly employed on such work.

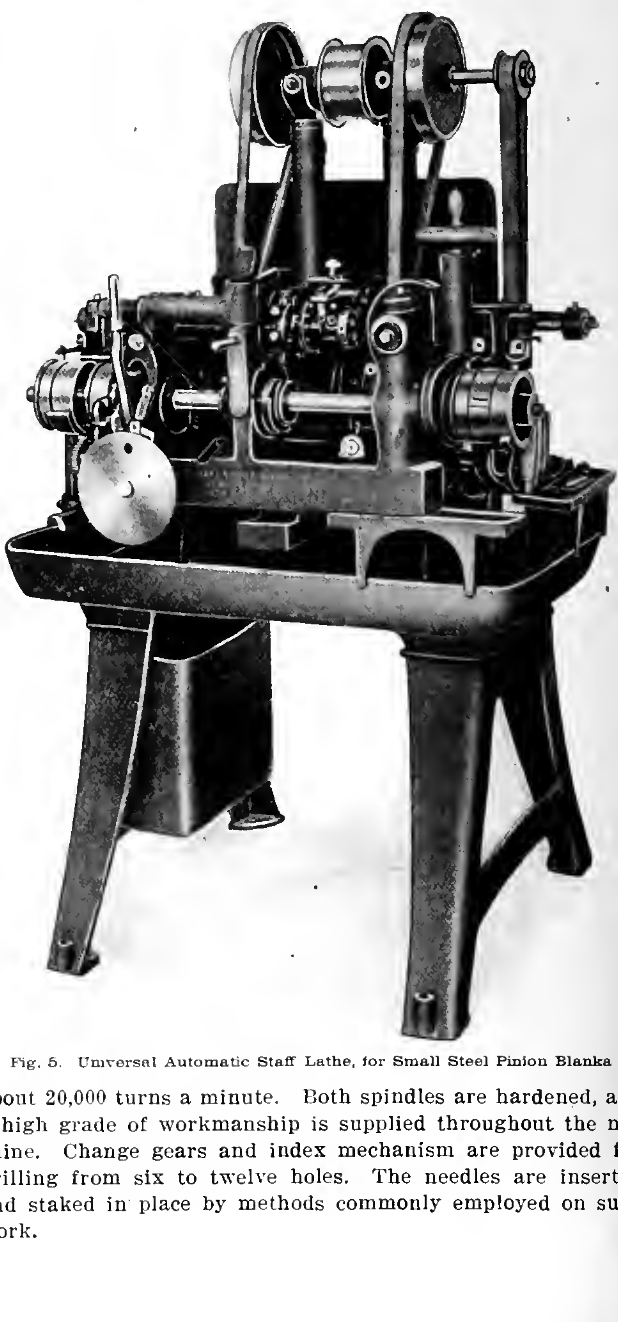

Fig. 5. Universal Automatic Staff Lathe, for Small Steel Pinion Blanks

Universal Automatic Staff Lathe

Another machine in this line is shown in Fig. 5. This is an automatic staff lathe, particularly adapted for turning the staffs with solid pinions, met with in small clocks and clock watches. The main features of this machine are the provision of two spindles in line with each other, and the special form of turret used.

One of the spindles, as in the regular automatic screw machine, is provided with automatic stock feed and collet mechanism. The second one, in line with it, has a similar collet or chuck mechanism, but is not provided with a stock feed. Its purpose is that of grasping the outer end of the work, so that the delicate staffs or pinion blanks are driven from both ends. This is essential on work of this character. Each spindle is separately driven from the self-contained countershaft of the machine; but in addition, there is a shaft back of

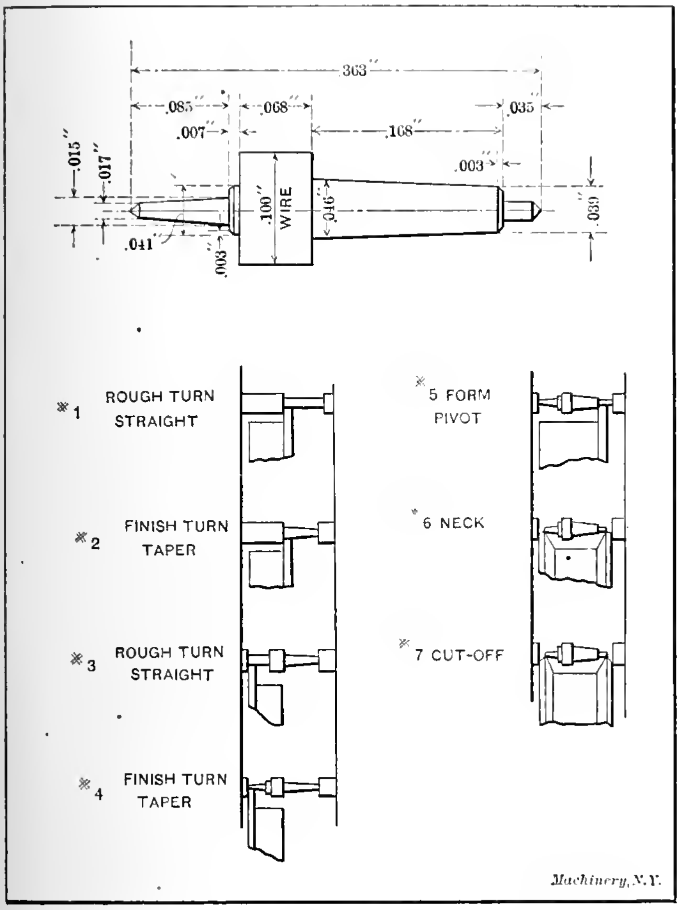

Fig. 6. Typical Order of Operations for Machine shown in Fig. 5.

the two spindles, connected with them by helical tooth spur gearing, which ensures their turning at exactly the same speed. This is essential to prevent small work from being twisted off. When the stock is fed it enters into the chuck of the second or supporting spindle, about 1/8 inch. After the pinion blank is completed and cut off, this piece is ejected before the next feeding of the stock.

The novelty of the turret lies in the fact that it has its axis parallel with the spindles, and has cam movements in line with the spindles for turning, and perpendicular to them for cutting-off, forming, etc.; and, furthermore, in the fact that circular forming tools similar to those ordinarily used for cross-slide work are employed. This construction makes it possible to use the same tool for forming and turning. After the tool is formed down to the desired diameter, it can turn lengthwise the same size; or it can turn taper, if desired, and as determined by the shape of the cams. This turret is really the old-fashioned clock lathe, described in connection with the lantern pinion turning machine, but made automatic, the tools being fed in the same way that the slide bar tools were fed in that lathe.

The tools used in this machine, as may be inferred from Fig. 6, are of the circular formed tool type. They are 1 5/8 inch diameter, and have 3/8 inch smooth holes, fitting on hardened and accurately ground pins in the turret. They are clamped with two screws each. There is a swing gage which can be brought down into position for setting the tool to the correct height to cut properly. This combination of a small hole in the tool and a gage for setting the height of the cutting edge, makes the setting of the tool after sharpening very rapid and accurate. For turning lengthwise, the periphery of the formed tools is notched in eight places, and side-relief is given them, this being done on the relieving attachment of the Hendey lathe. To ensure accuracy in the product, adjustable stop screws are provided for the diameters formed by each of the seven tools, while other screws are furnished for the lengthwise adjustment of each tool. Sizes and lengths are thus easily controlled. The work is usually kept within 0.00025 inch limit. Pivots as small as 0.015 inch for watches are easily made on this machine.

The operating cam shaft revolves slowly during the turning, through change gears; and quickly, and at constant speed, during the feeding of the stock. The handwheel for manually operating the feed is in a peculiar location, being mounted on a vertical shaft as shown. This has proved to be very convenient. The capacity of the machine is for stock up to 3/16 inch diameter. It feeds 1½ inch long and turns one inch long. The workmanship and materials used throughout are of the high character required for machines of this class. The ratchet disk shown at the front of the machine is arranged as a counter for setting the machine automatically when the number of pieces contained in a bar of stock of given length has been made.

Fig. 6 shows on an enlarged scale a sample of the kind of work produced on this machine, and the order of operations followed. The first operation is that of straight rough turning, the tool being fed in and then longitudinally to the required dimensions. In the second operation a similar tool is fed in, and then longitudinally, but it is slowly withdrawn during this longitudinal movement to form a taper as shown. The third and fourth operations of straight and taper turning are similar to the first and second, except that the tool in this case has a shoulder formed on it, which finishes the shoulder next to the body of the chuck. In the fifth operation the pivot at the right-hand end is formed. In the sixth operation a double form tool necks both pivots; and then, in the seventh and last operation, a similar tool cuts the pieces off.

GENERAL ELECTRIC IMPROVED SPEED CONTROLLER

The accompanying illustrations, Figs. 1 and 2, show different sizes of an improved type of speed controller, recently brought out by the General Electric Co., Schenectady, N. Y., and known as CR 162 speed controller. In this device the rheostats often used for the control of shunt-wound direct-current motors (one for starting the motor and the other for varying the motor field current for speed control) are combined in one box and operated by the movements of one rheostat arm.

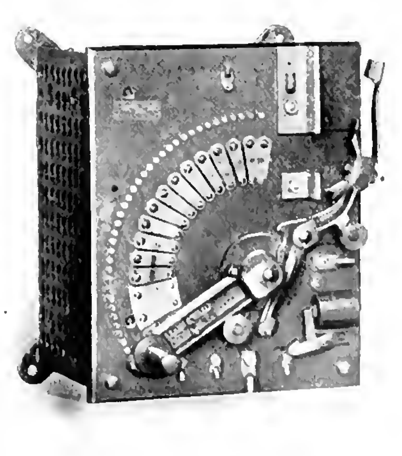

Fig. 1. Speed Controller, Type CR 162, made by the General Electric Company, Schenectady, N. Y.

The device consists of a starting rheostat, the arm of which is provided with a projection carrying a sliding contact which moves over the contact buttons connected to the field resistance. An auxiliary arm on the right hand side maintains a short circuit on the field resistance when starting the motor, and on the starting resistance when the arm is turned back for varying the running speed by regulating the field current.

When starting the motor, the starting arm, due to the action of a spring, cannot be left in position on any of the contact buttons, but must be turned to the right until it engages

the auxiliary arm and forces the latter to be retained by the no-voltage release coil. The auxiliary arm then withholds the spring actuating the starting arm and makes it possible to leave the arm in any position on the field contacts which will give the desired speed control of the motor. If the operator releases the arm at any position while it is being moved to the right during the starting period, it will immediately return to the "off" position. In case of voltage failure, the retaining coil is demagnetized and releases the auxiliary arm which, in turn, releases the spring which carries the starting arm to the "off" position, thus opening the motor circuit.

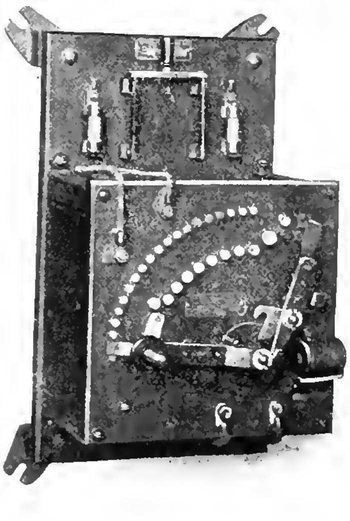

Fig. 2. A Controller of the same Type as shown in Fig 1, Mounted on a Slate Base

The design of the rheostat makes it necessary to apply a little extra pressure to move the arm beyond the maximum speed point, thus calling the operator's attention to the maximum speed position. When it is desired to stop the motor, the switch arm is thrown to the "off" position, de-energizing the retaining magnet and releasing the auxiliary arm which then opens the motor circuit.

The maximum obtainable speed variation is 3 to 1. The controller shown in Fig. 1 is for a 35 H. P. motor, 115 volts current. In Fig. 2 another controller of the same type is shown mounted on a slate base together with a double pole switch and fuses. The controller described is also made with an overload release coil, and is then known as type CR 163.

MILLING ATTACHMENT FOR THE ACME MULTIPLE SPINDLE SCREW MACHINE

A time-saving attachment for finishing parts requiring to be milled, on the screw machine, made by the National-Acme Mfg. Co., Cleveland, Ohio, was illustrated in the July, 1909, issue of MACHINERY. Another milling attachment for use on the Acme multiple spindle automatic screw machine, shown

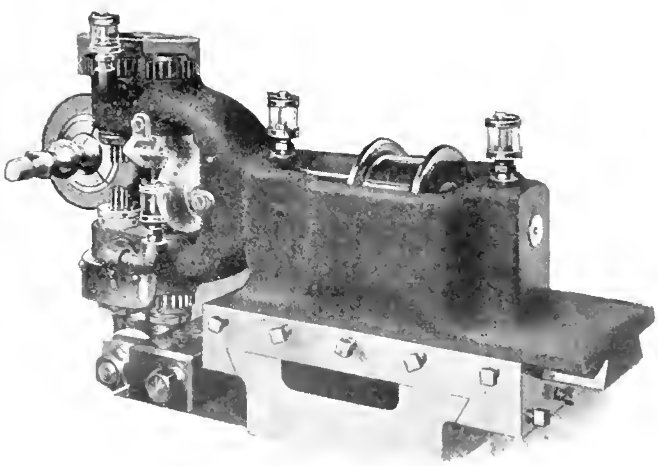

Fig 1. Milling Attachment for the Acme Multiple Spindle Automatic Screw Machine, showing Work Formed, Threaded and Milled in the Machine

in the accompanying engravings, Figs. 1 and 2, has recently been brought out by the same company. This attachment is especially intended for eliminating the handling in the milling machine of work of the character shown in the half-tone Fig. 3, this work consisting of a formed piece threaded on one end as shown, and having two flats milled as indicated. The making of this particular piece has always required two operations, one in the screw machine and one on the milling machine, the latter requiring the constant attention of an operator. The re-handling of pieces of that character is eliminated by the use of the attachment, which is fastened to the top of the slide carrying the cutting-off tool. The end mills shown are fed across the work by the cam movement which operates the cutting-off tool, and the increased movement necessary is obtained by the auxiliary lever shown in Fig. 2. The milling operation takes place at the same chucking as the forming and threading operations, and it will, therefore, be seen that the milling operation does not add to the time required for making the piece. The labor cost is

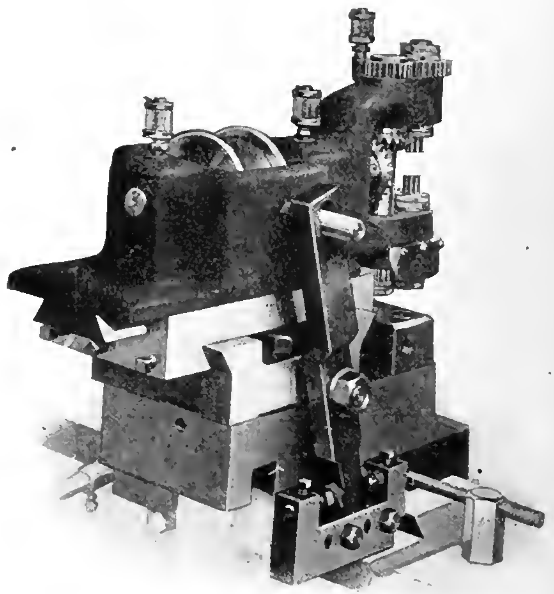

Fig. 2. Rear View of Milling Attachment, showing Feed Arrangement

very small, as the machine is taken care of by the regular operator with very little more attention than without the attachment. The mechanism of the device is simple and easily adjusted, and the attachment can be removed and put in place

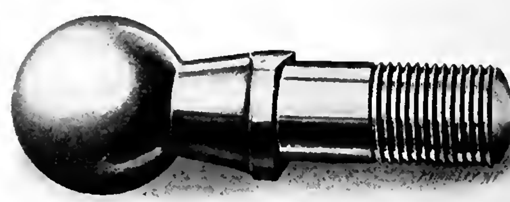

Fig. 3. Piece Milled on the Multiple Spindle Screw Machine

quickly. The cutters are driven from a pulley through bevel and spur gearing, as clearly indicated in Figs. 1 and 2.

SMITH & MILLS CO.'S GEAR-DRIVEN SHAPER

The Smith & Mills Co., of Cincinnati, Ohio, has recently brought out an improved design of back-geared crank shaper, which is illustrated in Fig. 1. As the engraving shows, the cone pulley has been dispensed with and an all-geared drive substituted. This new form of drive provides a simple and effective means for changing the speed of the shaper by the manipulation of one or two levers which are convenient to the operator; the danger incident to the shifting of a belt is also eliminated.

There are eight speed changes in all, four being obtained through the speed change gears and a like number through the back-gears. The speed change gears are divided into two sets of four each, which are contained in separate casings mounted on each side of the column at the rear. The arrangement of these gears and the way in which the various changes are obtained is clearly illustrated in Fig. 2, where the gear boxes are shown in section. As will be seen, the main driving shaft, which passes through the column, has mounted on it on each side a set of two gears which are free to slide longitudinally. Corresponding mating gears are also mounted on a secondary shaft above the main shaft, by which motion

is transmitted through the interior mechanism to the ram. By means of the lever *C* and a suitable connecting-rod, the different combinations of gears may be brought into mesh. Two changes of speed may be obtained by manipulating lever *C* when the small lever *E* at the back of the column, is in position *A*; by moving lever *E* to position *B*, two more changes are obtained, making four, and this number, as before stated, is doubled by the back-gears which are thrown in or out by lever *D*. As the engraving indicates, the shifting lever *C* is provided with a latch and quadrant which makes it possible to firmly lock it and the gears in position.

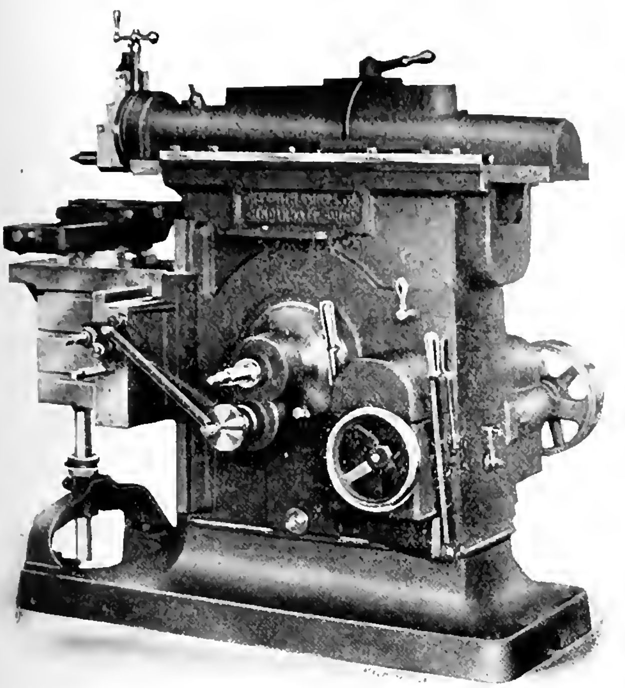

Fig. 1. Smith and Mills Variable All-geared Drive Back-geared Crank Shaper

It will be noted that tight and loose pulleys are shown in place on the main shaft in Fig. 2, whereas a single friction driving pulley is shown in Fig. 1. The former arrangement is fitted to standard designs, but the makers are prepared to furnish the friction driving pulley if this is desired. The company is also prepared to equip the machine with a complete self-oiling outfit, including a pump that will keep all gears of the drive, as well as those in the column, constantly lubricated.

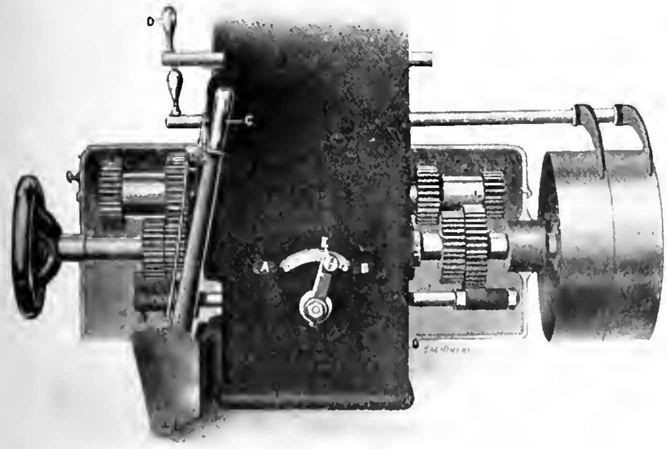

Fig 2. View showing the Arrangement of the Speed Change Gears

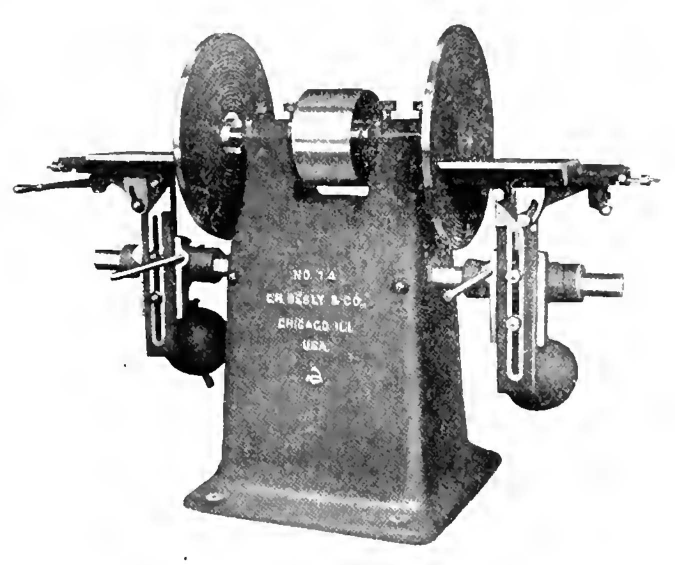
In addition to the improvements mentioned, this machine contains a numbers of others which are usually found on modern shapers. Among these may be mentioned the adjustable table support which not only gives rigidity to the table, but makes it possible to do more accurate work. If it is desired to have the machine electrically driven, the company recommends a No. 10 motor drive which consists of a projection or pad attached to the base for supporting the motor. Connection is made between the machine and the motor through a cast-iron gear and pinion on the main and armature shafts, respectively, which are connected by an intermediate rawhide pinion. These three gears are protected by a suitable guard. If a cheaper construction is desired, it may be had by placing the motor on the floor and connecting it with the machine by chain and sprockets.

These shapers are built in 16-, 20-, and 25-inch sizes. The weights of these three sizes for domestic shipment are approximately 2500, 3150 and 3950 pounds, respectively.

BESLY MANUFACTURING DISK GRINDER

The latest addition to the line of disk grinders manufactured by Charles H. Besly & Co., Chicago, Ill., is illustrated herewith. The principal distinguishing feature of this new grinder is its unusual size and capacity. The weight of the grinder complete is about 4000 pounds. The disk wheels, which are driven by a 7-inch belt, are 26 inches in diameter by 13/16 inch thick and weigh about 125 pounds each. Some idea of the machine's possibilities in the matter of output can be obtained from the fact that approximately 30 horsepower is required for driving, when it is being worked at its maximum capacity. In one instance, cited by the manufacturer, the tool, while being used for facing the bottoms of electric sad or flat irons had an output of 300 surfaces per hour and displaced ten milling machines which were specially designed for this work.



Besly Disk Grinder of Unusual Proportions

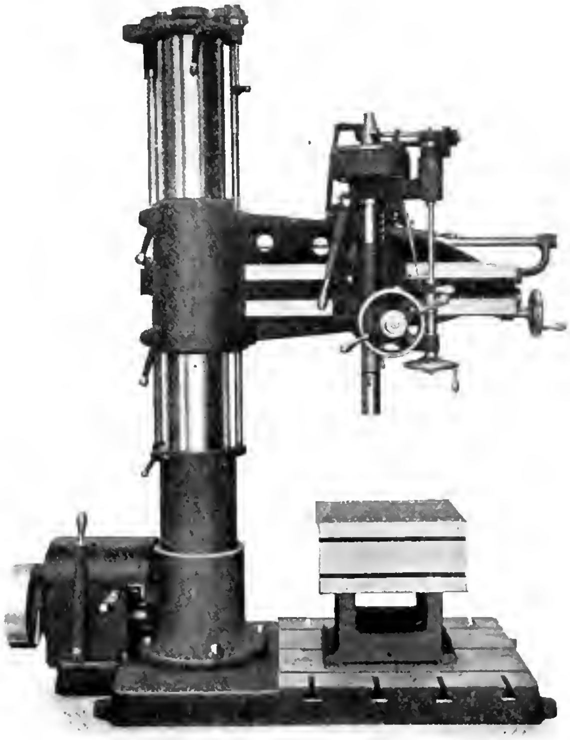
The tables, which have a working surface of 10 by 13 inches, are equipped with a geared lever feed. They are mounted on gibbed dovetailed slides and have a movement to and from the disk wheels of about 2 inches. This movement may be limited by an adjustable micrometer stop screw which is graduated to read to 0.001 inch, so that work may be ground accurately to size and duplicated. The makers state that these grinders are producing, commercially, cast iron printers' blocks to a given size within a limit of 0.0005 inch. Each table bed has two T-slots and a keyway for attaching angle-plates, magnetic chucks, or other forms of work holders in any desired position. The lever for feeding the table is comparatively short, but by the geared motion, a leverage of 14 to 1 is obtained, which makes it possible to force the work against the abrading disk with sufficient pressure to obtain efficient results without undue exertion on the part of the workman. The tables oscillate about a rockshaft and are adjustable in all directions; the weight of each is about 300 pounds. The end-thrust of the spindle is taken in either direction on a single bearing bushing by hardened and ground steel thrust collars. With this construction, the natural warming of the bearing, when running, does not tend to cause the thrust bearing to stick, owing to the fact that the expansion of the crucible steel spindle is greater than the cast-iron bearing bushing.

This grinder is designated as the No. 14-26-L. The design and construction throughout appears to be fully up to the standard of the best modern machine tools.

MUELLER RADIAL DRILL

The latest addition to the line of radial drills manufactured by the Mueller Machine Tool Co., Cincinnati, Ohio, is shown in the accompanying halftone. This tool, while not radically different from previous designs, has been simplified and is rigidly constructed throughout to adapt it to modern shop conditions.

In accordance with the usual practice of this company, the column is stationary, being firmly bolted to the base. It is



Mueller Radial Drill with Geared Speed-box and either Positive or Friction Feed

cast in one piece and has four internal webs, extending its entire length which add to its stiffness. To reduce the springing of the arm to a minimum, all columns are ground to size. The arm itself can be swung completely around the column and be instantly locked by a handle conveniently located. A graduated ring on the column enables the operator to set the arm to a definite position as often as desired. The arm can be lowered at twice the elevating speed, and its vertical movement is controlled by a lever located on the column cap. The head is traversed by means of a double-threaded screw, and it can be instantly locked to the arm by a small handle. A graduated dial connected with the traverse screw, enables the operator to adjust the head to within 0.001 of an inch. The back-gears, which are located on the head, can be engaged or disengaged without shock while the machine is in motion, by a lever that is located directly in front of the operator.

The feed mechanism gives eight changes in geometrical progression for each spindle speed, and is so arranged that either a positive or friction feed may be obtained. The construction and operation of this feed mechanism was fully described and illustrated in the department of New Machinery and Tools, January, 1906. Six variations in spindle speed are obtained through a geared friction type of speed box, which number may be doubled by the back-gears. The construction of this speed box is very simple and the different speeds may be engaged instantly and without shock. A handle for starting, stopping and reversing the spindle is conveniently located on the head. There is also a tapping mechanism on the head which is so arranged that very heavy tapping operations are possible. The tap may be backed out at an accelerated speed, and the spindle is caused to slip when the tap reaches the bottom of the hole.

The plain box table shown in the illustration is furnished with all machines. A universal table, plain swinging table, worm swiveling table or round table, can be had at an extra cost. These machines will be equipped, if desired, for any type of motor drive.

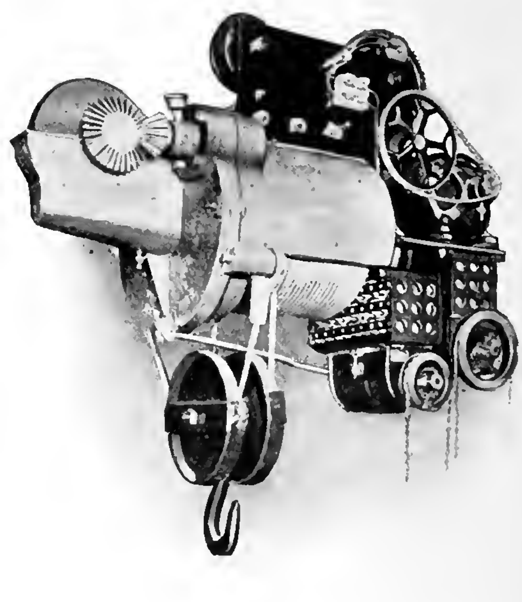
RASMUS FIVE-TON ELECTRIC HOIST

In the November, 1909, number of MACHINERY, we published a note describing a new form of electric hoist built by Gustav Rasmus, 514-16 West 57th St., New York City. This hoist was unusual in that the cable drum itself formed the field of the motor giving certain advantages which we will enumerate later. A new design of this hoist is herewith illustrated and described, which incorporates, among other improvements, an additional motor and mechanism for traversing the trolley on the I-beam.

In building this hoist the poles of a standard motor are removed from the field frame, and mounted on the interior of a cable drum of suitable diameter. The heads at each end of this drum are of special construction, to furnish bearings for the armature shaft which is placed within. These heads also are furnished with extension journals on which they and the drum itself are supported and rotated. The extension of the armature shaft carries a worm meshing with a wormwheel, which is, in turn, connected by bevel gears and spur pinions with the large gear on the cable drum. This, briefly, is the mechanical construction of the apparatus.

Besides the motor inside the drum, a second smaller motor is provided for traversing. This is mounted on a bracket to the right, as shown, and is connected by chain and sprocket, and spur gearing with one of the trolley wheels. Suitable controllers are mounted under the traversing motor bracket, provided with sprockets and operated by hand-chains from the floor.

The construction described has numerous advantages which are at once apparent from an inspection of the hoist, together with others which do not appear on the surface, but which do



An Unusual Design of Hoist, in which the Drum forms the Field Frame for the Motor

appear in the use of the device. Most important of all, the size, weight, number of pieces, over-all height and cost of the apparatus are greatly reduced over other designs. The mounting of the motor inside the drum does away with a great amount of bracing, supporting, etc., which would otherwise be required, and reduces the mechanism and framework to the simplest possible form. The over-all height of the apparatus is unusually small, being only 35 inches for a five-ton machine. This has been effected, as may be seen, without resorting to the expedient of reducing the diameter of the sheaves. In fact, these are larger than on other hoists of the same size, greatly adding to the length of life of the steel cable used. An automatic stop to prevent over-running is provided as shown, which acts directly on the controller through a mechanical connection.

One of the incidental advantages of the construction lies in the fact that the constant coiling and uncoiling of the cable on the drum serves to keep the latter (which, of course, is part of the magnet circuit of the field) constantly cool, even during rapid, heavy and continuous service. A drum section strong enough to carry the load is, by necessity, large enough for the magnet circuit. The area furnished by the cable as it is wound onto the drum, while not great, has the advantage of increasing the section as the speed of the hoist increases, and furnishes cool material at the same time. In lowering again, the extra section is unwound from the drum to cool in the air.

The worm drive employed has definite advantages of its own. The angle of thread is just within the angle of repose. On this account no brakes are required. This obviates the sudden straining of cables which results from the automatic setting of the brakes when the current is interrupted. The apparatus is thereby made very much safer in every way. The compactness and simplicity of the mechanism and the support given to all its parts reduces cramping and friction of every kind to the last degree. The maker is prepared to compare the efficiency of his hoist with that of any other on the market.

The hoist weighs complete as shown but 1000 pounds. The head room required with the hook raised is but 35 inches, and the price is materially less than that of any other hoist of similar capacity on the market. The gearing shown exposed in the engraving is provided with guards, which are here removed simply to show the construction.

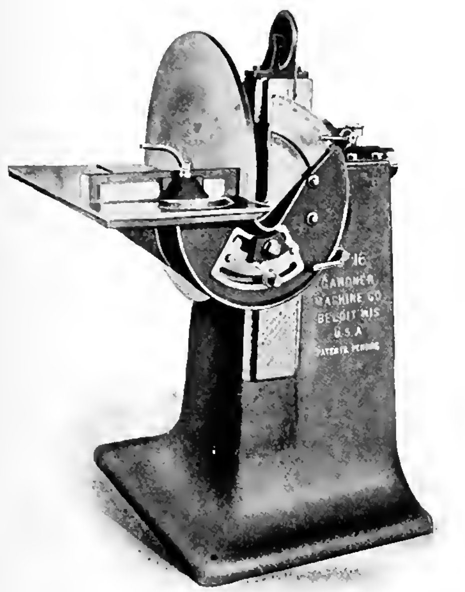


Fig. 1. Gardner No. 16 Patternmaker's Disk Grinder

This hoist can also be furnished simply with the motor, winding drum mechanism and geared connections, for use in direct service in general hoisting.

GARDNER DISK GRINDER FOR THE PATTERN SHOP

The Gardner Machine Co., Beloit, Wis., has just added to its line of disk grinding machinery by putting on the market a patternmakers' disk grinder. This machine is built along the same general lines as a metal-working grinder, the fundamental principle of a revolving wheel faced with flint or garnet paper being adhered to; there are a number of interesting changes, however, which were necessary to adapt the machine to the work of the pattern shop.

A grinder of the single-ended type is shown in Fig. 1. These machines are also made double-ended; that is with disk wheels and work-tables at both ends. The work-table constitutes one of the interesting features of this tool. It is adjustable vertically and it may be locked in any position by means of two quick-acting bolts. The entire weight of the work-table is counterbalanced by a weight within the base of the machine, which is connected by a steel cable passing over a grooved pulley at the top, as shown. This counterbalance, of course, makes it comparatively easy to adjust the table. Provision is also made for tilting the table to any angle with the face of the wheel, and the angle at which it is set, is indicated by graduations on the segment at the end, which also forms the bearing. The inside top corner of the table always remains close to the working face of the wheel regardless of the angular position; the advantage of this arrangement is so obvious that further comment is unnecessary. The original construction of this work-table and its mounting, indicates that it has been carefully designed to insure convenience in handling and also to adapt it for the work of the patternmaker.

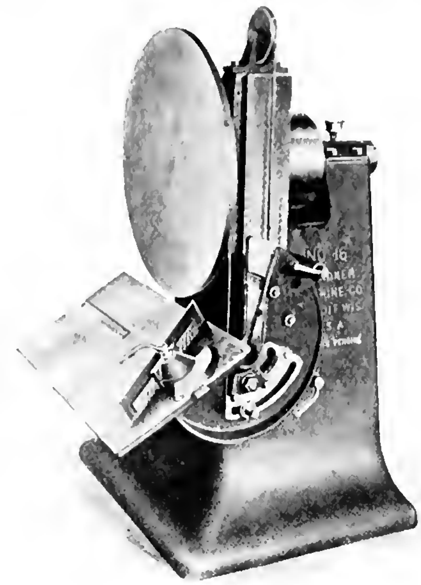

Fig. 2. Grinder with Table Inclined and Lowered

In addition to the angular adjustment, the table is fitted with a special form of protractor or "square gage" as shown in the illustrations. This gage is graduated from zero to 45 degrees in either direction, so that by using these graduations in conjunction with those on the head of the table, any combination of angles may be obtained quickly and accurately. Fig. 3 shows the machine being used to grind a double angle on the end of a pattern part and Fig. 4 shows how a built-up pattern is ground true and given draft at the same time.

Fig. 3. Grinding a Double Angle on the End of a Pattern Part

This protractor is equipped with a gage bar which locates and guides the work at the desired angle. A slight turn of the screw handle shown locks both the protractor and gage bar.

The disk wheels, which may range in size from 24 to 30 inches, are readily refaced without removing them from the spindle, no press being required for the refacing operation. In Fig. 2 the table is shown lowered to give free access for refacing the wheel. These wheels are supported on a 2-inch crucible steel spindle that runs in long babbitted bearings which are reamed and scraped. The end-thrust in both directions is taken at the right-hand box on hardened steel collars 4 inches in diameter which give 9½ square inches of thrust

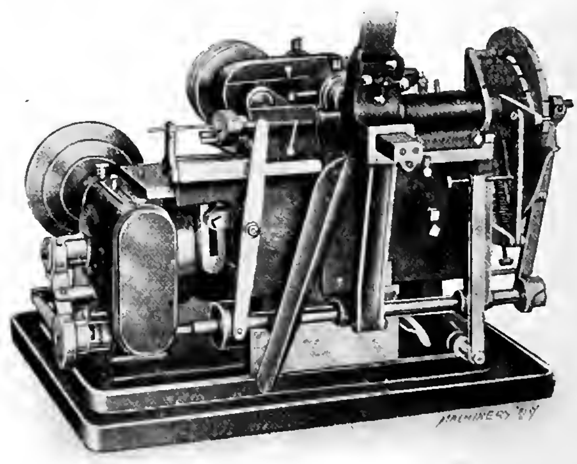
Fig. 4. Truing and giving Draft to a Built-up Pattern

bearing surface. These hardened collars bear against cast iron plugged with babbitt, so that if the spindle heats, the thrust bearing will not stick because of the unequal expansion. The spindle driving pulley is 10 inches in diameter with a 5-inch face, and the speed of the disk wheels is approximately 6000 feet per minute. Five horsepower is sufficient at all times for driving this machine. The weight of a single-ended grinder complete, with countershaft, is 12,000 pounds.

As this machine is equally effective for grinding knots, cross-grains, end-grains, hard or soft woods, and is not even affected by nails or screws, its efficiency as a pattern shop tool is apparent. The makers state that very favorable reports have been received from pattern shops where these grinders have already been installed, calling attention to the general efficiency of the tool and also to the ease with which accurate work may be finished in much less time than is required by the conventional methods.

WALTHAM AUTOMATIC PINION CUTTING MACHINE

In the February, 1908, issue of MACHINERY an automatic precision gear and pinion cutting machine, made by the Waltham Machine Works, Waltham, Mass., was illustrated and described. This machine, it will be remembered, is intended for small gears such as are used in various recording instruments, typewriters, clocks, etc. The magazine feed attachment was mentioned as one of the especially interesting features of the machine. When this magazine attachment is used the machine is entirely automatic in all its movements. An improvement in this magazine feed attachment has recently been made in the machine illustrated in the accompanying engraving, and by means of this improvement the production of the machine is materially increased. The improvement consists in stopping the main cam-shaft while the feeding operations are performed, instead of performing these operations during the time of the return of the slide after the last cut. This makes it possible to use a much quicker return of the work slide than was formerly the case. The feeding attachment automatically ejects the cut pinion and replaces it with a fresh blank, the movements being obtained from one

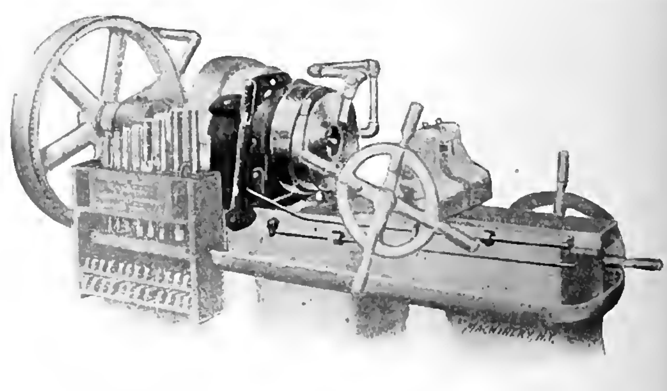


Automatic Pinion Cutting Machine with Improved Magazine Feed Attachment, made by the Waltham Machine Works, Waltham, Mass.

revolution of the cam-shaft attached to the work slide and operative only upon the completion of the last or finish cut. At that time the main cam-snaft stops, as mentioned, and starts again immediately upon the completion of the feeding operation. From 15 to 25 per cent may be added to the production of the machine by the use of this attachment. Its design is such that it is thoroughly reliable and not likely to get out of order.

"LITTLE GIANT" BOLT CUTTING, NUT TAPPING AND PIPE THREADING MACHINE

The accompanying half-tone shows a machine recently brought out by the Wells Bros. Co., of Greenfield, Mass., known as the "Little Giant" bolt cutting, nut tapping and pipe threading machine, the special feature of which is the automatic opening die head, the opening and closing of which is governed by the movement of the vise carriage. The die-opening mechanism consists of a cam ring with knock-out projection on the outside of the head, an upright spring stud



Bolt Cutting and Threading Machine built by the Wells Bros Co., Greenfield, Mass.

in the web under the head, a releasing rod which extends horizontally through the web from the spring stud to the outside of the bed, and two long rods carrying the adjustable stops at the side of the bed.

When the head is closed and the dies are cutting, the upright stud under the head is held within the supporting web so that its head is flush with the top surface of the web. The stud is mounted on a spring and is held down in the web by the releasing rod. When the rod support on the vise carriage strikes the stop shown, a pawl at the end of the rod is thrust

forward. As this pawl is mounted on the end of the releasing rod in the web, the forward movement of the pawl turns the releasing rod, and the upright stud springs up. The stud is so placed that it springs up just in front of the cam ring at its narrowest point, so that one revolution of the head with the edge of the cam ring bearing against the stud forces the head open and brings the knock-out projection around to the stud which is then "knocked-down" into the web and again locked. The rod extending from the hand lever shown to the end of the bed, parallel to the knock-out rod, is also provided with an adjustable stop and serves to close the head automatically when the vise carriage is run back. The heads can also be both opened and closed by hand, as in previous designs, if desired.

As compared with previous designs, the construction of the yoke over the back of the head has been made stronger. The yoke is linked to the yoke support at the top and to two forks on the lever shaft at the bottom, with toggle joints in the middle, one on each side. The yoke carries two segments, one on each side of the head, which fit into the groove in the back of the head. This form of construction gives ample power for instantaneous action.

In the operation of the machine, all that is needed is to put the work into the vise, set the stops, and the machine will do the rest. All holes will be tapped uniformly both as regards diameter and length, and blind holes can be tapped in work held in the vise, without difficulty. The machines equipped with automatic opening die heads are of 1-, 1½- and 2-inch capacity.

TAYLOR-WILSON REAMING MACHINE FOR PIPE COUPLINGS

The Taylor-Wilson Mfg. Co., McKees Rocks, Pa., has recently brought out a pipe-coupling or socket-reaming machine, which is adapted to couplings of a larger size than any machine previously manufactured by this company. The special features of this new tool, which is illustrated in Fig. 1, are its strength, simplicity and capacity for production.

The coupling is held in position while it is being operated on by a chuck composed of one stationary gripper and one

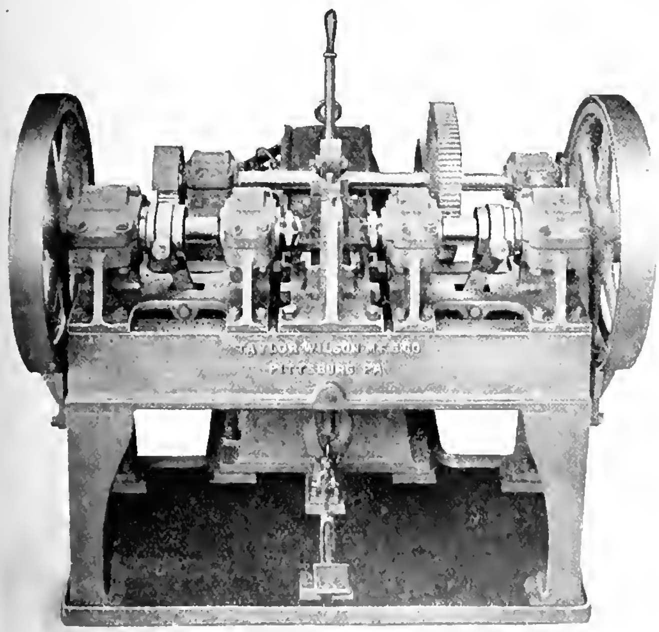


Fig. 1. Taylor-Wilson Pipe Coupling Reaming Machine

movable gripper. The movable gripper is actuated by a toggle joint, one member of which is a U-shaped spring. The purpose of this spring is to compensate for the variation in the diameter of the couplings due to the welding process; consequently when the machine is once set for couplings of any particular size, no further adjustment is necessary until a change of size is required. The toggle is operated by a hand lever, which extends above the center of the machine as shown. The coupling is placed in position to be gripped by the operator and is released by the opening of the chuck; it then drops through a chute which is located under the machine and is delivered into a receptacle provided for the purpose.

In Fig. 2 couplings are shown before and after the reaming operation has been performed. Both ends of the coupling are reamed simultaneously by tools which rotate in opposite directions. These tools are carried in heavy spindles, which rotate in bearings and are driven through cast steel cut gears, preferably by a variable speed motor. This motor, which is located at the rear, as shown, is connected by gearing with an

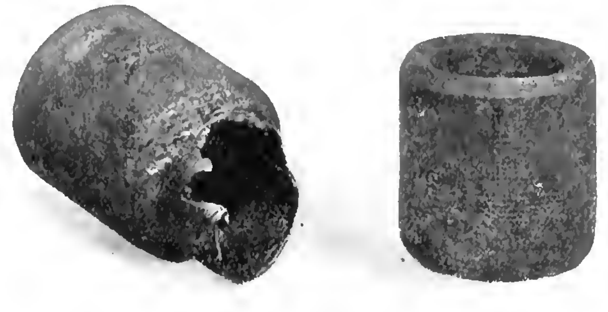

Fig. 2. Pipe Couplings before and after being reamed

intermediate shaft which, through a pinion on the end, drives the large spindle gear to the right, directly. The opposite end of this intermediate shaft drives the left-hand spindle through secondary gearing, which reverses the direction of rotation.

The necessary reciprocating movement is given to the tools and spindles by the foot of the operator through a treadle which is connected to a toggle-joint which in turn connects

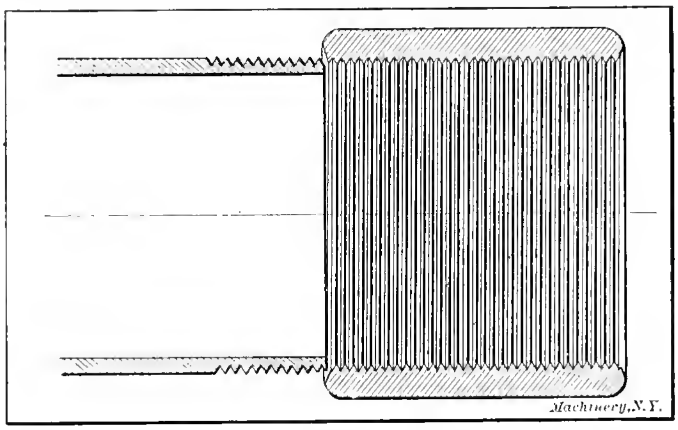

Fig. 3. Sectional View of Reamed Coupling

with the spindles by a pair of trunnions and levers. These levers are connected to the trunnions on the spindles on one end, and the toggle-joint on the other, and work about a pin near the center. The peculiarity of this movement is that when the tools, from a point of rest, are approaching the coupling to be operated on, the movement of the spindles is much greater than the movement of the treadle; but as the tools come near the coupling the condition gradually becomes reversed and the leverage of the treadle on the spindles becomes correspondingly greater.

The reaming of pipe couplings during the past few years has become almost as universal as tapping them, there being, of course, a number of advantages in having the couplings reamed. In the first place, reamed couplings make the process of tapping easier as all the fins which would interfere in starting the tap are removed. This will be understood by referring to Fig. 2. Another advantage in reaming couplings is that the thread is protected from injury in handling, as it starts at a point slightly back from the coupling end as shown in the sectional view Fig. 3. This beveled edge also acts as a guide when starting the coupling on the threaded end of a pipe. This is also made plain in Fig. 3. In addition to the foregoing advantages, a reamed coupling presents a neater appearance than one that has not been finished in this way.

This machine is self-contained and substantially built throughout, and all gears are properly protected by suitable guards. The builders claim that it is capable of very large

production; in fact, they cite one instance where an operator has been able to ream from 5000 to 8000 couplings, ranging in size from 2 inches down, in a day of ten hours.

ADDITIONS TO THE LINE OF FARWELL MOLDING MACHINES

In the accompanying illustrations we show a series of molding machines recently developed and placed on the market by the Adams Co., 623 White St., Dubuque, Ia. Figs. 1 to 6, inclusive, illustrate the construction and operation of a new pneumatic roll-over molding machine. Fig. 7 shows one of a line of new machines of the squeezer type.

Pneumatic Roll-over Molding Machine

The roll-over machine comprises mechanism for jolting the mold, turning it over to an evenly supported foundation, rapping the pattern, drawing it vertically, and then rolling the pattern back again ready for a new flask and a new mold. The machine is portable and of very simple construction. It is easy to operate, as all the heavy work is done by air.

The machine itself is shown in Fig. 1. The angle-plate frame M supports the flask. It is pivoted at one end to air cylinder E, and is supported at the other on heavy steel blocks A, resting on the cast-iron wheels J. The reason for the excessive weight of wheels J and for supports A is shown in Fig. 2, where a mold is shown in place on the frame with the flask filled with sand. The workman is jolting the flask, as shown, by operating the air valve so as to alternately admit air to the cylinder E and release it. As it is admitted, cylinder E rises slightly on the stationary ram. This alternately raises cylinder E and with it frame M and the mold, and on dropping it down again, supports A strike the heavy wheels J. This continuous jolting shakes the sand thoroughly into place around the platen, and makes a compact mold. The holes shown in M in Fig. 1 are for the purpose of attaching the pattern, as is more clearly seen in Fig. 6.

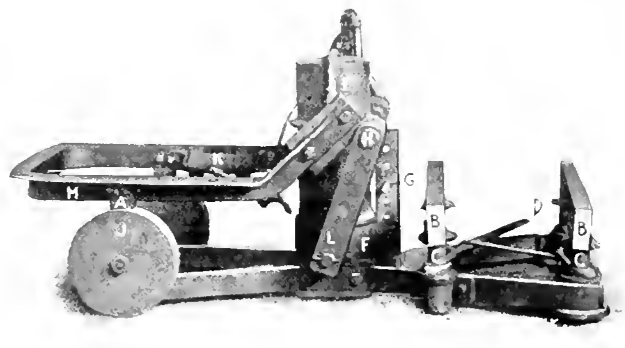

Fig. 1. Farwell Portable Pneumatic Roll-over Molding Machine

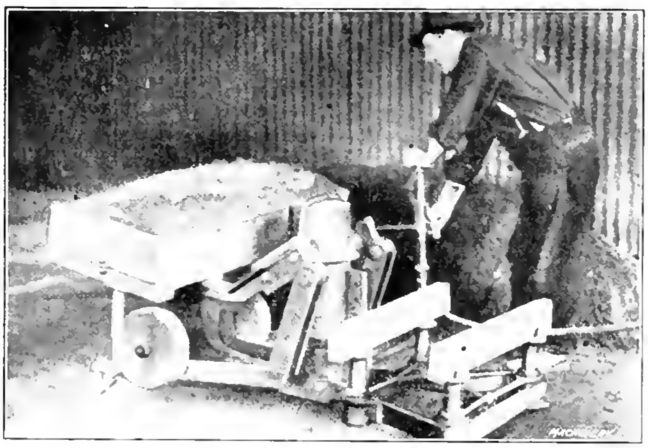

Fig. 2. Jolting the Mold

Operation of the Roll-over Machine

After jolting and striking off the top, the bottom board is placed in position and secured by adjustable clamps attached to the match-board. The molder then again opens the valve, as shown in Fig. 3, admitting air to cylinder E and raising the mold. As cylinder E rises, yoke F strikes stationary pin G (for all reference letters see Fig. 1) arresting its upward movement. The continuous movement of cylinder E then swings table M, and with it the flask and mold, about the pivot on the cylinder, through the action of the link L, which is pivoted to the frame at H. When the dead center is reached, the operator releases the air valve, allowing the mold to settle down on the other side of the dead center onto the supports provided for it, as shown in Fig. 4. This lowering can be done as quickly or slowly as desired.

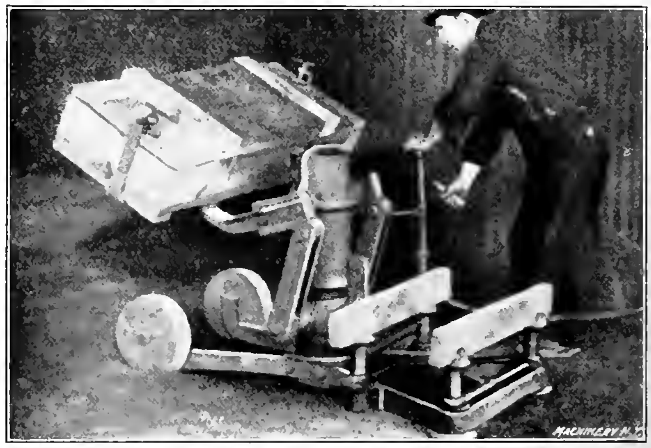

Fig. 3. Rolling over

Cross pieces B on which the mold now rests are supported on four plungers C, provided with springs so that they automatically equalize or adjust themselves at all four points to any irregularity of the bottom board. As soon as the mold rests on the cross pieces B, these plungers are locked in position by a single movement of lever D which is connected by links to all four plungers. This lever may be kicked into the locked position by the foot. The molder now releases the clamps and is ready to draw the pattern.

Fig. 5 shows the operation of drawing the pattern. With his left hand the operator opens a pet cock, admitting air to the Adams pneumatic rapper shown at K in Fig. 1, which is mounted on the frame carrying the pattern. Being thus loosened, the pattern is simultaneously drawn by the operator's opening the air valve for cylinder E, with his right hand. The pattern is drawn perfectly straight, as the movement is directly vertical so long as cylinder E and yoke F are rising together. When, however, yoke F strikes stationary pin G, the pattern again rolls as before, over to the dead center. The receding of the air causes it to settle back again onto wheels J, describing an arc in its progress as shown in Fig. 6.

Fig. 4. In Position for Drawing

By adjusting the position of pin G any desired straight vertical movement can be obtained before starting to roll over. This, in combination with the pneumatic rapper and the steady air control, insures a clean and careful lift. In addition to this advantage, it will be seen that this machine has the features of great simplicity, a method of instantly clamping the plungers so that the mold rests evenly on them, the elimination of concrete foundations, portability, hinged clamps for match-board, flask and bottom-board, and easy control. The wheels may be arranged to run on tracks embedded in the

floor, thus affording an ample foundation at small expense, and avoiding the necessity of a permanent location of the machine at one place.

New Machines of the Squeezer Type

The machine shown in Fig. 7 is of the squeezer type, intended particularly for use with the hinged match plate system invented by Mr. W. J. Keep of Detroit, Mich. This system employs hinged snap flasks and a match-plate, provided with lugs which fit into the hinges of the flask. This lines up pattern, cope and drag, and permits the whole to be turned over, so that both sides of the pattern may be molded at one time. In order to allow for this, the squeezer top is arranged so it will swing farther back, and the table is supplied with a special flask-supporting device not shown in the photograph. This device supports the back side of the drag while the cope is rolled up, and is required to prevent the drag from being tilted by the weight of the cope. The makers of this squeezer will supply it, together with all the special equipment re-

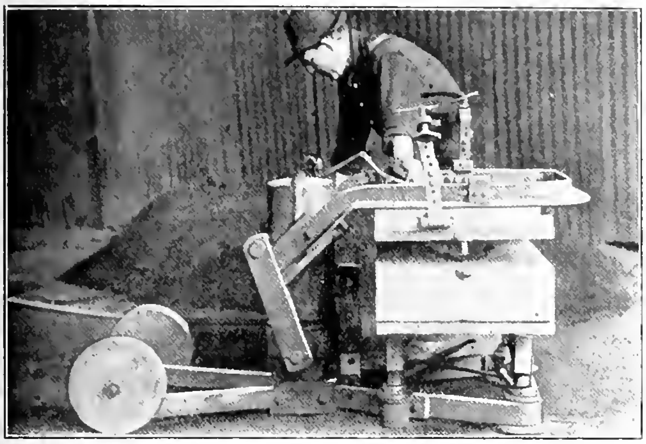

Fig. 5. Drawing the Pattern

quired, to any foundry licensed to use Mr. Keep's invention.

Another new product is a 34-inch portable low-down heavy-duty squeezer. This is an intermediate size between the 30- and 38-inch machines, but possesses some special advantages not found in the older designs. The principal improvement is a new style of counterbalancing spring which is adjustable to any tension. This can be set so that the squeezer top will come forward by itself, though it is ordinarily adjusted so

Fig. 6. Rolling Pattern Back to Molding Position

that the top stays out of the way until the mold is ready, when it will come forward with a very slight pull.

Still another addition to the line of squeezers is a 24-inch stationary machine similar in construction to others of the same make, except that the table is raised higher above the rocker shaft. With this table it is not necessary for the top to swing through so great an arc for clearing the table. This makes it easier to spring the top forward into the squeezing position. At the same time it brings the mold up above the operating links, so that a larger flask can be used in proportion to the width of the machine. This avoids all danger of

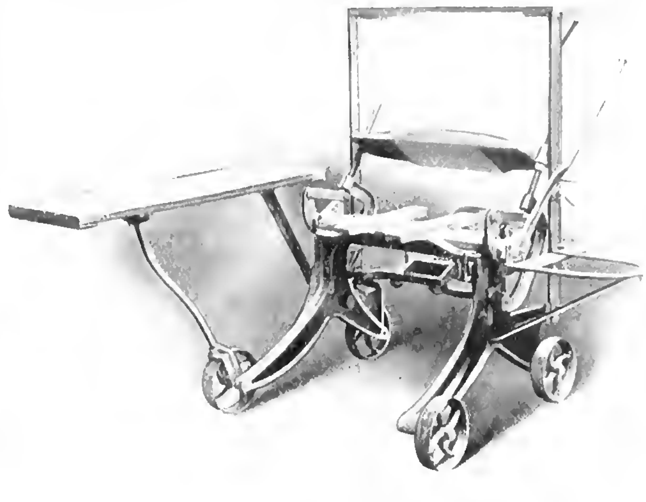

Fig. 7. A Machine of the Squeezer Type, adapted to the Keep Match-plate Process

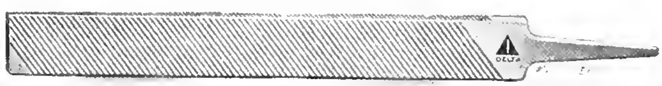
the molder's striking his knuckles against the links when riddling the machine. This will take a flask 18 inches long, or within 6 inches of the total width; whereas on the ordinary 30-inch squeezer, measuring 30 inches between the side rods, no flasks longer than 22 inches are handled conveniently.

"DELTA" HAND UTILITY FILE

A new type of file has been placed on the market by the Carver File Co., Philadelphia, Pa. This file, known as the "Delta" hand utility file, is intended for general use among mechanics and more particularly for machine shops. In addition to being adapted for use on metals, such as soft steel,



"Delta" Hand Utility File for General Work

iron, brass castings, etc., it can also be employed on wood, marble and similar materials. These files are made of high carbon crucible steel, which is especially hardened and tempered. As the engraving shows, the teeth are very coarse or of large pitch, the file being designed to cut rapidly and smoothly and at the same time to clear freely.

RYERSON PORTABLE CYLINDER BORING-BAR

The portable boring-bar shown in Fig. 1 has been added to the line of machinery manufactured by Joseph T. Ryerson & Son, Chicago, Ill. This bar was designed primarily for boring locomotive cylinders, but it may also be used with satisfactory results for such work as stationary engine cylinders, steam hammer cylinders, air hoists and work of a similar character.

In addition to being of heavy construction throughout, this boring-bar possesses a number of novel features, prominent among which may be mentioned the feeding mechanism. The old, so-called "star" feed is entirely eliminated and a positive geared feed substituted; this gives a continuous feeding movement to the cutting tool which results in a smooth cut, as the tool does not dig into the metal. In the engraving the feeding mechanism may be seen at the right end of the bar. The feed-screw, which feeds the tool-head along the bar, is actuated by the gearing shown at the end. When the bar is set up for boring a cylinder, a weight is suspended from the handle of the crank inserted on the pinion shaft, so that when the boring-bar rotates, the feed-screw is caused to turn in relation to it. Were it not for this weight, the pinions on the shaft with

the crank, as well as the feed-screw, would remain stationary with relation to the bar. This simple method of obtaining the feed makes it possible to easily adjust the tool at any time by simply turning the crank, as the suspended weight would not seriously interfere. For rapid adjustment of the tool-head, however, a handwheel is provided which may be used to turn the feed-screw direct. By means of change gears, which are mounted on the shaft with the long crank, two feeds are obtained on the No. 1 or 4-inch bar, and three feeds on the No. 2 or 6-inch bar. Thus a light or heavy feed may be had by merely shifting the gears, or both gears may be disengaged and the feed thrown out entirely.

It will be noticed by referring to Fig. 2 that the tool-head is designed to permit the use of straight boring tools, the latter being set at an angle so that a cylinder may be bored without tearing down the guides and removing the back head. With some types of tool-heads it is necessary to use bent tools in order that the cut may be finished before the tool-head comes in contact with the head of the cylinder. The disadvantage of the bent tool lies in its flexibility and tendency to chatter. Tool-heads of different sizes may be easily attached to the bar, as there is a permanently located master-head so arranged that other heads may be positively fitted to it. This master-head has a long bearing which insures smooth cutting with a minimum of vibration.

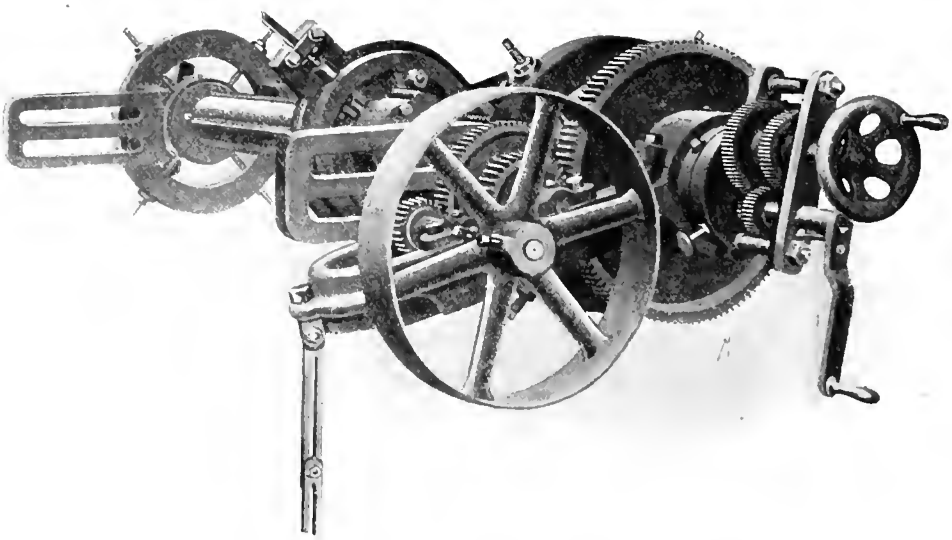


Fig. 1 Ryerson Cylinder Boring-bar with Adjustable Geared Feed

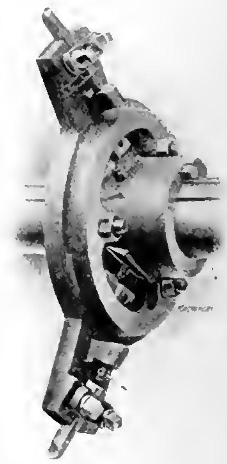

Fig. 2. Tool-head designed to permit Use of Straight Tools

All of the principal parts of this bar are made of steel. The frame containing the driving gears is of cast steel and it is so designed that it may be easily and quickly removed. The bar itself is accurately ground to size and cut gears are used throughout. These boring-bars are made in two standard sizes designated as Nos. 1 and 2. The manufacturers are prepared, however, to furnish special machines for boring cylinders of any length. The No. 1 machine will take cylinders from $9\frac{3}{4}$ to 30 inches in diameter and up to 44 inches in length where there are clearance blocks on one end of the cylinder only. If the bar is located in the stuffing-box of the back head, it will bore to a length of 50 inches. The No. 2 machine will bore diameters ranging from 20 to 50 inches, and lengths, with clearance blocks at one end, up to 35 inches. When the end of the bar is located in the stuffing-box, the maximum length is 46 inches.

These machines can be arranged for either pulley drive, direct gear drive, or with a Morse taper shank for operating with air or electric drills. It is customary in most railroad shops, to employ a motor with a capacity from $2\frac{1}{2}$ to $3\frac{1}{2}$ horsepower.

The approximate weight of the No. 1 or 4-inch bar with equipment necessary for diameters up to 13 inches is 1000 pounds. This machine, when furnished complete for boring to the maximum diameter of 30 inches, weighs 1500 pounds. The approximate weight of the No. 2 or 6-inch bar, varies between 3000 and 3700 pounds, depending upon its capacity.

REED QUICK-CHANGE GEAR MECHANISM

The accompanying illustration, Fig. 1, shows an engine lathe built by the F. E. Reed Co., Worcester, Mass., provided with a new patent quick change gear mechanism which may be applied to the company's 14-, 16-, 18-, and 20-inch lathes. The illustration, Fig. 2, shows a detailed view of the change gear mechanism proper. This illustration is a phantom view of the device so that all the gearing is indicated, although on the lathe itself it is carefully covered by suitable cast gear-guards. The simplicity of the design and the small number of parts are clearly indicated in this illustration. The gear case is securely fastened to the front of the bed and contains a shaft on which is mounted a cone of gears, any one of which can be instantly engaged by the movement of the lower lever shown. Another shaft is located above the cone of gears. This shaft is in line with the lead-screw and connects with it by means of the clutch operated by the knob at the right. When this clutch is released, it brings a gear into mesh with another gear on the feed-rod, this arrangement insuring that both the lead-screw and the feed-rod cannot be thrown into operation at the same time. On the same shaft a double clutch gear is provided which is operated by moving the upper lever to its three different positions.

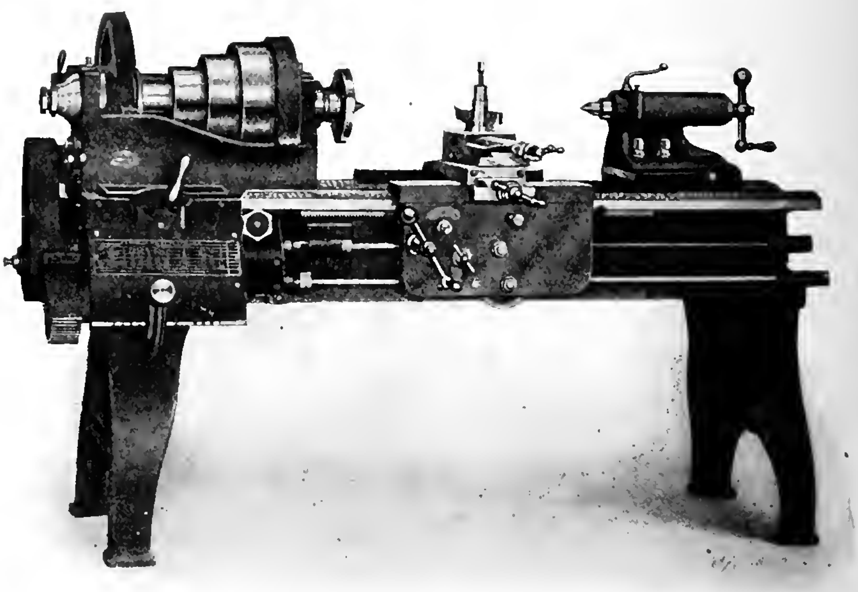

Fig. 1. Reed Lathe provided with Quick-change Gear Mechanism

The combination of the changes thus obtained with the two changes obtained by sliding in or out a gear at the end of the lathe provides for not less than sixty changes of speed for both lead-screw and feed-rod. This is an unusually large number of changes with so simple a mechanism. All gears in the front case are made of steel, are of coarse pitch and are practically unbreakable in service. The whole device is so designed that, in whatever position, the levers and sliding gears will not lock the mechanism and cause breakage. At the same time it is so simple in its arrangement and operation that it can be readily understood and operated by comparatively inexperienced workmen.

The index plate, not shown in the detailed view, but indicated in Fig. 1, is mounted on the front of the gear case. The plate clearly indicates the location of the levers for all

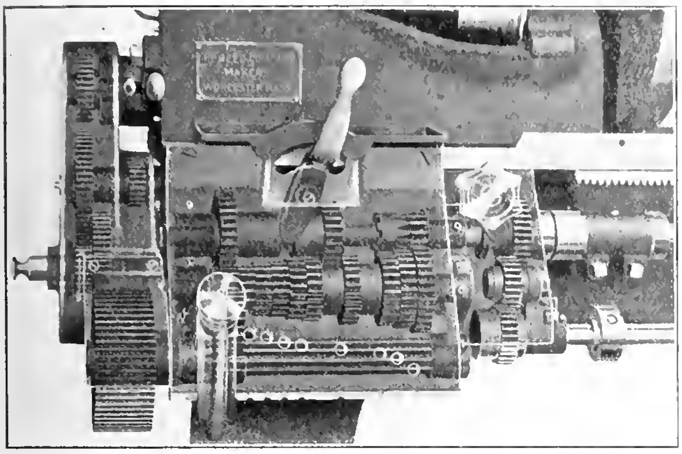

Fig. 2. The Quick-change Gear Mechanism of the F. E. Reed Co.'s Lathe

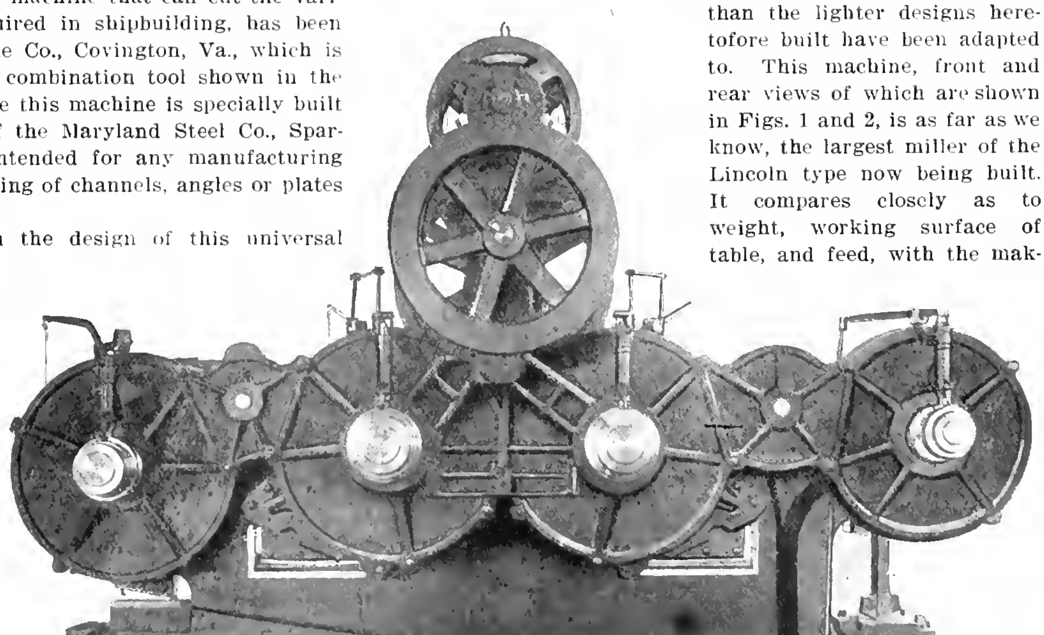
threads and feeds. Standard threads from 2 to 128 per inch, including 11½, can be cut, and feeds from 10 to 640 per inch can be obtained.

COVINGTON UNIVERSAL SHEAR FOR CHANNELS, ANGLES AND PLATES

The need in shipyards for a machine that can cut the various channels and angles required in shipbuilding, has been met by the Covington Machine Co., Covington, Va., which is now manufacturing the large combination tool shown in the accompanying halftone. While this machine is specially built for the marine department of the Maryland Steel Co., Sparrows Point, Md., it is also intended for any manufacturing establishment where the shearing of channels, angles or plates is done in quantity.

The most novel feature in the design of this universal shear, lies in the combination of four tools in one compact unit. It is provided with a coping attachment at one end, a plate shear at the other and two angle shears in the center of the frame. These angle shears operate at an angle of 45 degrees, thus securing a vertical and horizontal shearing action. Each shear is controlled by its own clutch, and the machine may be operated by different groups of men all working at the same time without interfering with each other.



Rear View of Combined Angle, Coping and Plate Shear manufactured by the Covington Machine Co.

The angle shears in the center have a capacity for cutting channels up to 15 by ¾ inch, and 6 by 6 by 1 inch or 8 by 8 by ¾-inch angles. The plate shear has a capacity for material up to 1 inch in thickness. Channels or angles may be cut either square or at an angle for mitering.

The four tools are driven by one motor which develops 25 horsepower. This motor is mounted at the top of the machine in the center, as shown in the illustration, which is a view taken from the rear to more clearly show the general arrangement of the driving gearing and the automatic stop clutches. A pinion on the motor armature shaft engages a large gear located on an intermediate shaft on which two flywheels are mounted, one at each end. The motion is transmitted from this intermediate shaft to a second shaft just below it, which carries a pinion engaging with the two large gears which operate the central or angle shears. These two gears are also connected through pinions to the large driving gears of he coping and plate shears at the ends.

A patent stop motion is used, which automatically throws out a clutch on each shear when the latter reaches its highest point. To again start a shear, it is simply necessary to pull a chain, which is suspended at a convenient point. These chains are connected with the single-revolution clutches, through counterbalanced levers as shown. For the coping attachment, which may also be used for punching, the stop mechanism is adjustable so that the plunger may be stopped at any point of its own stroke. This allows the tool to be brought close to the work, so that the latter can be properly adjusted.

The frame, plungers, clutches, and all parts subject to shock, are made of semi-steel castings. Hammered steel shafts containing from 0.4 to 0.5 per cent carbon are used. The gears are provided with long sleeve hubs and are thoroughly protected by guards which are bored to receive them. The question of lubrication has been given special consideration. Arms, which are provided for supporting the angles or channels while they are being cut, are so designed and placed that they do not interfere with plates that are being sheared, as the latter pass under them. The weight of this machine is about 23 tons.

LARGE DOUBLE-HEAD LINCOLN MILLING MACHINE

The Hendey Machine Co. of Torrington, Conn., is now manufacturing a double-head milling machine of the Lincoln type, which is intended to handle a heavier class of work than the lighter designs heretofore built have been adapted to. This machine, front and rear views of which are shown in Figs. 1 and 2, is as far as we know, the largest miller of the Lincoln type now being built. It compares closely as to weight, working surface of table, and feed, with the maker's standard No. 3 plain knee type machine. A comparison of the two types shows, however, that the Lincoln machine has a greater capacity on some lines of work, as the direct mount-

ing of the table and saddle on the bed gives it a more rigid support than is afforded with the column and knee construction.

On the standard size machine, the table has a working surface of 15 by 54 inches. There is an automatic cross-feed of 36 inches and a longitudinal adjustment in line with the spindle of 12 inches. The table is fitted to the saddle with an angular lock and taper gib, and it has a length of bearing on the saddle of 34 inches. A bearing contact on the shoulders of the saddle supports the table clear to the edge, thus enabling work to be machined to its full width without any tendency to spring under the cut.

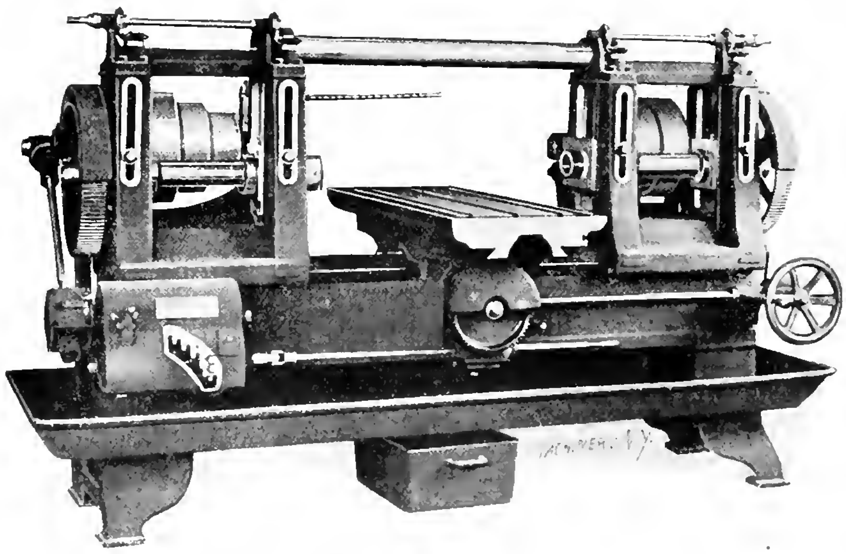


Fig. 1 Double-head Lincoln Milling Machine built by the Hendey Machine Co.

The feed movement is positively obtained direct from the driving spindle through gearing and shafts. There are twelve changes of feed available, ranging from 0.010 inch to 0.130 inch per revolution of the spindle. The feed motion is reversed by means of a toothed clutch operating between right and left bevels. This reversing mechanism is enclosed in the box at the left of the machine (Fig. 1), which receives the ends of the transmission shaft from the driving spindle and the gear-box cone shafts. The feed worm, which is free to slide on the splined feed shaft, is carried in a self-contained bracket, which takes all the end thrust from the feed shaft when a cut is being taken, and thus prevents any twisting strain on the saddle. This worm is well lubricated, as it runs in an oil bath in a pocket of the bracket. The feed mechanism is mounted entirely on the outside of the bed, thus making it unnecessary to core holes in the bed for feed connections.

The main spindles are made of hammered steel forgings and have 1¼-inch holes through their centers. Taper journals are provided at both the inner and outer ends, and the bearings are cast annular and are bushed with Lumen bronze. The ends or noses of the spindles are 3½ inches in diameter, and they are threaded 3½ per inch, left-hand. Slotted driving collars for arbors are fitted to the nose of each spindle, and No. 12 Brown & Sharpe taper holes are provided.

The cone pulleys on the driving shafts have three steps, and the driving belts have a width of 4 inches. The ratio of gearing between the driving shafts and spindles is 6 to 1, the width of the gear faces 2¾ inches, and the diametral pitch 6. The driving shafts are carried in rocking frames by which quick adjustment can be made when the spindles are raised or lowered, and which constantly maintain the shafts in parallel alignment with the spindles. Binding bolts are provided for locking these frames securely in place after an adjustment has been made.

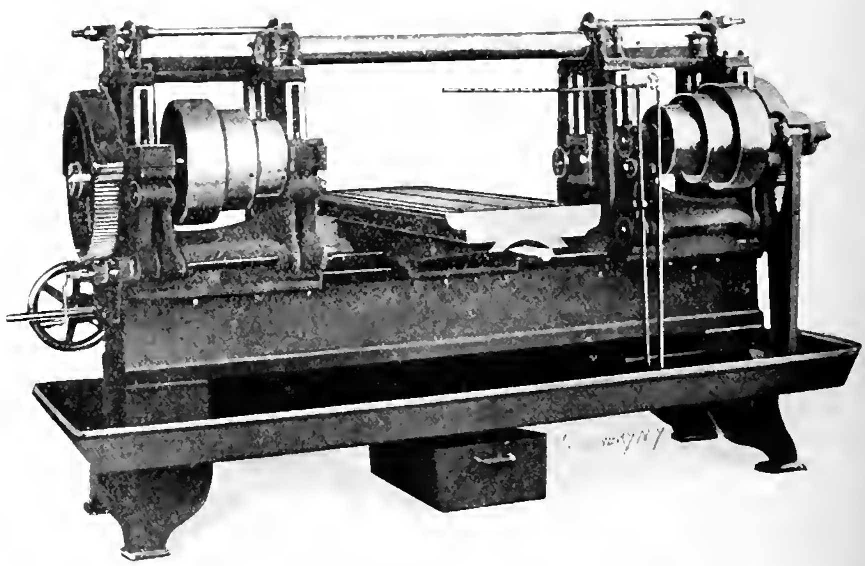

Fig. 2. Rear View of the Double-head Lincoln Milling Machine

The elevating and lowering mechanisms for the spindles, which are located on top of the head-blocks, are fitted with micrometer dials reading to thousandths of an inch, so that accurate vertical adjustments can be obtained. The spindles are held securely in a fixed position, after being set, both by means of the elevating screws and also by binding bolts which pass through the upper part of the boxes, as shown. These bolts serve to clamp both the uprights and the boxes firmly together, after the spindles are adjusted to the desired elevation.

Both the head-blocks and saddle are gibbed to the bed with angular locks to insure a perfect alignment of the spindles with the travel of the table. A hand adjustment of the table is secured by the large handwheel shown bracketed to the right end of the bed in Fig. 1, and the saddle adjustment is obtained by means of a screw which passes through the center of one head-block casting and is mounted in a bracket at the end of the bed. This screw, which is more plainly shown in Fig. 2, has a graduated dial reading to thousandths, thus permitting accurate longitudinal adjustment of the table.

These machines are built with six different lengths of bed, ranging from 62 to 97 inches, and with tables either 15 or 20 inches in width. The maximum distance between the heads for the six different bed lengths, ranges from 15 to 50 inches, while the maximum distance between the spindle noses varies between 9 and 44 inches.

* * *

NEW MACHINERY AND TOOLS NOTES

Quick-acting Swivel Vise: Charles Parker Co., Meriden, Conn. This is a swivel vise which may be adjusted instantly to any desired position and tightened by a single movement of the hand. It is mounted on a swiveling base, permitting it to be set at any position convenient to the operator.

Pressed Steel Gearing: Johnston Pressed Gear Co., Ottumwa, Ia. This firm is furnishing steel rims for gears, having teeth of successive folds made in a strip of steel. It is intended for slow, heavy work, and is said to be superior in strength to cast gears of the same pitch and width of face.

Oilstone Holding Handle: F. J. Badge, 286 Taaffe Place, Brooklyn, N. Y. This tool consists of a handle with suitable clips, whereby oilstones of various sections such as round, square, flat, triangular, etc., can be held for toolmakers' use. It should be very convenient in lapping dies, "touching up" fine tools, etc.

Self-contained Ventilating Outfits: B. F. Sturtevant Co., Hyde Park, Mass. These outfits comprise a small motor with a direct connected multiple vane blower, which may be quickly located in any position and connected with a lamp

socket. They can be used for exhausting vitiated air or supplying fresh air from the outside.

Double Inserted Blade Tool-holder: Colton Combination Tool Co., Chester, Vt. This tool-holder provides for the use of two blades, the second of which is set slightly ahead of the front one so that roughing and finishing cuts can be taken. With this arrangement a fine finish can be given, even while the leading blade is removing a heavy chip.

Power Hammer: New Metal Tool Steel Co., 338 Cumberland Ave., Portland, Me. This hammer provides for ready adjustment, both of the force of the stroke and of its length, while the machine is in operation. It is of the crank and pitman type, with a spring helve which gives the form of blow which has been found most desirable for machine forging.

Standard Punch and Holder: American Die & Tool Co., Reading, Pa. This is an improved construction which permits making the punch of smaller stock than usual, thus lessening its cost. As in previous designs, the strain is taken by the direct bearing of the punch on the stub of the ram, so that full strength for resisting the cutting strain is provided.

Portable Oxy-acetylene Welding Apparatus: F. C. Sanford Mfg. Co., Bridgeport, Conn. This outfit is a smaller size of the apparatus described in a note published in the December, 1908, number of MACHINERY. It is adapted to a wide range of work in welding, cutting, etc., with the high temperature flame. It operates on chemicals which may be bought in the open market.

Spring Controlled Collets for Speed Lathes: Garvin Machine Co., Spring and Varick Sts., New York City. With this design of collet mechanism the gripping of the sleeve at the rear end of the spindle, while the lathe is in motion, releases the work. When the sleeve is released the chuck is closed by spring pressure. It is very rapid in operation, as it is not necessary to stop the spindle on ordinary work.

Combination Wrench Set: C. M. B. Wrench Co., Syracuse, N. Y. This set of wrenches comprises a ratchet handle, sockets for bolts and nuts of various sizes, together with extension sockets, screw-drivers, etc. This permits a wide range of work to be done in all sorts of inaccessible places. The wrenches and universal joints are made of a non-rusting alloy, and the connections are of square section steel tube.

Self-Lubricating Bearing Metal: New Era Mfg. Co., Kalamazoo, Mich., has brought out an anti-friction alloy in which the metal portion is reduced to a sponge-like form, highly attenuated and of irregular or interrupted surface formation. The metal is treated with lubricating oil and is then coated with mineral lubricants making a compound mass of metallic packing. It is used for packing piston rods, valve stems, and as a bearing metal for lining journal boxes, bushings, etc.

High-speed Steel Treating Furnace: C. U. Scott, Davenport, Ia. This is a furnace of improved construction which, it is said, makes possible the heating of high-speed steel tools to the high temperatures required, without any scaling, pitting or blistering. Even polished steel can be treated so that it will be free from scale. This result is obtained by doing away with the door and the combustion chamber. Provision is also made for confining the heating to the cutting ends of tools.

Bench Milling Machine: B. C. Ames & Co., Waltham, Mass. This is a miller of the precision type, built on the general lines of the standard column and knee type machine, though, of course, of much smaller size. It is provided with a lever feed for the horizontal table movement, and is furnished with swiveling vise and index head. The latter may be set at any angle from 10 degrees below the horizontal to 5 degrees above the perpendicular. The table has a working surface of 12 by 3 inches.

Mica Annealing Mixtures: United States Mica Co., Chicago, Ill. This is a substance prepared from mica which is used for annealing in the same way in which charcoal, etc., are used now. Its inertness to chemical combinations and its non-absorbent qualities result in the production of a clean surface on the steel, without oxidization. The material is an exceedingly poor conductor of heat, so that the cooling takes place very slowly, giving the best results in annealing.

Inserted Tooth Milling Cutter: Union Twist Drill Co., Athol, Mass. These cutters use inserted teeth instead of blades. The teeth are set into drilled holes, and are made from round stock. They are held in place by being split longitudinally for the greater part of their length, and are provided with taper pins in the splits, the driving of which locks them firmly in place. To remove the teeth when they are all ground away, the taper pin is drilled out, it being left soft for this purpose.

Arch Type Press: Blake & Johnson, Waterbury, Conn. The distinctive feature of this press is the type of adjustment used for the ram. The ram is split in two parts, held together by a double, dovetailed wedge, which is controlled by a fine screw adjustment. This device puts into the hands of the operator a means for making minute changes in the depth of the ram stroke, which is controlled with the greatest delicacy. It will be seen, therefore, to be particularly adapted to sub-press work.

Automatic Buffing Machine: Automatic Buffing Machine Co., Buffalo, N. Y. This is a device for presenting plain cylindrical or other simple work to a wheel mounted on an ordinary buffing head, rotating it and moving it back and forth automatically so as to cover the whole surface. It does this with a uniform pressure, which is said to insure a longer life to the wheel than with hand buffing. It has the further and main advantage of permitting the operator to take care of several machines at once.

Pipe Expanding and Flanging Machine: Lovekin Pipe Expanding and Flanging Machine Co., Philadelphia, Pa. This is a machine which might be likened to a gigantic flue expander. It is intended for pressing steel piping into a tight fit with the flanges, rolling the metal into internal grooves in the latter. This process allows the use of a thinner pipe than is possible where threaded joints are used. The line of machines will handle all sizes from 2 to 24 inches in diameter. Larger machines will be built to special order.

Inserted Blade Boring-Head: George Braithwaite & Oscar B. Elder, Chicopee Falls, Mass. This is a boring-head of the inserted blade type, particularly adapted to finishing out cored holes preparatory to reaming. The blades are held in place by taper pins, bearing on the bottom sides of elongated slots, thus holding them to their seats in the head. A threaded collar serves to set all the blades forward together, changing the diameter adjustment slightly as may be required. The body of the tool is made of soft material, while the blades are made of high-speed steel.

Bethel Cutting-off Machine: Matson Machine & Tool Co., Bethel, Vt. This is a machine of the friction disk type for cutting off high-speed or other steels. The wheel is 12 inches in diameter by 3/32-inch thick, and should run at about 4,000 revolutions per minute. The machine has the capacity up to 1 1/8-inch round, and will cut flat stock up to 3 inches wide. A special feature of the machine is the fact that the cutting is done at the rear of the wheel, allowing the front to be guarded so as to keep the dust of the cutting operation from the operator's eyes.

Air Hoist: Weir & Craig Mfg. Co., Chicago, Ill. This firm has developed a form of geared air hoist which possesses a number of advantages, chief among them being the small head room required as compared with the plunger and cylinder type of hoist, and the provision made for holding the load at any given point irrespective of leakage. The best of material is used, the gears being cut from hammered steel and the crank being made of forged nickel steel. The bearings are bronze bushed and the machine is built on the interchangeable plan throughout.

All Geared Lathes: Niles-Bement-Pond Co., 111 Broadway, New York City. These lathes have the motor mounted directly on the enclosed headstock casting, and connected with the spindle by guarded gears. The quick change gear mechanism has 32 rates for feeding and thread cutting. This has previously been described and illustrated. (See article entitled "Assembling a 24-inch Engine Lathe" in the November, 1909, issue of MACHINERY, engineering edition). The lathes are built in sizes from 36 to 72 inches, and are furnished either with single pulley drive, or with motor drive.

Portable Electric Drill: Lamb Electric Co., Grand Rapids, Mich. This firm is developing a line of direct and alternating current electrical drills, of which the first size has recently been put on the market. This is a machine capable of drilling 3/8-inch holes in steel, or ½-inch holes in wood. It is provided with a ball thrust, and is furnished with the Jacobs No. 2A chuck. A special feature of the construction is the fact that no ventilating fan is provided, as the motor has been designed to keep cool without requiring a current of air, with the accompanying trouble of chips and dust blowing through the armature.

Sherardizing Equipment: Globe Machine and Stamping Co., Cleveland, Ohio. In the December, 1909, number of MACHINERY we describe an improved drum arrangement, dust hood, etc., for the process of sherardizing or dry zinc plating. The apparatus has been recently improved by the addition of two transfer tables, which permit a continuous movement of the work. This movement is from the loading platform, through the furnace, into the dust hood (where the work is dumped), and back to the loading platform again. This arrangement materially increases the output of a given size of furnace.

Gas Furnaces: Westmacott Gas Furnace Co., Providence, R. I. This firm has recently added three new furnaces to its line. One of these is a quick heating furnace for hardening by the barium-chloride process, obviating the long waits usually required for getting this substance to the hardening temperature. The second furnace is for oil tempering. It is provided with a pot of sufficient size to take a basket of 12 inches in diameter and 14 inches deep. The

third is a lead hardening furnace of rectangular shape, carrying a pot 20 inches long, 10 inches wide and 7 inches deep. It can be furnished either of cast iron or steel.

Double Cold Sawing Machine: Newton Machine Tool Works, Inc., 24th and Vine Sts., Philadelphia, Pa. This arrangement consists of two cold sawing machines, one right- and the other left-hand, mounted on a baseplate on which one of the units may be adjusted to give any required distance between the blades, from 1/4 inch up to any reasonable maximum, depending on the length of the baseplate. The use of a double machine of this kind is designed to reduce the idle time of the machine materially, as two cuts can be made at one setting of the work. The machines are of standard design, and belt-driven from the same cone pulley.

Surface and Wet Grinding Machines: Valley City Machine Works, Grand Rapids, Mich. One of this line of tools is a combination surface and tool grinder, comprising a disk wheel of the usual type with suitable work-table at one side of the frame, and an emery wheel at the other with tool-rest and surface grinding platen underneath. The grinding disk is 18 inches in diameter, and the work-table used with it has an angular adjustment. Another member of this line is a combination wet and dry grinder. The wheel for dry grinding is mounted on a heavy hanging arm away from the column, and is provided with a tool-rest.

Ashcroft Valve Grinder, Breast Drill, etc.: Ashcroft Mfg. Co., 85-89 Liberty St., New York City. This device resembles a breast drill in its appearance, but is provided with certain special features adapting it particularly to valve grinding. By the operation of the mechanism provided, the valve is given a rotary motion back and forth, but advancing with each movement a little further to the right, thus bringing it into a new position at each stroke. The surfaces are thus ground to a bearing under the conditions best adapted to prevent scoring, and to give a true seat. It can also be used for a breast drill, or for a right- or left-hand ratchet drill or screw-driver.

Transfer Press: Standard Machinery Co., 7 Beverly St., Providence, R. I. This line of transfer presses is designed on the arch type, and comprises four sizes, ranging from 700 to 4,200 pounds each in weight. As implied in its name, the machine is particularly adapted to double operation work in which the blank is cut out and drawn or simply cut out in the first operation, and then transferred to a second position where it is again drawn, while a new blank is being formed in the first position. It is provided with an adjustable roller feed of improved construction. The transfer mechanism is adjustable to give any stroke from 1 to 3 inches.

Automatic Tapping Machine: Garvin Machine Co., Spring and Varick Sts., New York City. This is a power tapping machine with vertical spindle, having forward and reverse pulleys driven by a single belt. A special feature of the machine is the provision of an automatic reverse for the spindle, set to operate at any required depth of tapping by means of an adjustable stop, and of a friction slip incorporated in the driving clutch. The machine will tap holes from 1/4 to 3/4 inch in diameter in cast iron, to a depth of 1 1/2 inch. The automatic reverse cannot be accidentally thrown out of operation, even by the continued pressure of the operator on the feed lever.

"Oil Drag" Speed Changing Mechanism: Robert E. Newcomb, Holyoke, Mass. In this apparatus a familiar principle, employed in the common multiple disk automobile clutch, has been used to operate as a speed changing device. A series of alternate disks is fastened, one to the driving and the other to the driven member, spaced slightly apart, and submerged in oil. The drag between the driving and driven disks, effected by the oil, is used to permit relative motion between the two members. By means of a piston arrangement the level of the oil in the chamber is raised or lowered, increasing or decreasing the drag, and the speed in proportion.

Four-spindle Cylinder Boring Machine: Moline Tool Co., Moline, Ill. This is a machine of the same general design as others of this line we have previously described. (See, for instance, the multiple spindle drill in last month's department of New Machinery and Tools.) The drive, however, is made unusually heavy, and two spiral gears are provided, allowing the alternate spindle gears to overlap each other so as to permit their being of large diameter, suited to the heavy service required. The spindles are bored for No. 5 Morse taper; the ends will be threaded to fit cutter-heads, or left blank, as required. The machine is back-geared and provided with a double countershaft, giving six changes of speed.

Fuel Oil Crucible Furnace: Alfred Fisher, 103 West Monroe St., Chicago, Ill. This furnace is built in four sizes to hold crucibles from No. 30 to No. 350. The two smaller sizes are equipped with one burner, and the two larger ones with two burners apiece. The fire brick is so arranged as to draw the heat upward and close to the crucible, and also to permit the use of charcoal to prevent oxidization of the charge. As compared with the coal furnace it is intended to replace, it is always ready; it will melt alloys of brass and copper without burning out the brass borings; and its use results in a saving in fuel and shrinkage. It is stated that it will melt any kind of metal from scrap to sheet zinc, at an operating cost of 6 1/2 cents for 100 pounds.

Rotary Elastic Blow Riveter: Charles Greiner Co., New Haven, Conn. In the December, 1909, number of MACHINERY, we published a note describing a riveting machine in which a series of hammer blows was struck on a spring cushioned hammer by projections on a revolving flange. The hammer was rotated at the same time so as to distribute the action around the head of the rivet and make a symmetrical and thorough job. The present design of this machine is a larger size, and is provided with a vertically adjustable table for accommodating work of various heights. The hammer is brought down to the work by a foot-treadle, which regulates the force of the blow. When the treadle is released the hammer rises, clearing the work automatically.

Rim Friction Clutch: Lehigh Clutch Co., Denckla Building, Philadelphia, Pa. This is a clutch of the type in which the rim of one member is grasped between two or more sets of double jaws on the opposite member. A separate set of toggles is provided for each jaw, drawing the outer ones toward the center and forcing the inner ones outward, gripping the rim between them. Turnbuckles are used to maintain the proper adjustment. The operation is entirely positive, no springs being employed. The friction blocks or wooden shoes can be renewed very expeditiously without dismantling the chuck. The device is made on the interchangeable plan, permitting repairs to be easily effected. Twenty-six sizes are made, of capacities ranging from 4 to 128 horsepower, and in sizes of from 12 to 36 inches diameter.

Squeezer Type Molding Machine: Arcade Mfg. Co., Freeport, Ill. This machine, which is adapted to the use of the double-faced match-plate system of molding, is notable among other things for the convenience provided for the molder. A table for flasks and bottom-boards is mounted on the machine at the left. A support for the riddle is provided at the right, while convenient shelves are mounted on the top of the machine for the parting sand, tools, etc. A gage at the rear of the table serves to locate the flask accurately under the ramming head. The ramming is accomplished by a double-geared toggle device of original design. A vibrator is furnished, operated by a knee pad. The whole machine is mounted on three wheels, so as to always be firmly supported even though the floor be uneven.

Bevel Gear Hobbing Machine: Carpenter-Kerlin Gear & Mch. Co., 77 White St., New York City. This firm has taken the agency for the Chambon gear hobbing machine which is now built by the Société Francaise des Machines-Outils of Paris. This machine was illustrated on page 12 of the September, 1908, number of MACHINERY (engineering edition) where the principles of its operation were fully described. It employs a hob for a cutting tool, and the process of generation is continuous from start to finish, the same as for hobbing spur gears. Owing to the approximate character of the generation, this machine is particularly adapted to roughing out bevel gears which are to be finished by planing. For such work it is very rapid, and cuts closer to the finished shape than any other roughing process hitherto employed.

Plate Planing Machine: William Sellers & Co., Inc., Philadelphia, Pa. This machine for planing the edges of steel plates will take in work 3 inches thick and 24 feet long at one setting. The shape of the housings permits any greater length to be machined by shifting the work as many times as may be required. The carriage is so arranged as to permit its ready removal when necessary, without dismantling the end housings or taking out the driving screw. The feeds are hand controlled, and the tool-holder is turned over by the operator at each end of the stroke. An improved clamping construction makes use of a series of air cylinders. These have the advantage over hydraulic or screw actuated jacks in that they automatically follow up any distortion in the beam due to the pressure gripping the plate from one end to the other equally at a single movement of the operating valve. The machine is intended for heavy duty in planing vanadium steel plates.

Motor-driven Roll Grinding Machine: Norton Grinding Co., Worcester, Mass. It was for a long time supposed that rolls as accurate as those required for paper machinery and similar work could only be successfully ground by the double-wheel calipering process. Modern improvements in grinding machinery, however, have demonstrated that they can be finished accurately in machines similar to the standard plain grinding machines for regular work. In the special roll grinder built by the Norton Grinding Co. the only radical changes made have been in the provision of supports for the neck bearings of the roll (so that they revolve on their own journals in the grinding process) and in the provision of a self-contained motor-drive. Two motors are used, one at the back for driving the wheel, pump and feed, and one mounted directly on the headstock for revolving the roll. A floating device is used for connecting the roll and the headstock faceplate. The

work may be ground on centers as usual, if desired. This machine weighs 18,500 pounds, and will grind rolls from 12 to 22 inches in diameter.

Multiple Spindle Automatic Screw Machine: Davenport Machine Tool Co., New Bedford, Mass. This screw machine incorporates a great number of radical improvements in design for machines of the multiple spindle type. These improvements include separate cam control for each of the five turret tools and the four cross-slide tools; separately adjustable rate of feed for each of the five turret tools and the four cross-slide tools, and individual stops for each of the five spindles and four cross slides, making 20 in all. These individual stops give accuracy in cross-slide operations in spite of irregularities due to the wear of the spindle. The quick-acting, idle movements, such as stock feeding, turret revolving, etc., are performed at the highest rate of speed. Special provision is made for rapid and precise indexing of the spindle head. Other features are wide range of speeds and feeds, single belt drive and removable plate cams for the cutting operations. These various improvements have been applied to a machine capable of taking in ½-inch round rods, feeding up to 2½ inches in length, and turning up to 2 inches in length. The provision of the independent adjustable control for each of the five spindles and four cross-slide tools is especially important in that it permits shortening the time of the longest operation, thus materially increasing the production of the machine over other types not provided with this feature. From the size of the machine it will be seen that it is expected to be used on the finer grades of work, for which the multiple spindle idea has often been considered unsuited.

* * *

APPRENTICESHIP CERTIFICATE

The accompanying halftone shows the apprenticeship certificate granted by the Bantam Anti-Friction Co., Bantam, Conn., to its apprentices when they have completed their full three and one-half years term in its shop. The certificate is

Apprenticeship Certificate issued to Journeymen by the Bantam Anti-Friction Co.

shown about one-third size, its dimensions being about 9 x 11 inches. The company finds that the certificate is an incentive to the completion of the apprenticeship term, and that the boys highly appreciate it. It states that the journeyman to whom issued has received instruction in the operations of lathes, milling machines, drills, tool-making, bench work and other practical shop work. It is signed by the works manager and approved by the president.

* * *

PATENT OFFICE PRACTICE LEGISLATION

The Board of Managers of the Patent Law Association of Washington, D. C., has published a small pamphlet in which objections are made to two bills now pending in Congress relating to certain changes to be made in the tribunals of appeal in the patent office. The passage of these bills apparently would place too much power in the hands of the Commissioner of Patents without any specific benefit being gained. In the place of these two bills the Patent Law Association recommends the provisions contained in the House Bill No. 23,916 recently introduced, which provides that the present courts of appeal in *ex parte* cases shall remain undisturbed, but that appeals in interference cases shall be taken directly from the Examiners-in-Chief to the Court of Appeals of the District of Columbia, and that only in case of a temporary disability of one or more of the members of the Board of Examiners-in-Chief, the Commissioner of Patents may designate a primary examiner to sit temporarily upon the board. This bill removes one of the objectionable features of the former bills which gave the Commissioner power always to designate the three members on the board. As it, of course, does not seem desirable to give to one man the power to designate the members or judges in the appeal cases, it would undoubtedly be to the interest of the efficient conduct of the patent office if the bill approved by the Patent Law Association were passed, and the two previous bills rejected.

* * *

EDISON STORAGE BATTERY STREET CAR

In the March number of MACHINERY some details were given relating to the operation of a street car in New York by the storage battery with which Mr. Thomas A. Edison has been experimenting for a number of years. Some figures were deduced, estimating the size of a storage battery for a street car of the common type, and on account of the weight of the battery for a car of this kind, the opinion was advanced that the additional power required for hauling the dead weight of the battery would likely make the storage battery street car proposition impracticable. Additional information since furnished by Mr. R. H. Beach, 10 Fifth Ave., New York, who is conducting experiments with the Beach street cars using Edison storage batteries, puts the developments in another light.

Mr. Beach found that when the Edison storage battery was applied to an ordinary street car the current consumption was about 125 watts per ton mile. Storage battery operation was out of the question unless the consumption could be reduced. An excellent opportunity to improve the design of the cars, however, offered itself, inasmuch as there has been little improvement in street railway cars during the past twenty years except as regards increasing the size and capacity. Practically nothing had been done to increase the mechanical efficiency of the trucks or the motor. The first important improvement made in the Beach car was the introduction of the differential axle. This device permits the wheels to run independently, and cuts down the current consumption very materially, especially on tracks with many curves. The superstructure of the car was lightened, while the underbody was made as heavy or heavier proportionally than that of standard cars. Instead of chilled cast-iron wheels weighing 500 pounds or more, manganese steel wheels weighing only 125 pounds were used. Instead of a three-to-one gear reduction motor a six-to-one reduction chain drive motor was used, thus reducing motor weight and increasing efficiency of drive. By these and other improvements made in an endeavor to fit the storage battery proposition to street cars a considerable improvement in mechanical efficiency has been brought about, and the current consumption has been cut down to 70 watts per ton-mile, with possibilities remaining for further reduction.

Under these conditions the proposition of using storage batteries assumes a different aspect, although it must also be conceded that if the same improvements are introduced in cars using current from a central station directly, they too will prove much cheaper to run than at present. It should be understood, however, that while the lighter construction can be profitably used for underground conduit system, it could not be used so successfully for trolley systems taking power from an overhead wire, as then a stronger superstructure is necessary to support the trolley and its accompanying mechanism and withstand the racking stresses. Whatever the ultimate outcome of the experiments with storage battery cars, much credit is due to Mr. Beach for inaugurating the improvements in mechanical efficiency and construction which have resulted from his desire to utilize the Edison storage battery.

* * *

Another large ocean liner will soon be built by the Hamburg-American Line at the Vulcan works at Stettin, which will rival, if not exceed in size, the giant White Star liners now under construction. The vessel will be 800 feet long, with a displacement of from 45,000 to 50,000 tons and a speed of 20 knots.

NATIONAL METAL TRADES ASSOCIATION CONVENTION

The twelfth annual convention of the National Metal Trades Association was held at the Hotel Astor, New York, April 13 and 14, with the following official organization: Howard P. Eells, Bucyrus Co., president; J. H. Schwacke, William Sellers & Co., Inc., first vice-president; H. W. Hoyt, Great Lakes Engineering Works, second vice-president; William Lodge, Lodge & Shipley Machine Tool Co., treasurer; Robert Wuest, commissioner. The membership numbers 738, there having been a net gain of twenty during the past year. The association is in a most flourishing condition, and its influence is broadening far beyond the original conception of its charter members. Originally it was almost purely a defensive organization designed to resist the aggressions of union labor, and that work is still its principal function, but now the policy is constructive as well as defensive.

The members generally have recognized the great need for industrial education, and the convention reflected the common desire to promote it in the papers presented. The recognition of the employers' responsibility to workmen worn out in service or disabled was also reflected in papers on old-age pensions and insurance against unemployment. The program of papers following was one of the best ever presented before the association, comprising the subjects of industrial education, compensation of workmen, old-age pensions, liability insurance, shop management, cooperation, etc.:

"The Old-Age Pension Problem and Its Relation to the Industries," by M. W. Alexander.

"The Compensation of Workmen," by H. L. Gantt.

"The Premium System; Some of its Drawbacks," by Carl G. Barth.

"Employers Liability Insurance," by Miles Dawson.

"Modern Method of Shop Management," by Frederick A. Waldron.

"The Fitchburg Plan of Industrial Education," by W. B. Hunter.

"Cincinnati's Continuation School," by Dr. Frank B. Dyer.

"The Necessity for Continuation Schools to Develop Higher Intelligence," by J. Howard Renshaw.

"The Manufacturer's Point of View," by Fred A. Geier.

"The Originator of the School," by B. B. Quillen.

"The Growth of the Cooperative System," by Prof. Herman Schneider.

"Insurance Against Unemployment," by John L. Griffiths.

Prof. W. B. Hunter of the Fitchburg High School, Fitchburg, Mass., described the "Fitchburg Plan" (see MACHINERY, October, 1908, August, 1909, and November, 1909), which is based on the cooperative engineering school and shop work course originated by Prof. Herman Schneider of the University of Cincinnati, and described by him at the N. M. T. A. convention in April, 1908. This plan provides for high school boys what the Cincinnati plan provides for its engineering students.

Dr. Frank B. Dyer, superintendent of schools, Cincinnati, Ohio, described the Cincinnati continuation school work, begun last September. This plan provides for the education of regular apprentices in the Cincinnati shops without loss of time or pay. The school is in session eight hours a day, four and one-half days a week and forty-eight weeks a year. The boys attend one-half day a week and are paid regular wages for the time of attendance. Dr. Dyer said in part:

"Some years ago in Cincinnati we opened night classes for apprentices," said Dr. Dyer. "Pattern making may be taken as an example. We advertised a course for apprentices in every shop in the city. There were fewer than thirty responses. The attendance was irregular and capricious, though the teaching was excellent. Though the courses were continued they did not appeal to those we were wanting. The night school fills a need with older workmen, but the apprentice is a day-time proposition. He must come regularly and through a series of years. The employer must make it worth his while to come, and, in fact, must see that he does come.

"Some of the progressive manufacturers of our city for several years tried to cope with the problem by employing teachers for their apprentices, but such teachers are scarce, and only very large concerns could afford it. The obstacles to the extensive operation of such a plan are too obvious to

need discussion. The only agency that is adequate to cope with the situation is the state, and the state will cooperate when it understands that it is the great industrial class that is to be helped. Employers may have to make some slight sacrifices. They may have to concede to young workmen a little time for their intellectual betterment, but in the end it will be money well spent as an investment. If authority is not given to require employers to send their apprentices to receive the instruction which is the right of every youth, in a democracy at least, it is the privilege of every city to offer an opportunity to such youth in part-time day schools as well as in night schools.

"These ideas ripened in the minds of some of our wisest Cincinnati manufacturers, and thus it came about that the Board of Education of Cincinnati last summer proposed to offer continuation courses for apprentices in any trade, and proceeded to open a school for machine shop apprentices as soon as 150 students were guaranteed. More than 200 students were registered by eighteen manufacturers, and the school started September 1. A man was placed in charge who had been a teacher, a practical shop man, and for many years an instructor of apprentices. He trained his own assistant. The average attendance has been 180 per week. The boys came four hours per week, a new squad coming each half day. The employers pay them for their time, and if they do not show up at school they are reported and docked. The school runs forty-eight weeks a year, eight hours a day, four and a half days a week, and the instructors spend two half days a week, besides, visiting the boys in the shops, talking with the foreman and keeping a line on the needs of the boys. The school is costing the board about $15 a year per boy.

"The course of study is arranged to cover four years. The greatest difficulty was encountered in getting the boys classified correctly and placed in similar groups. While this was gradually accomplished with the assistance of the foremen, it is still necessary to do considerable individual instruction, thus requiring an assistant, though there are but twenty boys in a group. The course taken by the boys is not narrow, nor it is without cultural elements. It includes mathematics, mechanics, drawing, civics, and reading, writing, and spelling. The interesting thing about it is that every study is given a practical coloring, and is made to function in the shop or experience of the boy. The boy sees the purpose of what he is studying, and has a motive in mastering every difficulty. The end of all this is not, as some suppose, simply to send him back next day, able to turn out more and better work; it is to awaken his dormant powers and make him alert, thoughtful, original, and competent.

"These mental exercises relieve him of the monotony of shop routine. As he learns of the great industry in which he is engaged, and of its captains and inventors, and as he discusses its relations with other occupations and with human life, his interest in his work increases, and he comes into sympathy with the great body of the world's workers. As he learns to find new problems in his shop experience, and applies his knowledge to them, his work becomes transformed into a fascinating art. He ceases to be a mere hand, and aspires to be a free master of an honorable craft.

"A great many expert educators from different parts of the world have visited the school and examined carefully into the course and the methods of instruction and have questioned the boys at length. They pronounce the course as one of the most significant efforts yet made to adapt education to vocation, and the method used as representing the most advanced pedagogical views.

"We think so much of the plan in Cincinnati that the Board of Education has offered to open a continuation school for any other classes of apprentices that may be sent, and also for young saleswomen in stores, or girls working in trades. A bill is now before the Ohio State Legislature empowering boards of education to require the attendance of all youth under 16 at part-time continuation schools. If I had the determining of it, there would be a law requiring the attendance of all apprentices through their apprenticeship. Such schools will do much to elevate the standard of work, the degree of intelligence, and the moral character of young workers, and will lift them in the scale of living so that they may be what they should be—the strength of our nation and the envy of the world."

J. Howard Renshaw, the originator of the jig sheet system of mathematical instruction for apprentices, and Dr. Dyer's assistant, illustrated, with a large number of lantern slides, typical apprentice classes sent from the Cincinnati shops, and boys at work (see Figs. 1 to 9, inclusive); also jig sheets used in teaching geometry, trigonometry, analysis of machines, etc.

J. H. Schwacke, of the William Sellers & Co., Inc., was elected president of the association for the coming year; F. C. Caldwell, of the H. W. Caldwell & Son Co., first vice-president; Paul B. Kendig, of the Seneca Falls Mfg. Co., second vice-president; H. P. Eells, of the Bucyrus Co., treasurer. The commissioner is Robert Wuest, New England Building, Cleveland, Ohio.

PERSONALS

F. X. Cleary has been appointed advertising manager of the Western Electric Co., 463 West St., New York.

Harry F. Mesener has been promoted to the position of superintendent of the Grant Automobile Co., Orange, Mass.

W. F. Hittle, who for the past four years has been in charge of the machine department of the Dayton Motor Car Co., has resigned.

B. D. Jackson, for the past five years with Walter H. Foster Co., 50 Church St., New York, is now with the Modern Tool Co., Erie, Pa.

W. C. Wilcox has been appointed manager of the Chicago branch store of the Reeves Pulley Co. to succeed Mr. E. O. Winterowd, resigned.

Louis I. Howard has resigned from a position with the Lamb Knitting Co., Chicopee Falls, Mass., to become manager and treasurer of the National Scale Co. of the same city.

Walter M. McFarland, acting vice-president of the Westinghouse Electric & Mfg. Co., Pittsburg, Pa., has resigned to take an official position with the Babcock-Wilcox Co., New York.

H. C. Fay, foreman of the chucking, punching and shaving department of the Remington Arms Co., Ilion, N. Y., has been appointed to succeed Mr. A. C. Brown in the tool and gage department.

Henry T. Merriam, manager and engineer of the R. F. Hawkins Iron Works, Springfield, Mass., has resigned the position to assume the management of the Grip Coupling Co., Ware, Mass.

Matthew Harrison has resigned the position of superintendent of the Grout Automobile Co., Orange, Mass., to become assistant superintendent of the Stevens-Duryea Automobile Co. at Chicopee Falls, Mass.

George E. Tiffany, foreman of the drop forge and die sinking department of the Remington Arms Co., Ilion, N. Y., will assume charge of the chucking, punching and shaving department, succeeding Mr. H. C. Fay.

Benjamin K. Hough has been appointed Boston sales manager of the Wisconsin Engine Co., Corliss, Wis., with offices in the Oliver Building, Boston. Mr. Hough will represent the company in the New England states.

E. G. Matter, who has been with the National-Acme Mfg. Co., Cleveland, Ohio, in the Ohio and Chicago territory for the past five years, has been put in charge of the newly-opened Detroit office at 1222 Majestic Building.

C. A. Nourse, for the past three years with the Alden Sampson Mfg. Company, Pittsfield, Mass., as superintendent, has resigned to take a position with the American La France Fire Engine Co., Elmira, N. Y., as machine shop foreman.

Alfred C. Brown, for the past four and one-half years foreman of the tool and gage department of the Remington Arms Co., Ilion, N. Y., has resigned to take a position as superintendent with the Denver Rock Drill & Machinery Co., Denver, Col.

George S. Perkins, Springfield, Mass., who for the past four years has been draftsman for the Fisk Rubber Co., Chicopee Falls, Mass., designing molds and special machinery, has resigned to take a position in the drafting department of the Confectioners' Machinery & Mfg. Co., Springfield, Mass.

J. A. Brown, who has been employed in the ordnance department as mechanical engineer and as chief draftsman, and for the past five years as constructing engineer, at the Frankford Arsenal, Frankford, Pa., has resigned to engage in private practice. Mr. Brown will also represent several well-known manufacturers of machine shop equipment.

Morgan K. Barnum, who was recently appointed superintendent of motive power, for the Illinois Central R. R., is a graduate of Syracuse University. He began his railway career as a machinist apprentice with the Erie R. R. Mr. Barnum will have charge of the entire mechanical department of the Illinois Central R. R.

F. Mueller, partner of A. Engelman & Cie, Liège, Belgium, is in the United States on a business trip. He will call upon manufacturers of machine tools and accessories in order to learn of new inventions and improvements and to make contracts for representation abroad. His address while in the United States will be the Waldorf-Astoria Hotel, New York.

Jonah E. Titus, an employe of the New Home Sewing Machine Co., Orange, Mass., for forty-three years, over thirty-five of which were spent as foreman, recently resigned on account of continued ill health, his resignation to take effect on his sixty-fifth birthday. Mr. Titus had more men under his supervision than any other department foreman in the building.

James Cordner has resigned the position of general foreman at the Stevens-Duryea automobile factory, Chicopee Falls, Mass., to become general foreman of the Locomobile Co. in Bridgeport, Conn. Mr. Cordner was tendered a farewell banquet at the Haynes Hotel, Springfield, by about sixty-five of his associates and was presented with a full jewelled gold watch suitably engraved.

The personal in the March number of MACHINERY stating that Frank A. Foster had sailed to China as representative of the American Locomotive Co. in Tientsin was erroneous as regards his connection with that company. Mr. Foster held a position with the American Locomotive Co. in Providence, R. I., but went to China to take another position in which he will have considerable to do with the machinery and mechanical part of railway work.

Charles H. Norton of the Norton Grinding Co. was recently elected president of the Worcester Mechanics Association, Worcester, Mass. For several years Mr. Norton has been prominent in this association, which was formed about the middle of the last century by those interested in mechanical trades as a means of mutual improvement. This association owns its own building, library, etc., and by means of its activities has done much to develop the industries of Worcester.

* * *

OBITUARIES

Eugene Stuart Bristol, president of the New Haven Mfg. Co., New Haven, Conn,. died April 2, in his sixty-seventh year.

David A. Jones died at Springfield, Mass., April 4, aged eighty-five. Mr. Jones had been employed by the United States Government for more than fifty years, working at Windsor, Vt., and Springfield, Mass. He gave up work at the United States Armory at Springfield, Mass., about a year and a half ago.

Lucien F. Bruce, for more than fifty years an employe of the United States Armory, Springfield, Mass., died at his home March 13, aged seventy-six years. Mr. Bruce had been assistant foreman, and was the inventor of many improvements on guns and machinery for making them, the most important of which was a mechanism for feeding cartridges in the Gatling gun. He was an expert engraver on metal. Mr. Brnce had charge of the government armory exhibit at the Centennial Exposition at Philadelphia, Pa., in 1876.

* * *

COMING EVENTS

May 4-5.—Annual meeting of the Iron and Steel Institute at the Institution of Civil Engineers, London. G. C. Lloyd, secretary, 28 Victoria St., London.

May 10-13.—Seventeenth annual convention of the Air Brake Association, Indianapolis, Ind., Dennisson Hotel, headquarters. An interesting program has been prepared on air brake construction, air pumping, piping inspection and cleaning, triple valves and brake cylinders, recommended practice, etc. F. M. Nellis, secretary, 53 State St., Boston, Mass.

May 11-13.—Joint convention of the American Supply and Machinery Manufacturers' Association and the National Supply and Machinery Dealers' Association at Atlantic City, N. J. F. D. Mitchell, 309 Broadway, New York, secretary-treasurer, American Supply and Machinery Manufacturers' Association.

May 16-18.—Fifteenth annual convention of the National Association of Manufacturers, Waldorf-Astoria Hotel, New York. George S. Budinot, secretary, 170 Broadway, New York.

May 24-25.—Spring convention of the National Machine Tool Builders' Association at Rochester, N. Y., Hotel Seneca, headquarters. Charles E. Hildreth, secretary, Worcester, Mass.

May 31-June 3.—Spring meeting of the American Society of Mechanical Engineers, Atlantic City, N. J.

June 1-4.—Second annual state convention of Pennsylvania engineers, for the furtherance of the organization of the Engineers Society of Pennsylvania, Hall of Representatives, Harrisburg, Pa. Engineers Society of Pennsylvania, Gilbert Building, Harrisburg, Pa.

June 6-10.—Convention and exhibition of the Foundry and Manufacturers' Supply Association, Detroit, Mich. C. E. Hoyt, secretary, Lewis Institute, Chicago, Ill. Cadillac Hotel, Detroit, headquarters of the association convention week.

June 7-9.—Convention of the American Foundrymen's Association and American Brass Founders' Association, Detroit, Mich. Headquarters, Hotel Ponchartrain. Richard Moldenke, secretary, American Foundrymen's Association, Watchung, N. J. W. M. Corse, secretary, American Brass Founders' Association.

June 13-16.—National Gas and Gasoline Engine Trades Association convention at Cincinnati, Ohio, Hotel Sinton, headquarters. Albert Stritmatter, secretary.

June 15-17.—Annual convention Master Car Builders' Association, Atlantic City, N. J. J. W. Taylor, secretary, Old Colony Building, Chicago, Ill.

June 20-22.—Annual convention of the American Railway Master Mechanics' Association, Atlantic City, N. J. J. W. Taylor, secretary, Old Colony Building, Chicago, Ill.

June 20-July 6.—Detroit Industrial Expositiou, Detroit, Mich., under the auspices of the Detroit Board of Commerce to accelerate the city's industry and commerce. The exposition grounds will be on the Detroit River where a large exposition building is being erected to be used in conjunction with the Wayne Pavilion. W. G. Rose, manager, Detroit Board of Commerce, Detroit, Mich.

July 26-29.—Joint meeting of the American Society of Mechanical Engineers and the British Institute of Mechanical Engineers in Birmingham and London, England.

August 16-19.—Annual convention of Traveling Engineers Association, Clifton Hotel, Niagara Falls, Canada. Subjects to be discussed are: "Fuel Economy," "Superheating," "Education of Firemen," "Development of Air Brake Equipment," "Locomotive Lubrication," and "New Valve Gears." W. A. Thompson, secretary, N. Y. C. Car Shops, East Buffalo, New York.

NEW BOOKS AND PAMPHLETS

THE BELOIT COLLEGE BULLETIN. Catalogue for 1909-1910. 152 pages, 5½ x 7½ inches. Published by the Beloit College, Beloit, Wis.

COLUMBIA UNIVERSITY BULLETIN OF INFORMATION. Announcements of summer sessions, 1910. 90 pages, 6 x 9 inches. Published by the Columbia University, New York City.

THE WEATHERING OF COAL. By S. W. Parr and W. F. Wheeler. Bulletin No. 38. 43 pages, 6 x 9 inches. Published by the University of Illinois Engineering Experiment Station, Urbana, Ill.

BULLETIN OF THE MASSACHUSETTS INSTITUTE OF TECHNOLOGY. Announcements of summer courses, 1910. 20 pages, 6 x 9 inches. Published by the Massachusetts Institute of Technology, Boston, Mass.

BULLETIN OF THE UNIVERSITY OF NEW MEXICO. Catalogue for 1909-1910, and announcements for 1910-1911. 136 pages, 5½ x 7½ inches. Published by the University of New Mexico, Albuquerque, New Mexico.

UNIT COAL AND THE COMPOSITION OF COAL ASH. By S. W. Parr and W. F. Wheeler. Bulletin No. 37. 67 pages, 6 x 9 inches. Published by the University of Illinois Engineering Experiment Station, Urbana, Ill.

THE PENNSYLVANIA RAILROAD AND THE FARMER. The Creating of Traffic through the Cooperation of Farmer and Railroad. 14 pages, 5½ x 7½ inches. Published by the Pennsylvania Railroad, Philadelphia, Pa.

BULLETINS OF REVENUES AND EXPENSES OF STEAM ROADS IN THE UNITED STATES. Nos. 8, 9, 10 and 11, covering the months September-December, 1909. Prepared by the Bureau of Statistics and Accounts, and published by the Interstate Commerce Commission, Washington, D. C.

ENGINEERING INDEX ANNUAL. 471 pages, 6½ x 9½ inches. Published by the *Engineering Magazine*, New York and London. Price, $2.

This well-known publication fills an established place in the reference library of the engineer. It is compiled from the monthly indexes of periodical literature in the *Engineering Magazine*, and gives the title, a brief statement of the contents of the article, the approximate number of words in the article, and the name and date of the publication in which it appeared. The subjects covered include civil, electrical and mechanical engineering, mining and metallurgy, railway engineering, marine and naval engineering, street and electric railways, and industrial economy. The usefulness of the new and simpler method of classification adopted has been proved by the extraordinary demand for last year's annual as compared with that of previous years.

ENGINEERING THERMODYNAMICS. By C. F. Hirschfeld. 157 pages, 3¾ x 6 inches. 22 illustrations. Published by the D. Van Nostrand Co., New York City. Price $0.50.

This book, which is now in its second revised edition, is one of the numbers in the Van Nostrand science series. The author, who is assistant professor of power engineering at the Cornell University, has treated the important subject of thermodynamics as applied to engineering in nine short and concise chapters on Heat, Gases, Entropy, Cycles, Flow of Gases, Vapors, Expansions and Compressions of Vapors, Vapor Cycles, and Flow of Vapor. The science of thermodynamics is based upon a few fundamental principles. The difficulties met with in the study of thermodynamics are usually due to the fact that the average student in his first attempts to obtain a working knowledge of this science fails to thoroughly observe and fix these fundamental principles in his mind, and build up a superstructure on this basis. In the present book the author has presented the subject in such a manner that the underlying principles may be clearly recognized. The study of this book will enable the engineering student to more easily follow the generalized and complicated cases considered in larger standard works on the same subject.

PRACTICE AND THEORY OF THE INJECTOR. By Strickland L. Kneass. 175 pages, 6 x 9 inches. 53 illustrations. Published by John Wiley & Sons, New York City. Price, $1.50.

This book, now in its third revised edition, has been prepared with a view of presenting solutions of some of the more interesting problems met with in injector practice, and of describing in detail the functions of the different parts. Complex formulas have been avoided in the mathematical discussion; the treatment, in general, is direct and simple, and is based on carefully conducted laboratory tests. The third edition has been improved by including an additional chapter on the requirements of modern railroad practice. This chapter has been made necessary by the marked changes in the construction of locomotives during the last few years, which changes have reacted upon the method of feeding boilers and upon the injector design. The book treats of the early history of the injector and its development and describes the important parts of the device; detailed attention is then given to the delivery tube, the combining tube and the steam nozzle, and complete reference is made to the action of the injector. One chapter is devoted to the application of the injector in American and foreign practice, and another to the determination of sizes, based upon practical tests. The methods of feeding locomotive boilers, as already mentioned, have been touched upon, and the subjects of feed water heating, efficient feeding, scale-bearing water, check valves, etc., have been given some attention. Owing to the lack of books upon this subject which have been based directly upon experimental research, this book should be of especial interest to steam engineers who are interested in the practice and theory of injectors.

APPLIED MECHANICS. By David Allan Low. 551 pages, 5½ x 8½ inches. 850 illustrations. Published by Longmans, Green & Co., London and New York. Price, $2.75.

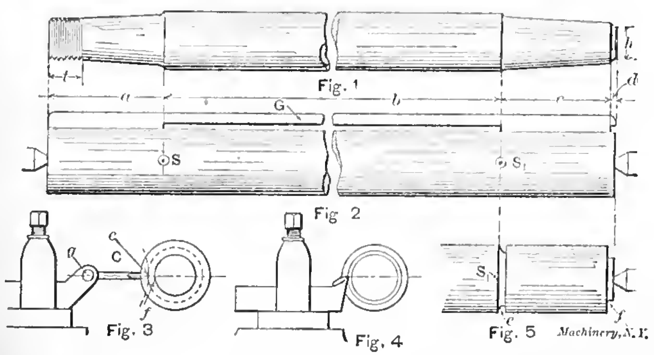
This book includes a treatise on the strength and elasticity of materials, the theory and design of structures, the theory of machines and hydraulics, and is especially intended as a text-book for engineering students. The author, who is professor of engineering at the East London College of the University of London, England, has given particular attention to the matter of exercises, of which not less than 780 are given, 600 of them being original. The remaining 180 exercises have been selected with great care from the examination papers of various examining bodies. The answers to these exercises are given at the end of the book and will be useful to students who study at home without the aid of a teacher. The subject matter is as clear and concise as is possible in a work of this kind, and covers a wide field. It pre-supposes, however, a considerable knowledge of mathematics, as calculus is freely used in the demonstrations and examples whenever necessary. The scope of the work is best indicated by a general review of the contents. The book opens with a preliminary chapter reviewing the most fundamental mathematical formulas, then deals with motion, force, work and energy, the polygon of forces, moments, stresses, beams and bending; the deflection of beams, columns and struts; testing materials, stress diagrams, design of roofs, plate girders, braced girders, etc.; acceleration, velocity diagrams, piston and crank effort diagrams, governors, brakes and dynamometers; belt, rope and chain drives; gearing and balancing. Several miscellaneous mechanisms are also treated in a chapter by themselves, and considerable attention has also been given to friction and lubrication. The book is concluded with five chapters on hydrostatics, hydraulics, water wheels, turbines, pumps, and some other hydraulic pressure machines. On account of its highly technical nature and its exceedingly thorough treatment of the subjects involved, it is recommended rather to the student who wants to make a thorough and fundamental study of the subjects than to persons who would use it merely for occasional reference.

Supplement to MACHINERY, June, 1910

Operations for the Article in this number entitled "Machine Shop Practice—Laying Out and Machining a Piston-rod Key-slot"

SHOP OPERATION SHEET NO. 136

Franklin D. Jones MACHINERY, June, 1910



Machining a Locomotive Piston-rod—I
Turning the Rod

NOTE.—We shall assume that the steel stock from which the rod (Fig. 1) is to be made, is cut off to the correct overall length, and that deep centers have been drilled in each end.

1. First turn the body b of the rod to the finish diameter; then locate and mark with a punch as at S, S_1 (Fig. 2), the piston and crosshead shoulders, locating the latter next to the tailstock. The required dimensions a, b and c may either be taken directly from a standard gage G or from a drawing.

2. Caliper carefully the largest diameter of the hole in the crosshead, and turn a groove (cutting shoulder mark S_1) to three or four thousandths over this diameter. The tool used should have a rounded corner so as to leave a fillet as shown in Fig. 5. Next with a square-nose tool, reduce the end d, for about 3/16 inch, to say three thousands larger than the diameter of the crosshead hole at a distance c from the end.

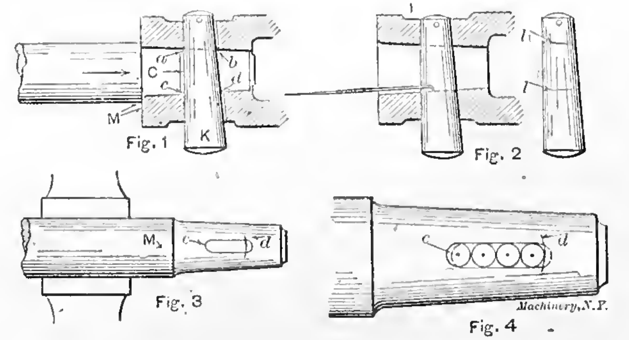
3. The taper attachment (or tailstock if there is no taper attachment) must now be set so that the tool's cutting edge, when to the height of the centers, moves parallel to a line passing through points e and f. This can be accurately done by using a caliper tool as shown in Fig. 3. The caliper C swings about pin g which should be set to the height of the centers. When the end of C just touches at e and f, the taper attachment is correctly set. If such a tool is not available, inside calipers may be used instead, the measurements being taken between the squared end of a tool and the work.

4. With the tool set to the height of the centers as in Fig. 4, turn the taper end to within say 1/64 inch of the finish size; then reduce end d to diameter h, and drive the rod tightly into the crosshead. A piece of soft metal should be held against the rod end to prevent damaging the center. When the rod is removed, the bearing marks will show whether or not the taper is correct. If the bearing is uniform, take a finishing cut with the tool set to just graze points e and f, and finish by filing until the rod can be driven in against its shoulder.

5. Proceed to fit the opposite end in the piston, getting the correct taper in a manner similar to that described for the crosshead end. The thread t for the nut which holds the piston and rod together, should not be cut until the taper fitting is finished, as otherwise it is likely to be damaged when driving the rod out of the piston. The body of the rod is next filed and polished with emery cloth.

SHOP OPERATION SHEET NO. 137

Franklin D. Jones MACHINERY, June, 1910



Machining a Locomotive Piston-rod—II
Laying Out the Key-slot

NOTE.—After a locomotive piston-rod has been turned, the keyway or slot for the key which holds the rod into the crosshead is laid out. This key or cotter K, Fig. 1, has a straight side which bears against the crosshead and a taper side which bears against one end of the slot in the rod which has a corresponding taper. When the key is driven in, it tends to draw the rod, as shown by the arrow, thus wedging it tightly into place. It is desirable to have the key, which is usually machined to a standard size, in approximately the position shown when it is driven in tightly.

1. To lay out this slot for drilling, first insert the key in the crosshead with the narrow end flush with the inner side I as shown in Fig. 2; then holding the key against the front side of the slot, draw lines across one side of it so that they coincide with the inner sides of the crosshead, using a hook scriber.

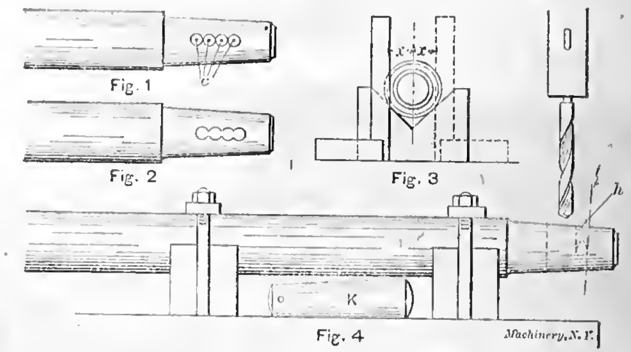
2. After the key is removed, insert the piston-rod, drive it home, and with a fine-pointed scriber, transfer the outline of the crosshead slot, on both sides, to the rod. Next mark the crosshead and rod lightly (as at M, M, Fig. 1) so that the scribed line representing, say the outer half of the crosshead slot may be known after the rod is removed.

3. After removing the rod clamp it between copper-protected vise jaws (Fig. 3) with, say the outer side M up. Then caliper the exact width of the key at the point where the outer line l was previously scribed. Set a pair of dividers to this width and with one point of the dividers on the end c of the scribed slot on the rod, draw a line d which represents the point d, Fig. 1. Caliper the width of the key at l_1 and locate a point on the opposite side of the rod which will correspond to point b, Fig. 1.

4. With the dividers set to a radius of one-half the slot width, scribe a circle just within the line d as shown in Fig. 4. Scribe another circle 1/8 or 3/16 inch beyond the end line c, and between these two circles scribe as many others as will come within the length of the slot. Proceed in the same manner on the opposite side of the rod, first scribing a circle just within the point corresponding to b (Fig. 1) and then another say 3/16 inch beyond the end line a; this 3/16 inch is to provide the clearance C for the straight side.

SHOP OPERATION SHEET NO. 138

Franklin D. Jones MACHINERY, June, 1910



Machining a Locomotive Piston-rod—III
Drilling and Finishing the Key-slot

1. After the keyway has been laid out as described in the preceding sheet, make deep punch marks c (Fig. 1) in the center of each circle on both sides of the rod, so that a drill can be started more easily. Then clamp the rod, which should rest in two V-blocks, to the table of a drill press, as shown, with say the inner or shorter side of the slot up. Before clamping the work tightly, set the laid-out slot vertical by turning the rod until the dimension x (Fig. 3) from a square blade to the center line, is the same with the square set on first one side and then the other, as shown.

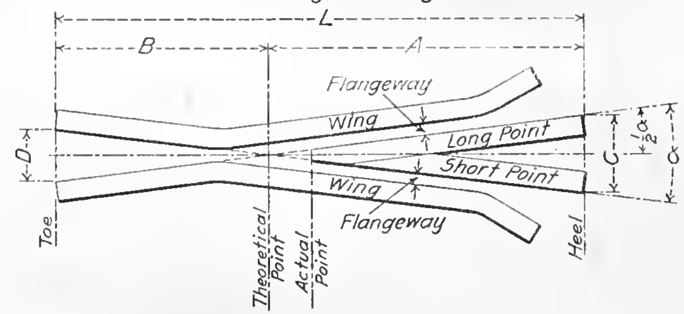
2. Next drill each alternate hole and then the remaining holes about half way through the rod. Care should be taken that the drill does not run to one side when starting, as it is likely to do, particularly on a curved surface. After the holes are drilled half way through from one side, the rod should be turned so that the remainder of the drilling can be done from the opposite side. This is a quick and easy method of machining the slot to conform to the scribed lines. When drilling the last hole h in the longest side of the slot, the piston end of the rod should be lowered until the cylindrical part is parallel with the taper key K when the latter is placed on the table in the position shown. This is done so that the drill will follow the line t of the finished slot, and not remove any metal outside of this line.

3. When the slot is drilled, it will appear as in Fig. 2. The ridges which have been left on the sides are next removed by chipping and filing, and the ends of the keyway are straightened with a round file. When filing these ends, the work should be held in a vertical position in the vise. The finished end of the rod should, of course, be protected from the hard vise jaws by copper or other soft metal.

4. After the burrs have been carefully removed from the edges of the slot, the rod should be inserted in the crosshead and the key driven in. If the ends of the slot have been filed straight and to the lines, the small end of the key should project through the crosshead far enough for a cotter pin. After the key has been driven in tightly, it should be removed and the bearing marks in the slot end examined. If these marks do not show an even bearing across the slot, the "high" spots should be filed until the key fits the slot perfectly.

FROGS, SWITCHES AND CROSS-OVERS—I

Rigid Frogs.



Formulas for Rigid Frogs

N = no. of frog,
L = length over all,
C = heel spread,
D = toe spread,
α = angle of frog.

$$N = \frac{L}{C+D} \qquad \tan\frac{1}{2}\alpha = \frac{1}{2N}$$

$$C = 2A \times \tan\frac{1}{2}\alpha = \frac{A}{N}$$

$$D = 2B \times \tan\frac{1}{2}\alpha = \frac{B}{N}$$

There are three types of rigid frogs.

1. Bolted: Filling in flangeway and held together by bolts.
2. Clamped: Filling in flangeway and held together by clamps.
3. Riveted: Rail bases riveted to a base plate.

Table of Frog Numbers and Angles.

Number	Angle	Number	Angle	Number	Angle	Number	Angle	Number	Angle	Number	Angle

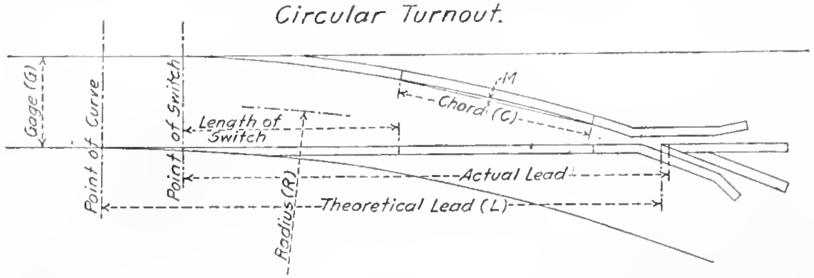
FROGS, SWITCHES AND CROSS-OVERS—II

Circular Turnout.



G = gage (inside width between rail-heads),
R = radius of curve,
L = theoretical lead of switch,
C = chord (see illustration above),
M = middle ordinate (see illustration),
N = number of frog (see Sheet I),
α = frog angle (see Sheet I),
δ = degree of curve.

$$L = 2G \times N = (R + \tfrac{1}{2}G)\sin\alpha$$

$$R = 2G \times N^2 = \frac{50}{\sin\frac{1}{2}\delta} = \frac{L^2}{2G}$$

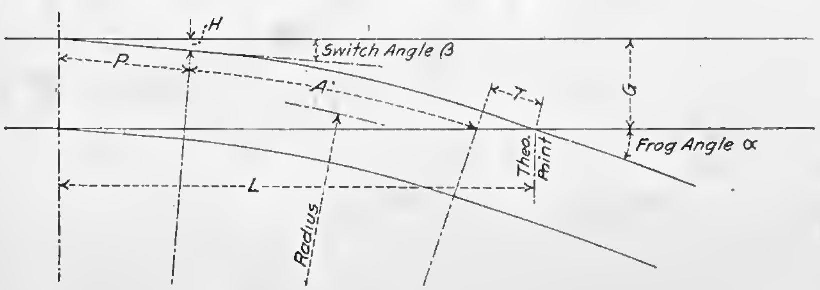
$$\cos\alpha = \frac{R - \frac{1}{2}G}{R + \frac{1}{2}G}\ ;\ \tan\frac{1}{2}\alpha = \frac{G}{L}$$

$$R = \frac{1}{2}\left(\frac{(\frac{1}{2}C)^2}{M} + M\right)$$

$$\sin\frac{1}{2}\delta = \frac{50}{R}$$

$$R = \frac{G}{\text{vers}\,\alpha} - \frac{1}{2}G$$

Turnout Using Straight Frog and Switch.



H = heel spread of switch,
T = distance from theoretical point to toe of frog,

P = length of switch,
β = switch angle.
Otherwise same notation as above.

$$R + \frac{1}{2}G = \frac{G - H - T\sin\alpha}{\cos\beta - \cos\alpha}$$

$$L = (R + \tfrac{1}{2}G)(\sin\alpha - \sin\beta) + (T \times \cos\alpha) + P$$

Length of arc $A = (\alpha - \beta)(R + \frac{1}{2}G) \times 0.01745$
(α and β are expressed in degrees)

LIMITATIONS OF THE COMMON THEORY OF FLEXURE

THE DESIGN OF CURVED MACHINE MEMBERS UNDER ECCENTRIC LOAD

By JOHN S. MYERS

THE article in the December number of MACHINERY on "The Design of Curved Machine Members Under Eccentric Load," as well as the original paper and the discussion in the *Journal of the American Society of Mechanical Engineers*, opens up an interesting subject to designers and draftsmen. The article referred to shows a remarkably close agreement between the results of the tests cited and the stress at the elastic limit as calculated by the formula of Messrs. Andrews and Pearson; however, the readers of MACHINERY will undoubtedly welcome further discussion of this and kindred subjects.

Stress Proportional to Strain

All analysis for the supporting power of members subjected to flexure is based upon Hooke's law of the proportionality of stress to strain, and hence is applicable only within the elastic limit, which "limit" is not always sharply defined. In fact, there exists no method of analysis whereby ultimate or breaking loads may be calculated for such members, and if it be desired to proportion such parts by basing the working load upon the breaking load, which is the usual conception of the significance of the factor of safety, it can only be accomplished by empirical formulas based upon tests of the ultimate strength of parts similar in form, of the same material and similarly loaded.

It is unfortunate that so many designers do not seem to thoroughly understand the limitations of the common theory of flexure, and persist in applying it beyond its obviously intended range of application. It cannot be too strongly emphasized that the common theory of flexure must be limited to stresses within the elastic limit, and that factors of safety for such parts do not show true ratios between the load at which ultimate failure would occur and the working load, as would be the case in simple tension members. For flexure, we should consider a factor with regard to the elastic limit instead of with regard to the ultimate strength of the material.

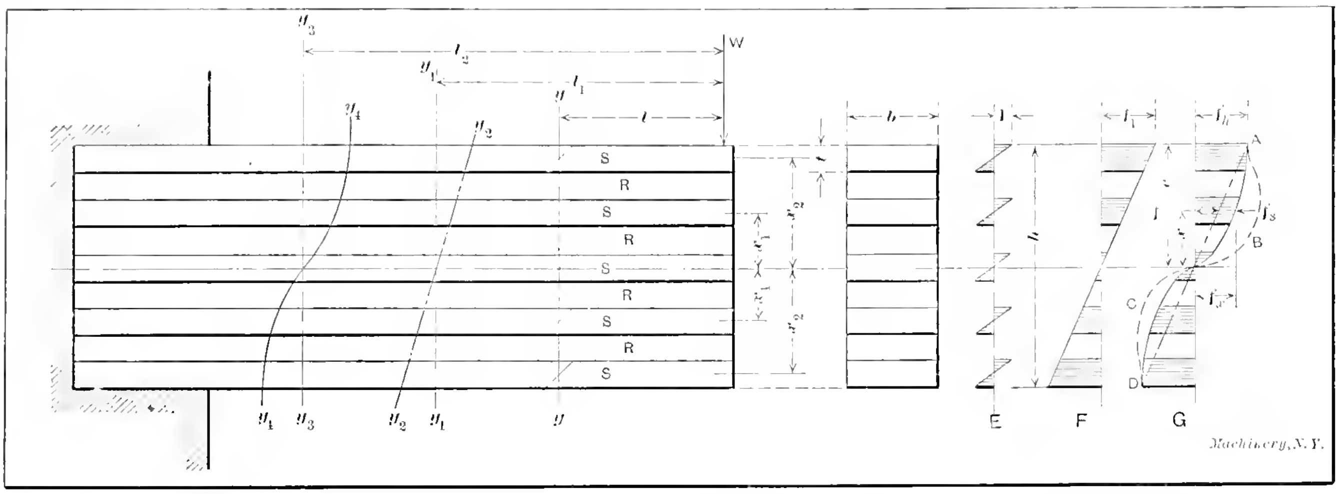

Fig. 1. Composite Beam for Illustrating the Influence of Horizontal Shear on the Distribution of Stresses over the Section

Effect of Horizontal Shear on the Distribution of Stresses

The common theory of flexure *assumes* that a section which is plane before flexure remains plane after flexure. While this may be practically true for beams with a span comparatively great in proportion to the depth, it does not necessarily hold true for short beams heavily loaded. For this reason it is not uncommon to find in bridge specifications an allowable fiber stress in pins about 50 per cent higher than that in tension members. One of the prime reasons for this will be found in the deformation due to shear parallel to the neutral axis. To give an elementary explanation of what is meant, pick up this magazine by grasping it at the back in one hand and attempt to hold it in a horizontal plane. It is found to be quite flexible—will not remain flat when so supported, be

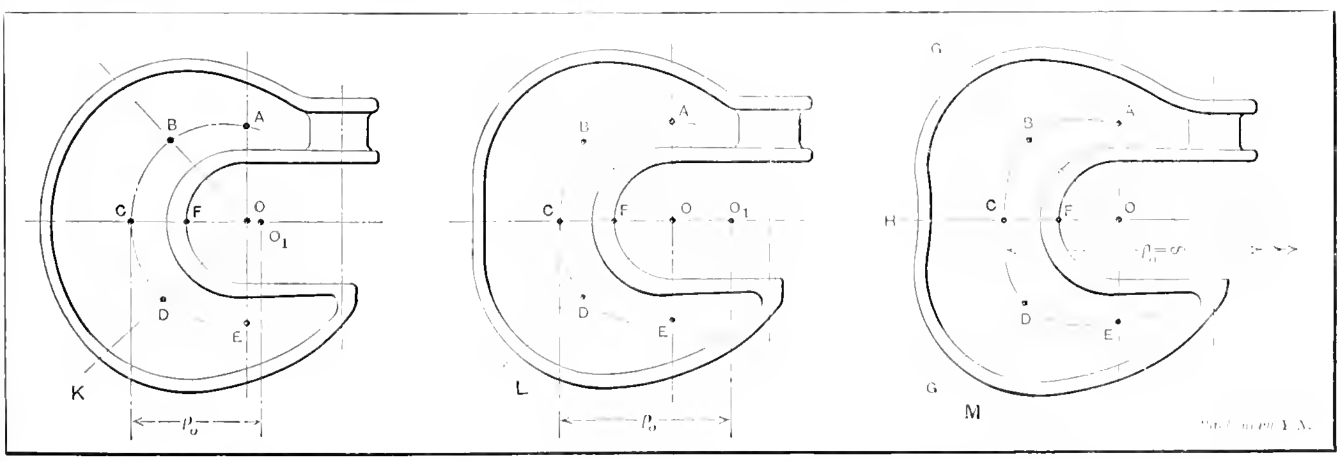

Fig. 2. Illustrations showing that the Curvature of the Gravity Axis does not bear a Direct Relation to the Flange Curvature

* Address: 2156 Almond St., Philadelphia, Pa.

cause the leaves are free to slide laterally upon each other; but if mucilage be applied to each leaf, and the whole thus united together, it would become quite as strong as a beam, and would be able to sustain considerable load.

A bundle of fibers such as a rope or a layer of leaves in an unbound book does not constitute a beam, because in neither case does there exist capacity for resisting shear parallel to the neutral plane. In any beam sustaining a vertical shear there exists also a shearing stress on all planes parallel to the neutral plane, this horizontal shear being zero at the extreme fibers and a maximum at the neutral axis; without such a horizontal shear there can exist no difference of tensile or compressive stress in successive layers of the material. (For a discussion of the intensity of this shear, based upon the common theory of flexure, see "Applied Mechanics," by Gaetano Lanza, pages 319 to 321.)

Any stress, be it tension, compression or shear, always produces a corresponding strain or deformation; consequently this horizontal shear is accompanied by a sliding of the "fibers" upon each other, and if this action were pronounced, it would completely demoralize the analysis for the extreme fiber stress as based upon the assumptions of the common theory of flexure.

To illustrate the foregoing, let Fig. 1 represent a cantilever of composite structure in which the layers S are of steel and the layers R of India rubber. Assume that the layers of rubber are not attached in any way to the layers of steel, and neglect any friction which may exist between them. The distribution of stress over the five layers of steel at any cross-section is then as indicated at E, and with five layers as shown, the extreme fiber stress in any lever at section yy, for these conditions, is $f = \frac{6Wl}{5bt^2}$, and, if N = number of layers of steel, $f = \frac{6Wl}{Nbt^2}$, or the supporting power is $W = \frac{fNbt^2}{6l}$. Now if h = height of section, and the thickness of the layers R be negligible, then $t = \frac{h}{N}$, and $W = \frac{fbh^2}{6lN}$, or with a given height of section the supporting power varies inversely with the number of layers and if the number of layers were infinite, corresponding to an infinitesimal thickness, the supporting power would be zero. The precise meaning of this is that a bundle of fibers does not constitute a beam.

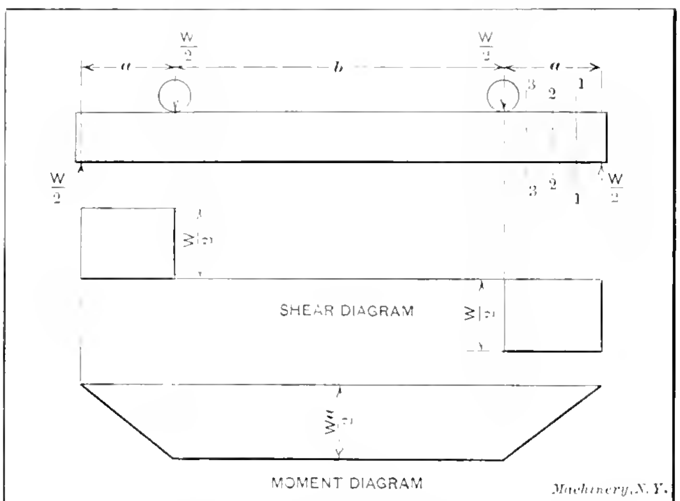

Fig. 3. Beam with Portion of the Span subjected to neither Vertical nor Horizontal Shear. The Stress in this Section, however, is built up at Sections where there is such Shear

Now assume that the layers of rubber R are firmly cemented to the layers of steel S, and that the rubber is absolutely rigid as regards shear in the horizontal plane but so elastic in tension or compression, when compared to the steel, as to be entirely negligible in this respect. Then any section, such as y_1y_1, which was plane before flexure, would remain plane after flexure, shifting to position y_2y_2, under action of the load W. This is one of the assumptions upon which the common theory of flexure is based, and for the case of the composite beam under consideration the distribution of the stress over the section would be as indicated at F. The assumption that the layers of rubber R are absolutely inflexible as regards horizontal shear is, however, obviously an assumption which cannot exist in fact, for in an actual beam of this nature the rubber would distort under this shearing action, and a section such as y_3y_3, which was plane before flexure, would not be plane after flexure, but would assume some position such as y_4y_4, and the stress in successive layers of the steel would not vary directly as the distance from the neutral plane. The distribution of stress over the section would then be somewhat as indicated at G. If f_h = the stress at the extreme fiber, and f_x = the stress on any fiber located at a distance x from the neutral plane, it is then obvious that the stress f_x is made up of two parts: first a stress f_t, which varies directly as the distance from the neutral plane; and second, a stress f_s, which is such as to cause a sliding of one layer upon another sufficient to transmit the horizontal shear. Then $f_x = f_t + f_s$ in which $f_t = \frac{f_h x}{e}$ while f_s is a function of several quantities, the precise mathematical relation of which has not as yet, so far as is known to the writer, been deduced. It can be stated, however, that the greater the vertical shear as compared to the bending moment, the greater the depth of section compared to its breadth, the greater the coefficient of elasticity for tension and compression as compared to the coefficient of elasticity for shear, and the smaller the value of x, the greater will f_s be in comparison to f_t. It is even within the range of possibility that for exceptional cases the maximum fiber stress may not occur at the extreme fibers but that the distribution of stress over the cross-section of the member may be as indicated by the dotted line $ABCD$, shown at G, Fig. 1.

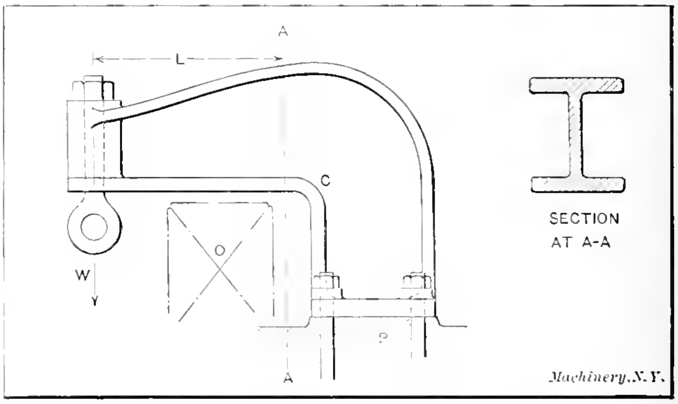

Fig. 4 The Mechanical Designer's Method of Constructing a Bracket

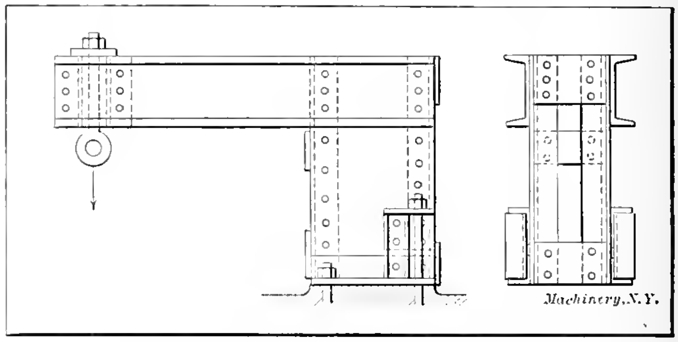

Fig. 5. The Structural Designer's Method of Constructing a Bracket. This Bracket is more Correct in Principle than that in Fig. 4

In any ordinary beam composed of homogeneous material, although it is not composite in structure as the example illustrated in Fig. 1, there are analogous conditions which the common theory of flexure entirely ignores because it is based upon the assumption that any section being plane before flexure remains plane after flexure. This assumption could only be justified by assuming the coefficient of elasticity for shear to be infinite when compared to the coefficient of elasticity for tension and compression, or else by assuming the length

of the beam to be infinite in relation to the height of the section. But as both of these assumptions are entirely at variance with facts, we must concede that the horizontal shear may have an important influence on the distribution of stresses over the cross-section; hence it is to be expected that the resisting moment of a short, heavily-loaded beam for a given maximum fiber stress would be considerably in excess of that given by the common theory of flexure, even when the stresses were well within the elastic limit. This accounts for the high allowable fiber stress in pins, as given in bridge specifications, as well as the apparent excess in strength of other short members subjected to flexure.

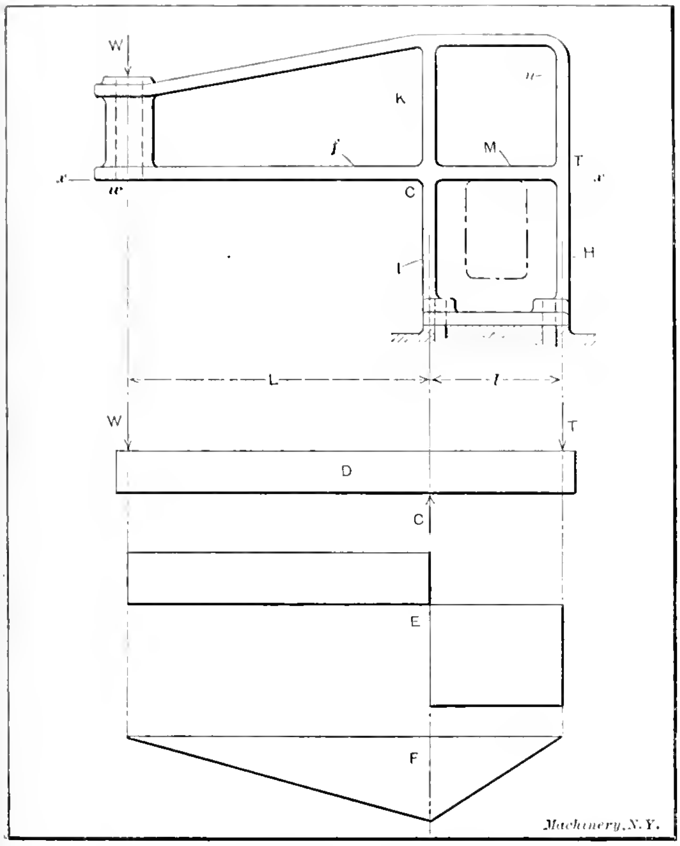

Fig. 6 A Cast Bracket designed along the Lines of a Structural Bracket

Stress Dependent Upon Conditions Outside the Plane of the Actual Section Under Consideration

Certain beams are, by reason of the nature of their loading, subjected to a constant bending moment over a considerable portion of the span upon which there is no vertical shear, and consequently no direct horizontal shear. One might be led to believe that for this portion of the member deformation due to horizontal shear could not possibly enter into the problem. Fig. 3 represents such a beam, and, while there is neither vertical nor horizontal shear between the two loads there is a heavy shear between each load and its adjoining support, as illustrated in the shear diagram. Now the stresses at section 1-1 are those incident to transmitting the vertical shear from the support to section 1-1. The stresses at section 2-2 are equal to those at 1-1 plus the additional stress induced by transmitting the shear from 1-1 to 2-2, etc. From this it is seen that anything affecting the distribution of the stress over the cross-section at 1-1 would also affect the distribution at section 2-2, 3-3, etc. The significance of the foregoing is that no stress due to flexure springs suddenly into being but is the result of a process of growth, and even though there be no vertical shear on a section, the stress in that section has been built up by reason of the transmission of such a shear in adjoining sections.

Crane Hooks

A crane hook is an exceedingly short beam very heavily loaded and, while there is no shear on the principal section, there is a heavy shear on the preceding sections which should be expected to affect the distribution of the stress over the principal section, so that, instead of this section remaining plane under load, it would be distorted. This, taken in conjunction with the fact that it is also a curved beam, is sufficient to completely demoralize the analysis if based upon the assumptions of the common theory of flexure. The analysis of Messrs. Andrews and Pearson takes cognizance of the curvature of the member through the theory of lateral contraction, yet assumes that the section remains plane after flexure, and therein the writer believes it to be at fault, notwithstanding the close accord between the calculated supporting power for a stress equal to the elastic limit and the supporting power at which the total deflection of the hook ceased to be proportional to the load as determined by tests.

The tabulated results of these tests given in the December, 1909, issue of MACHINERY, are here reproduced with the addition of factors of safety based upon the elastic limit. It will be noticed that five of the hooks were rated at capacities higher than the actual elastic limit as determined by the tests, while the other five were given rated capacities perilously near to this limit. It may also be observed that the sustaining power corresponding to an extreme fiber stress equal to the elastic limit, when that sustaining power is calculated by the usual Unwin formula, varies from 1.3 to 5.23 of the rated capacities, the average being 2.79. If we neglect the two strongest ones, the average of the remaining eight have a *calculated* sustaining capacity at the elastic limit of 2.23 times the rated capacity. This seems to indicate that the manufacturers of these hooks have been guided largely by experience rather than by an implicit but mistaken faith in the Unwin formula, and that they were proportioning and rating their hooks upon a basis of ultimate strength as determined by tests. The attitude of some designers is that they wish to design their hooks with a factor of safety based upon *ultimate* sustaining capacity, but they know the Unwin formula will not give this ultimate sustaining capacity, yet consider it to be the only well-known formula to apply. They therefore do the best they can with the available data by allowing a high working stress. If they were to concede that the analysis of Messrs. Andrews and Pearson was a more correct one than the usual Unwin formula, but yet desired to design with a view to safety against actual rupture only, instead of safety against the possibility of giving the material at the extreme fibers a slight permanent set, they would be little better off, if any. However, neither theory was intended to apply beyond the elastic limit and it is quite illogical to attempt to apply them in conjunction with factors of safety, so that if manufacturers wish to design crane hooks based upon ultimate sustaining loads, the only proper method of doing so is by using empirical formulas derived from actual breaking tests of a large variety of shapes and sizes.

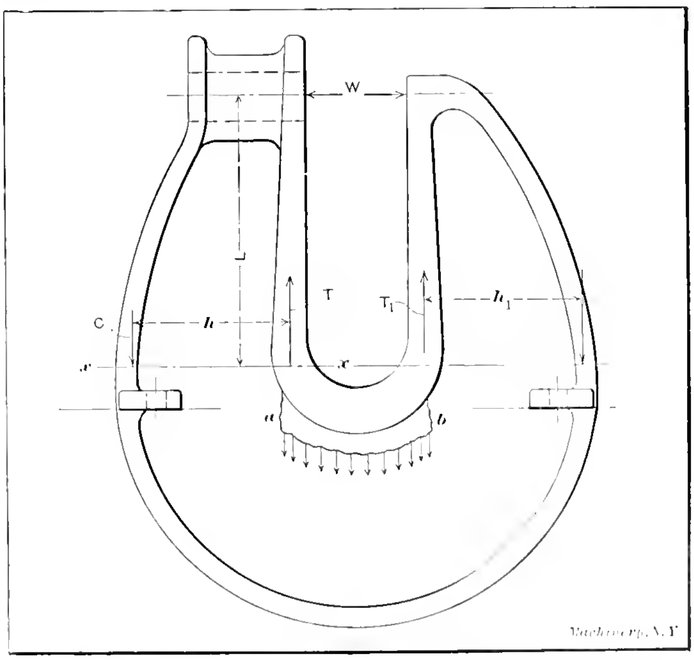

Fig. 7. A Riveter Frame Improperly Constructed Forces T and T_1 are concentrated upon the Web between the Points a and b

Curved Members of Machine Frames

The frames of all such machines as punches, presses, shears, riveters, etc., which are under heavy load, are invariably box or I-beam sections, in which the major portion of the load is carried by the flanges. This makes the problem considerably different from that presented by a member of solid section, such as a crane hook and, even if we grant that the analysis of Messrs. Andrews and Pearson is correct for the former, it by no means follows that it is correct for the latter; for, while the radius of curvature of the gravity axis would bear a fairly well-defined relation to the radius of curvature of the most strained fibers in the case of such members as the crane hooks experimented upon, it bears no such relation in the case of machine frames in general. It follows that while the radius of curvature of the gravity axis may be a logical quantity to insert in a formula for crane hooks, it is not the curvature of the neutral axis we are interested in when it comes to general work, but the curvature of the flanges where most of the stress exists.

To illustrate the foregoing, Fig. 2 represents at K a frame with semi-circular throat in which curve $ABCDE$ is the gravity axis of successive sections. Point O is the center of the throat radius while point O_1 is the center of a circular arc which approximately coincides with the gravity axis curve for points near to C. Then $O_1C = \rho_0 =$ radius of neutral axis as it would be determined for insertion in the Andrews and Pearson formula, and this radius being comparatively small would give us a high fiber stress.

In Fig. 2 at L the throat radius OF remains the same as before but a portion of the rear flange is now straight, in consequence of which ρ_0 has been materially increased, thereby reducing the extreme fiber stress. If we now go a step farther and actually make the rear rib concave, of such a curvature as to make the gravity axis at point C a straight line, as shown at M, we have $\rho_0 =$ infinity, and for this case the new formula reduces to the same form as the usual Unwin formula.* This would give an extreme fiber stress for the case at M of possibly one-third that at K if calculated by the new formula. Now in all three cases the throat radius remains the same and there would undoubtedly be as rapid a transition of stresses for the case at M as for that at K or L, yet the formula would give quite different results. This is because the quantity ρ_0 in the formula has absolutely no mathematical relation to the flange curvature as it may exist in general work. Stated concisely ρ_0 is not a function of OF. This, in the opinion of the writer, is sufficient reason for the rejection of the formula in its present form, at least for general work.

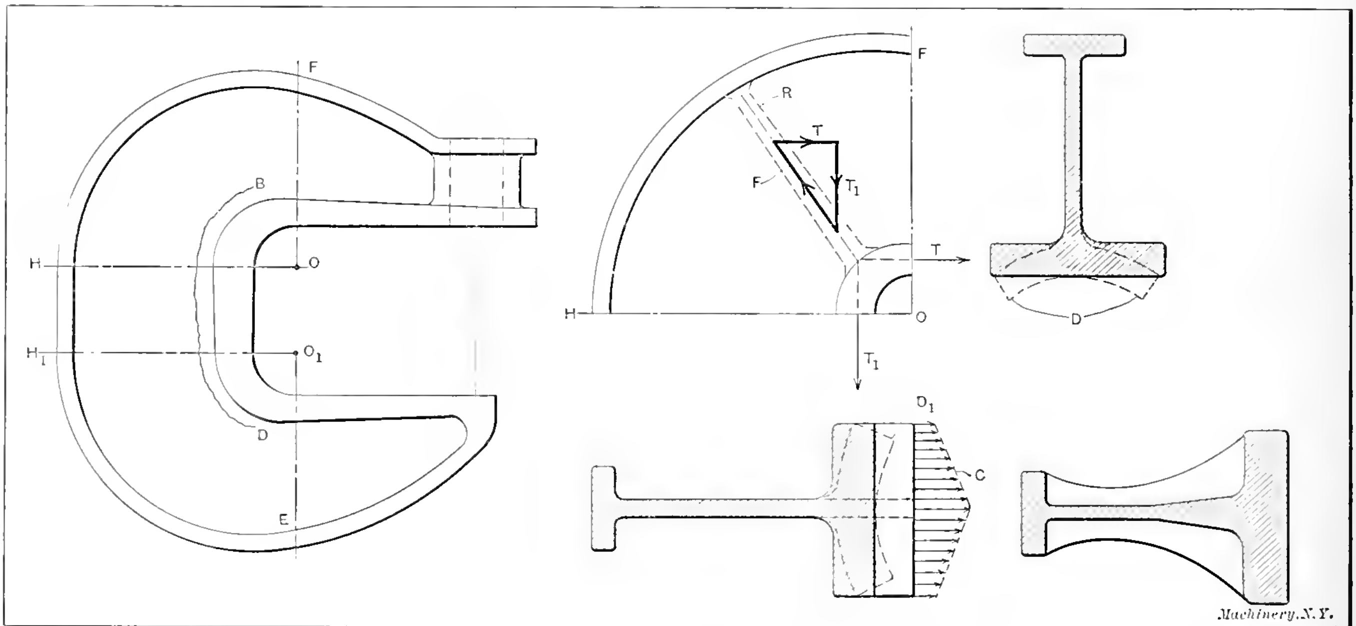

Fig. 8. A Small Portable Riveter Frame used for the Purpose of Illustrating Proper Design as indicated in Fig. 9

Fig. 9. Analysis of Stresses in Riveter Frame and a Proposed Rib for Partially Eliminating the Concentration of the Stresses in the Web

ANALYSIS OF HOOKS TESTED

	20000	16000	26000	15000	0.80	1.30	0.75
	10000	14000	20800	14100	1.40	2.08	1.41
Average of Wrought Iron					0.91	2.91	0.89
Total Average					1.13	2.79	1.13

* This is, of course, an abnormal construction, but while improbable is not at all impossible; in fact the compression flange is often considerably less in area at point H than at points G, which has an effect upon the curvature of the gravity axis similar to a reverse curve in the rear flange, although not so readily seen.

Structural Engineering Versus Mechanical Engineering Methods

Generally speaking the use of curved members is improper construction when it is possible to avoid them, and structural engineers never put in curved tension or compression members, excepting in portals, or for ornamental effect, because they consider that force travels in straight lines or else produces bending stresses. On the other hand, designers of machinery seem to delight in curved ribs, bent levers and the like. In fact the average mechanical draftsman makes layouts as though he held the opinion that force travels along

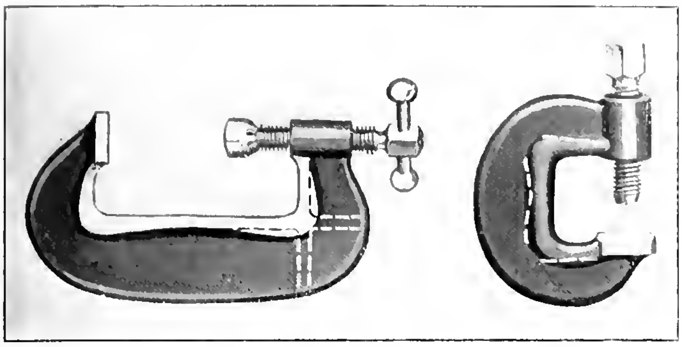

Fig. 10 Fig. 11
C-clamps as commonly designed and Indication of Suggested Improvements

a curved rib in a manner somewhat similar to water flowing in a pipe, and that it will, therefore, follow any course in which he may choose to distribute the material. The average structural draftsman may be absolutely helpless when confronted by some simple mechanical details, such as a shaft with its bearings or a set of bevel gears, but he would not be guilty of some of the improperly disposed curved members found in ordinary mechanical details.

To illustrate the foregoing, if a mechanical draftsman had a load W to be supported and a convenient place to put a pad

If the mechanical draftsman were to study the principles of structural engineering, he would make this bracket more like that shown in Fig. 6. With this construction the portion of the bracket above line xx may be considered a simple beam as shown at D, the shear diagram for which is shown at E and the moment diagram at F. With this construction I is a compression member sustaining a load $C = \frac{W(L+l)}{l}$ while H is a tension member the load on which is $T = \frac{WL}{l}$. The members K and n are stiffeners and serve to transmit the shear at C and T to the web. Note that flange f is not interrupted at the corner, as in Fig. 4, but is continuous, as it should be. The load on this flange is zero at w and T; it gradually increases to its maximum at C and it would be obviously improper to suddenly discontinue the flange right at its point of maximum load, which would be the case if member M were omitted, as was the case in Fig. 4.

A Riveter Frame

There is considerable analogy between the bracket of Fig. 6 and a punch or riveter frame, and the application of a little common sense should make it apparent that if we have a flange in tension or compression we must not suddenly give it a 90-degree or 180-degree bend and expect the stress in that flange to "go shooting around the corner like a cable car," but we must *provide means for the distribution of that stress* and carry it where it may meet an equal and opposite load to balance it; for no stress induced by flexure springs suddenly into existence or dies out suddenly; it is gradually built up and gradually dies out again.

The conception that no stress due to flexure springs suddenly into being is a direct result of the fact that all stresses due to bending are a function of length, *i. e.*, are the result of transferring the vertical shear from one point on the member to some other point.

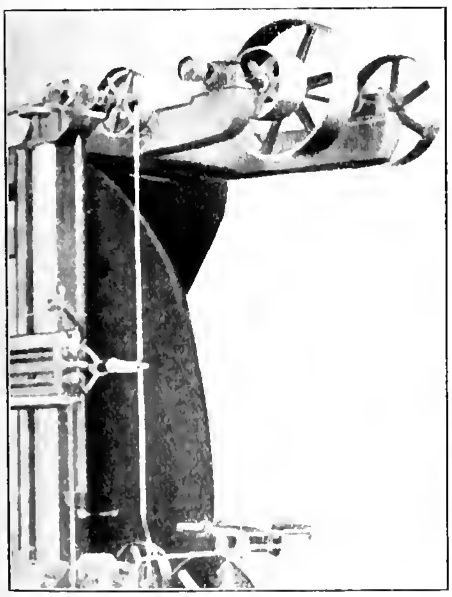

Fig. 12

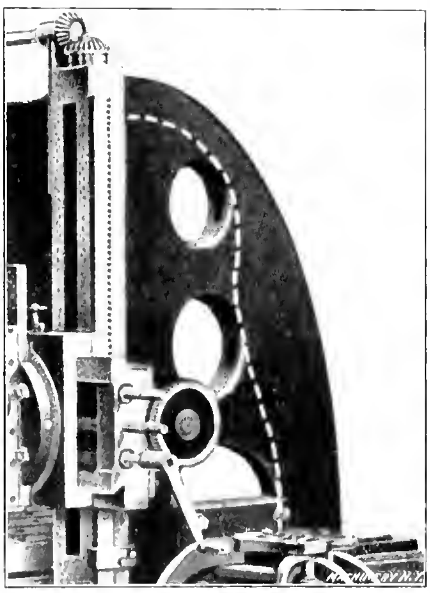

Fig. 13

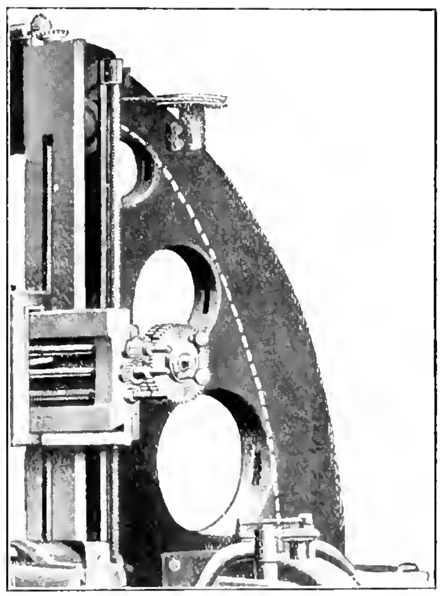

Fig. 14

Examples of Different Designs of Planer Housings

P, but an obstruction O between the load and pad, he would probably construct a bracket similar to that shown in Fig. 4. For the stress on section AA he would apply the usual formula $S = \frac{WLc}{I}$ but would probably not give the second thought as to just how the stress "got around the corner" at C. Give the same conditions to a structural draftsman and he would produce something like that shown in Fig. 5. Here the corner is eliminated, as far as transition of stresses around it is concerned, the flanges are continuous, and, as shown, the rear bolts are not attached to a little lug ¼ inch thick, as one frequently sees, but the nuts rest upon a shelf angle supported by stiffener angles riveted to the vertical member with sufficient rivets to transfer in shear the calculated load on these bolts.

As an example of improper construction, take the bull riveter frame shown in Fig. 7. Here it is quite obvious that if the web were to part along the line ab there would be nothing to balance the loads T and T_1 in the tension flanges, and failure to balance these forces would mean failure for the entire frame. The total flange loads are, approximately, $T \simeq \frac{WL}{h}$ and $T_1 \simeq \frac{WL}{h_1}$, and if w = thickness of web, the average unit tension distributed over the web along line ab is $t \simeq \frac{2\,WL}{hw\,(ab)}$, or, if h_1 does not equal h,

$$t \simeq \frac{T + T_1}{w\,(ab)} = \frac{WL}{w\,(ab)}\left(\frac{1}{h} + \frac{1}{h_1}\right)$$

From this it would appear that the sectional area of the web along line *ab* should be approximately equal to the combined area of the *two* tension flanges and, were it not for the fact that it is necessary to thicken up the web at this point in order to avoid shrinkage cracks, there would probably be more frequent failures due to this improper construction.

In the case of a frame having a wider gap, such as shown in Fig. 8, the conditions are more favorable in this respect, for failure from this source would require that the web rupture from some point near B to some other point near D, which brings into action more sectional area of the web in proportion to the flange area than in the case shown in Fig. 7. This is, however, none the less an improper construction, because the sharp bend of the tension flanges between sections OF and OH, and between sections O_1H_1 and O_1E destroys the continuity of these flanges for the direct transmission of stress.

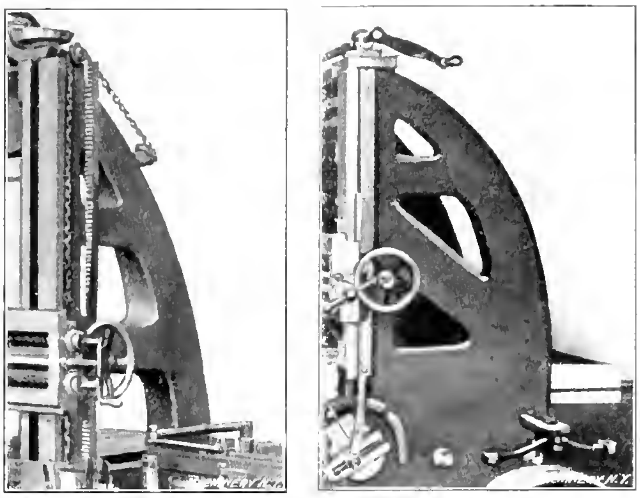

Fig. 15 Fig. 16
Additional Examples of Designs of Planer Housings

To illustrate the foregoing, Fig. 9 shows that portion of the frame of Fig. 8 which lies between lines OF and OH. Now, let T and T_1 represent the total tensions in the flanges on sections OF and OH, respectively. By combining T and T_1 graphically, it is seen that a resultant force F must, in some manner, be supplied to establish equilibrium. The most direct way of supplying such a force is by the addition of a rib as indicated by the dotted lines at R, which will distribute part of F into the web, and deliver part of the force at the compression flange where there is a smaller opposing resultant force. In the absence of any such rib the necessary resistance must be supplied by the web, partly through a local bending and distortion of the flanges as indicated in an exaggerated manner by the dotted lines at D and D_1, and partly by a concentration of stresses towards the central portion of the flanges as indicated at C, this concentration being a direct result of the deformation at D_1.

In designing a rib R, if it were intended to carry the entire force F, it would be necessary to make it about 1$\frac{3}{8}$ times the average thickness of the flanges, but since the web can readily take half or more than half of the load, it would seem that a rib of $\frac{5}{8}$ or $\frac{1}{2}$ of the flange thickness, narrowed down at the center as shown in the lower right-hand corner of Fig. 9, would be entirely sufficient if the web were judicially thickened and liberal fillets used; however, it could scarcely be considered as correct in principle as the construction given for analogous conditions in the bracket of Fig. 6.

Steel C-Clamps

Another method of taking care of the local stresses induced at a bend in a flange is to thicken up the metal at the corner. This method is well illustrated by Fig. 10, which illustrates a clamp regularly on the market. Instead of thickening up the flange at the corners, the surplus metal so used could be put into two ribs forming a continuation of the flanges, as indicated by the dotted lines at A, and thus, instead of trying to transfer the stress around the corner, permit it to gradually "die out" in a natural manner. This would be the same in principle as the construction of the bracket shown in Fig. 6.

Fig. 11 shows a shorter clamp of standard manufacture. Here the weakest place on the clamp is obviously the corner, so that it would be possible to take away some material, as indicated by the dotted lines, without weakening the clamp. But the saving so effected would, in this case, be but a small percentage of the total weight, and such a form would detract from the appearance of the clamp; and anything which detracts from the appearance of a tool hurts its sale. For, notwithstanding the fact that when a part *is* right it *looks* right it is sometimes difficult to educate the eyes of those not conversant with analytical mechanics.

Planer and Boring Mill Housings

Figs. 12 to 16, inclusive, illustrate five designs of planer housings. These are of the same general design as used on large vertical boring mills and illustrate a misconception of the principles of mechanics. In Fig. 13 the designer evidently considered the housing as a cantilever with the load applied at the end, and aimed at a uniform extreme fiber stress, hence the parabolic form as indicated by the fullness of the curve at the top. Just what mental processes led him to place the holes through the housing in the irregular manner brought into prominence by the dotted line is, however, a mystery. The designer of the planer in Fig. 12 evidently realized that material is useful at the neutral plane, and the writer agrees with him in that respect.

In Fig. 14 the rear contour is noticeably flat at the top, as compared with Fig. 13, which indicates that the designer did not follow the parabolic form supposed to give uniform strength in such cases. The disposition of the holes shows that he aimed at a gradual increase in the sectional area of the rear flange, which, in this respect, is an improvement over that in Fig. 13.

Just what the actual distribution of stresses over the various sections of a member so formed might be, constitutes a very complicated problem which, at best, would be attended with considerable uncertainty. It can, however, be stated in a general way, that they are both designed upon the erroneous conception that the material at the neutral plane of a beam is not under strain—hence is of no consequence, and should be removed if possible, on the score of economy. This is only another phase of the proposition that capacity for resisting shear on the neutral plane, and all planes parallel to it, is usually disregarded, notwithstanding the fact that it is a prime requisite in any member subjected to flexure.

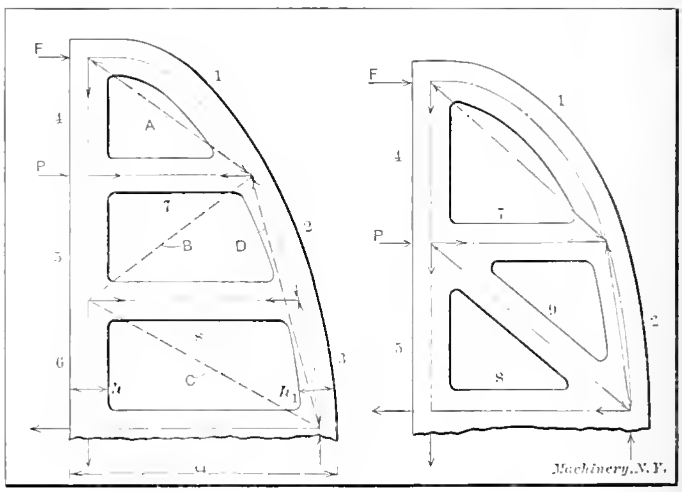

Fig. 17 Fig. 18
Analysis of Stresses in Planer Housings

Fig. 17 is an attempt at illustrating the internal forces in the housings of Figs. 13 to 15. When loaded at the top, as at F, members, 1, 2 and 3 are in compression and, in consequence of being curved, are eccentrically loaded struts. Members 7 and 8 are in tension while members 2, 3, 4, 5, and 6 are subjected to local bending in addition to direct stress. When the load is applied at P, members 2, 3 and 5, 6 are subjected to heavy bending action, and instead of having a beam of depth H it is more a case of two shallow beams of depth h and h_1. No such construction would be tolerated in structural engineering.

In Fig. 16 is shown a more modern type of planer housing in which the designer has pulled away from the stereotyped form and has approximated a true truss. He has not, however, had the temerity to eliminate the curved contour or make the center lines of his members intersect, and, while it is a step in the right direction, it does not go far enough to accomplish the ideal distribution of material.

Fig. 18 shows the principles underlying the construction of this housing. Members 1 and 2 are still eccentrically loaded struts, especially member 1, but members 4 and 5 would be plain tension members with the load at either *F* or *P*, if actually constructed as here shown. But in Fig. 16 it is seen that the center lines of members 7 and 9 do not intersect on the center line of members 4 and 5, and thus, as there constructed, members 4 and 5 are still subjected to a local bending action which might be avoided. For the application of the load at *P*, which is the usual run of work on a planer, this housing is almost ideal in its construction and should be very rigid.

The housing of Fig. 17 could be made a true truss by the straightening out of member 1, and the placing of members 2 and 3 in a straight line coinciding with *D* and the adding of members whose center lines are *B* and *C*. Member 8 could then be omitted.

Conclusion

To sum up the matter briefly:

1. No formula for flexure holds good beyond the elastic limit; hence ultimate supporting power cannot be calculated excepting by empirical formulas based upon tests.

2. No beam, unless a true truss, can sustain vertical shear without also possessing capacity for resisting horizontal shear; hence, do not cut away all the material from the neutral plane.

3. Horizontal shear must, of necessity, produce a corresponding sliding upon each other of the "fibers"; hence a section which is plane before flexure does not necessarily remain plain after flexure, and stress does not vary exactly as the distance from the neutral plane.

4. Short, heavily-loaded members should be expected to have a greater supporting power than that calculated by the common theory of flexure, unless crippling of the web be the determining feature.

5. No stress, due to bending, springs suddenly into being, but is built up from zero to a maximum by the transference of the vertical shear from section to section; hence anything which affects the distribution of stress on one section affects the distribution on succeeding sections.

6. Force travels in straight lines or else produces bending or other local stresses; hence curved members are to be avoided and it is entirely wrong construction to suddenly curve a flange without providing for the proper transference of the load in that flange.

7. A formula to take into account the stresses induced by curvature of flanges in compound sections should take into account the curvature of these flanges rather than the curvature of the gravity axis of the entire section.

8. Designers of machinery would do well to study the principles of structural engineering, use more straight members, fewer curved ones, and more nearly approximate true truss forms, thus securing more rigid members with less material.

* * *

An interesting method of making composite metal car wheels is in successful operation. The wheel produced has a manganese steel tread and a cast-iron web and hub. The practical result of the process is to produce an integral car wheel having a tread approaching in durability and strength a shrunk steel tire and costing much less. The principle of the process is substantially as follows: The mold is mounted on a vertical spindle and is rotated at a high speed when the molten metal is poured. The manganese steel is poured first and flows to the outside of the mold forming the flange and tread. Then the cast iron is poured to form the web and hub. The metals unite perfectly, making a sound casting, which, though variable in composition, is integral in physical structure. The wheels when struck with a hammer ring like a bell.

INEXACT MACHINERY TERMS

By T. S. BENTLEY

No one who has had much to do with machine tool specifications can have failed to remark the great lack of uniformity commonly met with in the descriptive terms employed. In many cases this merely shows curious variations without causing inconvenience or ambiguity, but in others it renders the meaning obscure and occasionally quite misleading. The desirability of adopting recognized and uniform standards in matters calling for the cooperation of many separate individuals, has been generally felt and has led to the formulation of definite rules in many instances for the guidance of those concerned. Such standards have repeatedly proved their value and are daily growing in favor and in use.

T. S. Bentley†

There is room for a similar understanding in the naming and identification of machine tools and their various component parts. This would make for clarity in description, save much unnecessary correspondence, obviate a great amount of uncertainty and prevent many mistakes. In short, a number of definitions of terms relating to mechanical matters are urgently required.

A few cases in point will serve to illustrate what I mean and to suggest numberless other instances of things which call for definite settlement on some uniform basis. The first example which presents itself relates to that most common of all machine tools—the lathe—whose description shows striking differences of usage between engineers in England, America and the continent of Europe. English manufacturers invariably designate their lathes by "centers" (that is, the height of the center points above the flat topped bed which is regarded as standard form) and "length of bed." This description fails to give any really vital information either as to the capacity of the machine or even the amount of space which it requires. The nominal "centers" multiplied by two would indicate the maximum diameter that can be turned were it not for the fact that the bed is commonly made with a gap whose depth must be taken into account. The length that can be turned is less than the "length of bed" by a considerable but unspecified amount, while the over-all length exceeds it to an equally indefinite extent.

The American practice classifies a lathe by the "swing" and the "length of bed." The latter, as we have just shown, is useless for the purpose of conveying any precise information either as to capacity or extent; and the former is in reality almost equally indefinite. The swing is supposed to be the lathe's maximum capacity in diameter, but in practice there is often a considerable discrepancy between the nominal and the actual swing—so much so, that some lathes styled 16-inch will, in reality, accommodate work larger than can be turned in others that are designated 18-inch.

Continental practice usually gives "height of points"—corresponding with the English "centers"—and "distance between points," which latter does give a definite piece of useful information, *viz.*, the maximum length that can be turned.

As lathes are mostly bought primarily to do work of certain known dimensions, the best description would seem to be that which clearly indicates the actual swing and maximum distance between the centers. This information is required in order to judge whether the lathe under consideration is of sufficient capacity for the work which has to be done. If this

†Thomas S. Bentley was born in Lancaster, England, 1868. He was educated at the School of Arts and Sciences, Wolverhampton and Coventry and the Northhampton Technical Institute, London. He served an apprenticeship in the locomotive works of the Great Western Railway, Worcester and Wolverhampton, and has worked also for the Rudge Cycle Co., now Rudge & Whitworth, Ltd., Coventry, the Enfield Cycle Co., Eadie Mfg. Co., both of Redditch, and Charles Churchill & Co., Ltd., London, E. C., with which concerns he has held the positions of toolmaker, section foreman, superintendent, mechanical engineer and consultant. His specialty is light repetition work. Mr. Bentley is now employed by Charles Churchill & Co. as consultant.

is not directly stated, it must be arrived at by some form of computation or estimate—and the direct statement is certainly preferable from every point of view.

If we turn to planing machines, we shall find a similar want of uniformity in terms relating to them. Customers will mail a manufacturer inquiries for "a 4-foot planer," and leave him to guess whether width or length is intended. In either case the other dimensions should have been stated also, to make the description complete; and it would be no more trouble to ask for a 22-inch by 22-inch by 4-foot or a 48-inch by 48-inch by 10-foot planer, as the case might be, and leave nothing to chance. In such descriptions, the figures themselves usually indicate the order in which the dimensions are given, but it would be well to have a clear and general rule as to the order which shall be recognized as correct and assumed if not definitely stated. This would preferably be: First, width; second, height; third, length—which is already adopted by many makers of repute.

An understanding of this kind is now generally current with regard to the dimensions of articles such as emery wheels, pulleys, and milling cutters of ordinary form; and much unnecessary writing is saved thereby. The order adopted is: First, diameter; second, face; third, bore.

How essential it is that any such practice should be based upon a generally acknowledged rule, is exemplified in the matter of dates when expressed in the common and convenient form of say 9/1/09. To an American, this is merely a concise way of saying September 1, 1909, but an Englishman would read it as ninth January, 1909, unless well aware of the differing practice on the two sides of the Atlantic. Of course there can be no mistake about dates later than the twelfth of the month, but there is ample scope for misunderstanding among the dates which bear no internal evidence of their sense. Probably each method would be upheld by those accustomed to it, and neither party would desire to give way, but a uniform standard is certainly to be desired. Personally, I prefer the English method because of what seems to me its natural sequence, *viz.*, first the figure which changes daily and which gives the closest indication of the time referred to, then the figure which holds good for a month at a time, and lastly, the figure which needs changing only once a year.

But to get back to machine tools; perhaps no single word is more loosely used in this connection than "automatic," and its meaning is frequently open to misconception. Strictly speaking a machine is automatic when all its functions are performed by mechanism which is self-acting instead of being dependent on an operator; but the term is also used in a partial sense referring to some single feature only, such as feed-motion, throw-out, etc., and there is often uncertainty as to which idea is to be understood.

In drilling machines there are always two elements to take note of, *viz.*, power and capacity; both are important and either may be allowed to take precedence. Inquiries for drilling machines frequently give no more information than say "with a 2½-inch spindle," leaving type and capacity to the imagination of the person addressed. Of course, where there happens to be only one machine with that dimension, it may be all right, but often there are several dissimilar tools having this particular feature in common, in which case the matter becomes altogether vague. Another indefinite inquiry will call for a "5-foot radial"—which may mean one having an arm measuring 5 feet overall, or one which will drill to the center of a 10-foot circle, and the difference in price will be considerable. The latter interpretation is really the more legitimate, but there is a temptation (especially where price is known to be the deciding factor) for the maker or merchant to adopt that meaning which will come within the wording at the lowest figure. The result is that many times the customer eventually gets what he does not want, and the maker who offered what was really desired, loses the sale to the one who quoted rather to secure the order than to supply what the customer required.

In connection with milling machines, there is now substantial unanimity of description. A "universal" machine is now always understood to mean one having a swiveling table and spiral cutting apparatus, whereas some years ago at least one maker applied the term "universal" to millers such as are now dubbed "plain." There is one curious diversity, however, in naming the miller's horizontal slides, although the dimensions being so dissimilar, no misconception is occasioned thereby. The table being long and narrow, it seems only natural to describe its lengthwise motion as "longitudinal feed" and the one at right angles as "cross or transverse." Some people reverse this practice and call the short feed longitudinal and the long one transverse, cross or in-and-out. Evidently the one view is based upon the position and shape of the table, while the other labels all motions in relation to the spindle.

It is interesting to note, in passing, the conflicting practice in the arrangement of universal millers of the usual type, some being right- and some left-handed. Apparently this disparity has arisen in a similar way. The lathe was doubtless the parent of the milling machine and it can be employed for milling in two ways: Either the cutter can be mounted in the lathe spindle while the work is clamped to the carriage, or the piece to be milled can be held between the centers and a cutter-spindle rigged up on the rest. In the former case the cutters would naturally be made to run counter-clockwise—the normal direction of the lathe spindle—and the work centers made to suit; but the latter method would suggest the use of left-hand cutters.

The very terms "right- and left-hand" are particularly subject to confusion, and depend entirely upon the point of view. It would therefore be a distinct advantage to have some definite and simple rules drawn up for regulating their application and use. In the first place it should be clearly determined whether the terms right- and left-hand should be stated in relation to the machine itself or with reference to the operator who usually faces it and whose right hand is towards the left side of the machine. If we say that a lathe is in the right-hand corner of the shop, we mean the side corresponding to our own right hand as we look down its length; but if we speak of a right-hand side tool in that same lathe, we mean one which faces to our own left hand, *i. e.*, towards the right side of the lathe. [In American practice, a right-hand side-tool operates on the right-hand side or end of the work, the right-hand side being to the right of the operator when in the working position.—Editor.] The "front" of a lathe is the side on which the operator stands and is never a matter of doubt, but the "front" of a milling machine may stand for the end view of the spindle or either side according to design.

That this whole matter requires revision and standardization is plain from the misunderstandings which are constantly occurring, and from the fact that the terms right- and left-hand, whether relating to the rotation of a fan, electric motor, etc., the hanging of a door, or the objects in an illustration, are always matters of uncertainty or guess-work unless determined by some additional indication. To suggest a remedy which is at once practicable and effective is no easy matter, but we are told that "difficulties are made to be overcome," and some of the achievements in the direction of standardization which have already been accomplished looked at the outset far more hopeless.

It is useless to expect buyers of machine tools to be precise in their descriptions until the makers set the example of careful and accurate phraseology. Undoubtedly the machine tool builders must lead the way, and the first step towards the desired end will be in the direction of a standard system among themselves, preferably on an international basis. Their catalogues and printed matter would then do much to extend the result among buyers and others who could not be directly reached. The subject is one that might with advantage be taken up by the machine tool builders' associations with a view to some practical action, and I trust that they may be induced to take an active interest in the matter and endeavor to bring about its accomplishment.

* * *

The largest part of the world's supply of asbestos is provided by Canada. The total amount of asbestos produced yearly in the world is about 75,000 tons, of which Canada produces about 65,000 tons. Russia produces practically the remainder, or about 10,000 tons.

GRITS AND GRINDING CHIPS*

Whether grinding the roughest work, such as draw-bars, alloy steel railroad switches, frogs, etc., or the finest and most delicate instruments of precision, the abrasive used, whether it is a grinding wheel, oilstone, or razor hone, removes the metal by cutting off minute chips. Each little particle of grit on the abrading surface is a cutting tool, which severs the chips on the same principle that the lathe tool removes metal.

The secret of the success of any abrasive wheel or stone is in the adaptability of its structure for the work on which it is used. The efficiency of aluminous abrasive materials used in the manufacture of grinding wheels depends largely on their purity and structure. By aluminous abrasives is meant those which depend for their abrasive action on the alumina content. The chief impurities found are the oxides of iron and titanium and silica. In some cases these minerals are merely intermixed with the abrasive and can easily be separated mechanically. In other cases the impurities are chemically or mechanically combined with the abrasive grain, so that purification is practically impossible. In all aluminous abrasives, the abrasive efficiency is directly proportional to the amount of crystalline alumina present. When silica is combined with alumina, it makes a brittle grain of weak structure which is unsatisfactory, and when iron oxides are present the grain lacks the necessary abrasive qualities; the tendency of such a wheel is to heat or burn the material being ground, and it also consumes a great deal of power.

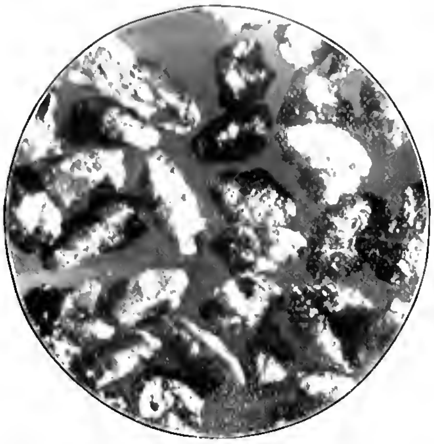

Fig. 1. Microscopic View of Emery Grains containing 50 Per Cent Crystalline Alumina

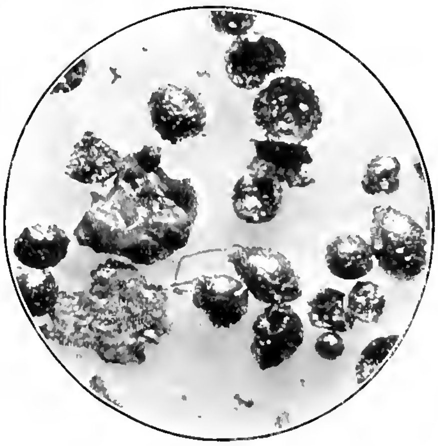

Fig. 3. Manganese Steel Chips produced by Dry Grinding with an Emery Wheel

Fig. 4. Manganese Steel Chips produced by Dry Grinding with an Alundum Wheel

Fig. 5. Razor Edge after Honing but before Stropping—Enlarged 750 Diameters

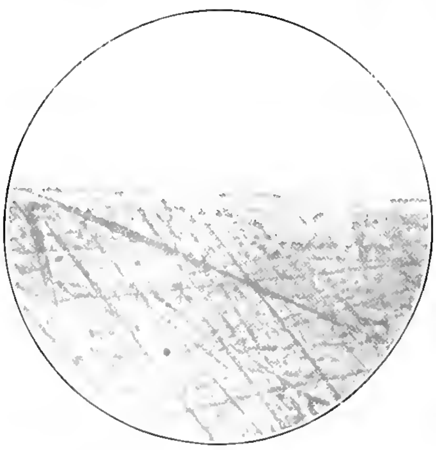

Fig. 6. Razor Edge shown in Fig. 5 after Stropping

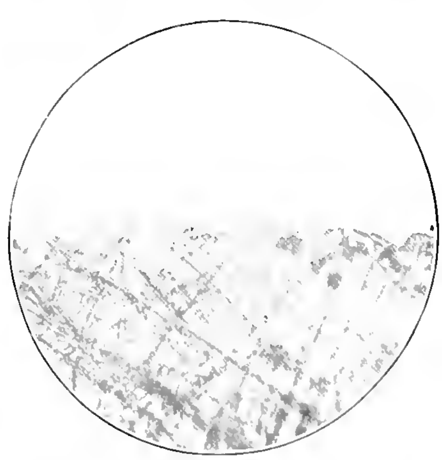

Fig. 7. Edge of Razor shown in Figs. 5 and 6 Honed on Coarser Hone and Stropped

In Fig. 1 some grains of Naxos emery are shown as they appear under the microscope. These grains have a considerable quantity of foreign minerals and they may be compared to a sponge, the interstices of which have been filled with impurities. The abrasive shown in Fig. 2 has only a small amount of combined impurities, none of which are mechanically mixed and it will be noted that these grains show a tendency toward crystallization, whereas those in Fig. 1 are entirely amorphous, that is, they have no determinate shape.

It is evident that the more round or blunt grains shown in Fig. 1 are not as good for abrasive purposes as those of Fig. 2, which have sharper cutting edges. All the commercial forms of natural abrasives have impurities of foreign material to a greater or less degree. They seldom have more than 85 per cent crystalline alumina and those that run as high as 80 per cent or over are considered exceptionally good. The common grade of emery used has only from 40 to 50 per cent crystalline alumina. In the artificial aluminous abrasives it is possible to get any degree of purity desired, as the purity depends on the electric furnace treatment. Alundum has from 92 to 98 per cent pure alumina.

In Figs. 3 and 4 are shown two lots of grinding chips as they appear under the microscope. Those shown in Fig. 3 were taken from under a grinding wheel made of an abrasive material similar to that illustrated in Fig. 1. The other chips shown in Fig. 4 were produced by a grinding wheel composed of an abrasive material of a high degree of purity. The material from which these chips were ground was the same in both cases and the grinding was done under the same conditions. Fig. 3 shows that there was so much heat generated that portions of the chips were melted as indicated by their

* Abstracted from the March and April numbers of *Grits and Grinds*, published monthly by the Norton Company, Worcester, Mass.

globular form, while those of Fig. 4 are seen to be, in form, identical with the chips from steel metal cutting tools, except that there are many different shapes, widths and lengths due to the fact that the cutting points of the grinding wheel are differently shaped and have different clearance angles. It is not intended to infer that the cutting properties of a wheel depend entirely on the abrasive, for there are many conditions that should be considered, as for example, the grade of hardness. That the quality of the abrasive is of considerable importance, however, is shown by these microscopic views.

The microscope and camera also furnish evidence that in the act of grinding, the principle of the cutting action is the same, whether a grinding wheel, oilstone, polishing and buffing wheel, or razor hone is used. For example, a keen edge on a knife or razor is produced by cutting from the side of the blade minute chips until the blade is worn down to a thin edge, and the chips differ from those produced by a coarse wheel only in size. Chips from two widely different forms of grinding are shown in Figs. 4 and 5. The first illustration shows the chips obtained from grinding with a coarse open wheel, while the second shows the edge of a razor that has been honed but not stropped, the photograph being taken under the microscope and enlarged 750 diameters. What is seen on the edge of this razor are minute particles of metal or chips clinging to the slightly magnetized edge. Fig. 6 shows the same razor after having been stropped. It will be seen that this operation removes the tiny particles of metal shown in Fig. 5. The even edge of the razor after honing is evidence that it was sharpened on a fine hone of even structure. Fig. 7 shows the same blade with a different edge, but having been honed on a stone of coarse and uneven structure and then stropped. It is plainly evident by these illustrations, which are magnified the same, that the hone used on the blade of Fig. 7, is made of coarser grit than that used on the blade of Fig. 6, as the edge is rougher and the marks on the side of the blade are deeper.

The form of chips produced by metal grinding indicates to a certain extent the temperatures at the point contact. If the chips are spherical instead of being long and curly, the heat generated has been excessive and a cooler cutting wheel should be substituted, as energy in the form of motive power is being consumed unnecessarily. Where there is too much heat generated, there is also danger of overheating and burning the work. Excessive heat and waste of power frequently result from the use of wheels that are too hard or too fine for the work. The combination of a hard bond and fine grit makes a wheel so dense that there is little opportunity for the particles to project enough to cut and there is no room for chips if they were removed. Such wheels, however, last longer than the proper grade and for this reason there is a tendency on the part of those economically inclined to use hard, fine wheels on work which calls for wheels which are coarse and soft, but this is poor economy. In this connection the microscope and camera have proved valuable in determining the proper wheel or stone for the various kinds of work. It is possible by this means, together with a similar examination of the surface ground, not only to select the grade and grain of wheel that does the work most effectively, but in many cases to improve grinding conditions in general.

* * *

IS THIS TRUE?

"It is a curious fact that it is immensely more difficult to write a good news article about a subject of which you yourself know much, than about a subject on which you are looking for information, as well as everybody else. I myself once wrote a book on how to run a steam engine (published anonymously) and though I had never touched a steam engine in my life, my book at once took precedence in popularity over all the other books on the market written by experts and was adopted in colleges as a text book."—*Sherwin Cody.*

* * *

The French army department has recently acquired an automobile which is capable of running as well in water as on land. It can be instantly changed from a land to a water machine. It has a speed of twenty-five miles on land and about eighteen miles in water, and can carry four persons.

REORGANIZING A RUN-DOWN ASSEMBLING DEPARTMENT—2

By ALFRED SPANGENBERG

In the previous installment of this article, the necessity for analysis of existing conditions, the relation of the machine departments to that of assembling, the value of an efficient stock tracing system, the importance of an inspection department, and wage systems, received consideration. The present installment will deal with problems encountered in the assembling department itself.

2.—DEFECTS OF ASSEMBLING SYSTEM AND METHODS FOR IMPROVEMENT

Arrangement and Equipment of an Assembling Room

The efficient organization of a shop requires the division of the shop into departments according to the machines used; for instance, the lathes should all be in one department, and so with the planers, milling machines, etc. A large number of concerns, however, still machine a part of the work in the assembling room, even though regular machine departments have been established for the machining operations. This leads to inefficient methods of machining in the assembling room, as the machines can generally be used to better advantage if installed in the proper machine department. This matter was fully treated in an article by the writer appearing in the August, 1909, issue of MACHINERY.

Again, the average assembling room is small, and the space taken up by operating machinery is generally needed for assembling work or for storage. In most cases, the reason given for having machine work done in the assembling room, is that difficulties arise in getting the parts promptly to the assemblers; if the machines are in the assembling department, delays will be avoided, because the assembling foreman will take particular care to get the work out in time. While this, no doubt, is true, yet, with an efficient stock tracing system, there should be no difficulty in obtaining the work from the machine departments in time.

Occasions will also arise in the assembling when it is necessary to adjust some of the parts, and it is then advantageous to have machines convenient to the assembler. Upon investigation it will generally be found, however, that much of this work is unnecessary and can be eliminated by the employment of a few simple gages.

In describing the arrangement and equipment of the machine tool assembling department, we will assume that the operations involved will include the cleaning and chipping; drilling; filling, rubbing down, and painting; assembling the small units; scraping; and erecting. As these operations differ widely, each being performed by a different class of workmen, a proper system requires their segregation. In large shops devoted exclusively to building one article these operations usually are carried on in separate departments, each under a different foreman. The usual plan where the product is of a varying character, is to have a separate assembling department for each class of machines; thus, in the machine tool line the lathes are erected in one department, the planers in another, etc. The last-mentioned plan is the one that will be considered here.

Cleaning and Chipping Operations

In some shops the cleaning and chipping is done in the assembling room, although it is more economical to clean the castings in the foundry, owing to the cheaper class of labor employed and the better facilities for this work. However, when this work is done in the assembling department, a suitable space should be provided, so as to keep the "muss" and dirt in one place. The old-time method of cleaning large castings by rubbing them with a file or emery brick should be supplanted by the more economical method of using an emery wheel driven by a portable motor and flexible shaft. The equipment should also include stationary emery wheels for grinding the small parts, and pneumatic hammers for chipping the heavier work. Vise benches and vises are needed by the chippers, and suitable stands or bins for the small parts will economize space.

* Address: 951 W. Fifth St., Plainfield, N. J.

As all castings should be cleaned thoroughly before any drilling or assembling operations are started, this work should be located near the receiving depot and convenient to the drilling machines, as nearly all castings require some drilling operation.

The filling, rubbing down, and painting, can be done to advantage in the cleaning space; these operations should be completed immediately after the drilling, and before the assembling operations are commenced. In many shops, however, the painters are allowed to fill and rub the finished or partly finished machines, to the annoyance of the assemblers, and with the certainty of getting dirt in the bearings. Of course, some of the painting and touching up with filler must be done on the assembling floor, but in most cases it can be confined to one place.

Drilling Operations

If special shop conditions render it advisable to have the drilling machines in the assembling department, they should be located near the place where the work is received. The

general arrangement of the machines and the requirements for their operation were outlined in the writer's article in the August, 1909, issue. Rapid drilling is essential, as some one of the assemblers will always be found waiting for the drilling operations to be completed. High-speed steel drills and *machines powerful enough to drive them to their maximum capacity* are, therefore, required.

Assembling

Even when the assembling and erecting processes are carried on in one department, it is best to provide a separate location for each, because the equipment for each differs widely. For assembling the small units it is convenient to have long benches on which to place the parts; these benches are provided in addition to the regular wall benches with vises, and should be arranged convenient to the latter and with aisles between them for trucking the work. These aisles should always be kept clear. When the parts are made in large quantities, it pays to provide fixtures for holding the parts that cannot be conveniently clamped in the ordinary vises during the assembling process. For holding the heavier pieces, as, for instance, lathe headstocks, trestles or wooden horses are required, which may be made of sufficient length to hold three or four headstocks. The space under the trestles can be utilized for keeping the smaller assembled units until needed.

The practice of allowing the benches to be littered up with small parts and stock supplies such as screws, pins, keys, etc., is a source of loss and waste. One of the greatest causes of annoyance to a foreman when this system, or rather lack of system, is followed, is that the workman soon forgets what members the stock supplies belong to, with the result that screws are used that are either too long or too short, or not of the right type. This defect may be overcome by providing boxes of uniform dimensions for keeping the small parts. These boxes should be made with a partition at one end for the stock supplies, and with a tin pocket on the side in which to place cards giving the necessary information, as will be explained in detail later.

Much time will be saved in the assembling department by having a specific place for such tools as wrenches, pneumatic drills and hammers, clamps, etc. While the men should be permitted to help themselves to these tools, they should be returned upon completion of a job. Little or no trouble will arise from lost tools if the foreman insists upon this rule being enforced. When there is a departmental tool-supply room, it is better, of course, to keep all tools there. Ratchet wrenches with removable sockets fitting different sized nuts, bolts, and screw-drivers, are most convenient for assembling work.

All parts to be assembled should be arranged in logical order and placed convenient to the workmen, so that their sole attention can be concentrated upon the assembling operations, thereby making it unnecessary for them to waste time in running around to find the parts. Every facility should be provided for the quick handling of the work.

Scraping Operations

The work of scraping usually does not receive the attention that its importance demands. The accuracy of the work produced by any machine tool is almost entirely dependent upon the accuracy with which the planed surfaces are scraped; it is essential that a proper equipment of straightedges, surface plates, test indicators, squares, etc., be provided for testing the truth and alignment. Each individual member should be tested separately, and it is often advisable to have special straightedges or surface plates which can be used both for testing the planing and scraping. Then the planing is easily tested, and if not within the allowable limits, the part can be sent back for replaning before any scraping is done. This is an important feature, since it is far more economical to plane work true than it is to scrape it.

Without the aid of such devices for gaging the work, errors may exist in the machining that may necessitate the use of a file before the scraping operation. These special straightedges or surface plates are, however, not intended to make the parts interchangeable in all respects. It is practicable only to carry out this feature in the planing process and up to a certain point in scraping, after which the pieces are scraped together and numbered accordingly.

In addition to trestles for the heavy parts, scraping trucks are convenient for supporting the movable members during the scraping. These trucks are portable benches mounted on castors, so that they can easily be moved about and turned around to any position that will secure good light on the work. Motor-driven, rotary oil stones should be provided for the sharpening of the scrapers. Each scraper-hand should be provided with a number of properly hardened scrapers. The necessity for ample crane facilities is too well recognized to need comment. Simple and inexpensive pulling devices, such as those described by the writer in the April, 1909, number of MACHINERY (reprinted in MACHINERY'S Reference Series No. 50, "Principles and Practice of Assembling Machine Tools"), will greatly facilitate this work, and enable the workmen to devote their energy to the actual operation of scraping.

Erecting

The arrangement of the erecting floor will vary with the character of the work; however, a few general principles may be stated. Where it is the practice to build machines in large lots, the beds are placed in rows with aisles between. Crowding should be avoided; in case there is not sufficient room to arrange all the beds in a lot on the erecting floor at one time, fill the available space without crowding, and store the remaining beds in some convenient place.

Suitable erecting pits are required for such machines as large boring mills and planers, which have driving works reaching below the floor line. The bottom of the pits is usually lined with concrete, with sides of the same material or brick, while cast-iron plates are placed all around the mouth. These pits are generally provided with movable girders or supports, to accommodate various sizes of machines. When a pit is not in use, it is covered with a plank floor made in sections, supported upon the girders set in pockets in the sides of the pits.

Emery wheel stands, speed lathes, small drill presses, and

portable vise stands should be located at convenient points on the erecting floor. Chalk, emery cloth, machine oil, and all special appliances used by the workmen should be handy, so as to avoid running to the tool-room. In regard to waste for cleaning purposes, it may be of interest to note that many shops are now abandoning it for raw silk towels which can be washed in a machine, and, besides being cheaper in the end than waste, are far more sanitary.

The relative importance of handling facilities, such as electric cranes, hoists, etc., varies according to the character of the work. What may be the most important feature for one class of work may not be essential in another class. In some cases it pays to have specially designed jib cranes with power hoists, so that the workmen need not wait for the over-head crane after the work is once placed within reach of the former.

In the handling of light work there are several points of importance that must be considered. Whenever possible the stock should be carried in boxes. These boxes should be of some standard sizes. For very small work it pays to arrange the boxes with removable trays so that the stock can be easily handled and better protected in carrying it through the shop. Erecting trucks with one or more shelves, and ordinary two-wheeled trucks are necessary for moving the light pieces. The features mentioned in this brief outline apply to the entire assembling department, and are of vast importance because an astonishingly large proportion of lost time can be attributed to lack of proper facilities and methods for handling work.

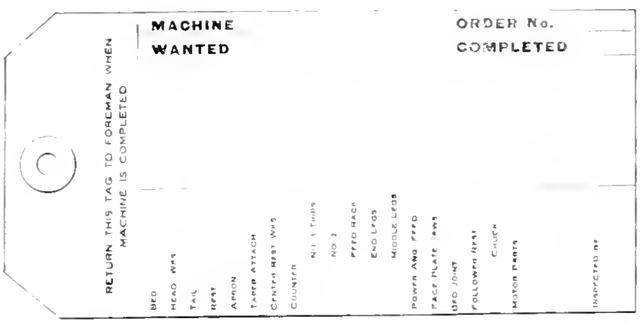

Fig. 5. Tag showing Data required by Erectors. The Tag Illustrated is for Engine Lathes, when properly filled out, it is placed on the Lathe Beds on the Erecting Floor

As all power-driven machinery requires to be "run off" when completed, some convenient source of power is necessary. This problem is easily solved in the case of motor-driven machines, but for belt drives, instead of moving each machine under a countershaft, it is more convenient to provide portable electric motors, which can be moved to any machine by the crane. If required, these motors may be back-geared and provided with different-sized pulleys, and in the case of small units the entire outfit can be mounted on a truck. When the machines to be run off require the application of power to more than one pulley, a suitable countershaft can be supported above the motor by braces bolted to the truck. Each outfit should be provided with a controller, as variable speed motors are best adapted to this work.

Necessity for a Departmental Stock-supply and Tool-room

One of the principal factors in the efficiency of an assembling department is the stock-supply and tool-room—the "heart of the department." Added to the loss of time in looking for lost or missing parts, due to haphazard methods of checking up and taking care of the parts as they are received, it is the usual custom in run-down assembling departments not to provide any regular place for keeping the work, but to dump it down anywhere. Frequently the only place provided for the small parts is under or on top of the vise benches.

When sufficient space is available for a stock and tool supply room in the assembling department, it is advisable to establish one immediately. In equipping this department, adjustable metal shelves and bins can be used, and for storing many of the small parts carried in the boxes already referred to, racks can be so arranged that any box can be placed directly into the rack in the same manner as a drawer. This arrangement saves extra handling of the work, and is better than piling boxes one on top of another, as any box is instantly accessible. The shelves and bins in the stock room are only for keeping the smaller parts, such as can be easily handled by the stock clerk; the larger pieces, not being so apt to get lost or misplaced, can be taken directly to the assemblers without passing through the stock room, although care should be taken in checking up this material when received.

Sufficient space should be assigned in the tool-room for storing all tools used in the assembling department. Some simple system must be inaugurated for keeping track of the work and avoiding delays in giving it out, for taking proper care of the tools and keeping them in good condition, and for charging up to the workmen the tools in their possession. A part of the space assigned to the stock and tool supply room should be partitioned off and fitted up for the foreman's office, as the foreman necessarily must keep in close touch with this department.

When the size of the department precludes the establishment of a stock-supply and tool-room some other place with suitable equipment must be assigned for keeping the small parts until wanted by the assemblers. Either wooden or metal shelves and bins should be erected near the receiving depot, and they should be numbered consecutively to facilitate putting the parts into the bins and locating the work when wanted. All of the larger pieces should be stamped with their order number and pattern or forging numbers for the purpose of identification in the shop and for the customer's convenience in ordering repairs. As it would not be feasible to stamp the stock supplies, such as screws, pins, etc., with their piece number, it is of advantage to have the stock supplies put up in suitable packages properly tagged. This can be done at odd times by the stock clerk, and the packages placed in the proper bins together with the members to which they belong. In case there are too many pieces belonging to any particular group for one bin, two or more bins can be assigned to the large groups. This matter should be determined in the beginning.

Methods of Routing the Work

In shops without established methods of routing the work, it frequently occurs that work reaches the assembling department without having all the machining operations completed, and if this is not discovered before the parts are put away,

time will be lost when the work is finally delivered to the assembler, and, in addition, unnecessary trucking is required. This is particularly likely to happen where there is no system of inspection, and the sequence of operations is not mapped out in the beginning on cards or tags, as shown in Fig. 4, which accompany the work in its course through the shop.

The receiving depot in the assembling department should consist of a long bench about the height of the moving trucks, for convenience in placing the small parts; the truckers who bring the work to the assembling department are merely required to put it on this platform, as the stock-room clerk may not always be in a position to immediately check up and dispose of the parts. He should, however, give a receipt for all work entering his department, these receipts being returned by the truckers to the respective machine departments, to be placed on file as evidence that the work had reached its destination. Cards for this purpose must accompany the work, and

the receipt may be given in the form of a distinctive punch mark, or with a rubber stamp. The data this card should contain are shown in Fig. 1, in the May issue.

As soon as possible after the work reaches the assembling department it should be disposed of in a proper manner. All small pieces that require cleaning and painting are sent to the cleaner's bench; those requiring drilling and no cleaning or painting are sent to the drilling machine and piled in a convenient place; all other small parts are placed in the stock-room bins. After being cleaned, the work is sent to the drill presses, and all small work as soon as drilled, is delivered to the stock room. Thus no work enters the stock room until ready for the assemblers. Large, heavy pieces are sent directly to the drilling machines and from there to the assembling or erecting floor. A regular place should be provided also for the large parts, as otherwise much unnecessary handling will result. It is advisable to mark or tag these parts, for identification, with their group number in addition to the piece and order numbers.

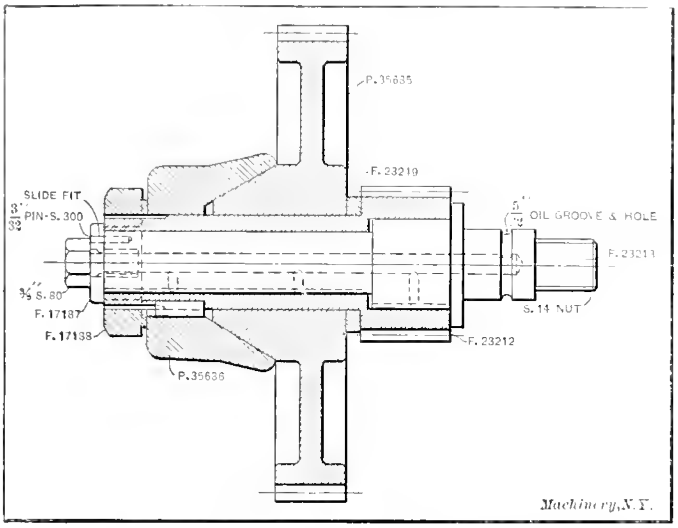

Fig. 7. Assembly Drawing of Parts Classified in Fig. 6

The Assembling Operations

When work is to be delivered to a workman who is nearly ready for his next job, the foreman or the job-boss sends a helper to the stock room with a work card properly filled out. This card contains the date, workman's name and number, group number, piece numbers, names of the parts to be assembled, operations, contract price, and estimated time for assembling. The stock room clerk delivers the parts to the helper, who, in turn, delivers them to the workman together with the card just mentioned, any shortages being noted on the card. All small pieces are carried in the boxes mentioned, which remain with the workman until empty, when they are returned to the stock room. The writer believes it unwise to provide the workmen with assembly drawings except under special conditions, as considerable time is wasted in studying the drawings. Better results are obtained by a proper subdivision or classification of the parts that can be assembled independently, each group containing a small number of pieces, so that only a few verbal instructions on the part of the foreman are necessary. This opinion is strengthened by the fact that comparatively few workmen can read an assembly drawing. Moreover, instructions should only be necessary in the case of new work or new men. All assembly drawings should be kept in a suitable cabinet in the foreman's office.

After each group is assembled, any parts requiring scraping are taken apart and sent to the scraper-hands, while all the remaining pieces are taken directly to the erecting floor and placed convenient to the bed of the machine to which they belong. Thus the erectors are supplied with work as soon as it is assembled. The parts that require scraping are immediately sent to the erectors upon completion of the scraping operations. This, of course, applies to the smaller members; the heavy members and beds of the machines are scraped on the erecting floor to save extra handling. The scraper-hands and erectors are furnished with contract tickets similar to those given to the assemblers.

On some classes of work, as, for instance, large lathes and planers, it is the practice to duplicate only the *parts* in quantities, because machines of this character have beds made to order, the lengths varying considerably. In this case, the parts when assembled are sent to a stock room for finished work, and kept there until a machine is ordered, when they are sent to the erectors to be fitted to the bed. The completed machines having passed final inspection, are then placed in the hands of the shipping department. The tag which is placed on each machine on the erecting floor is shown in Fig. 5.

It will be observed from the foregoing that the workmen are always supplied with jobs, and the work is not allowed to remain with a workman after he has finished his operations on it; it is immediately sent to the next operator. This condition fulfills a fundamental principle underlying the management of men—that they should ever feel the pressure of work yet to be done, and their inability quite to meet the demand ahead of them.

Method of Assigning the Work

Two fundamental principles of economical assembling must be recognized in the apportioning of the work among the workmen so as to secure a rigid subdivision of labor, and in the avoiding of unnecessary delays in getting work to the men, *before they are ready for it*. In fact, if nothing more were accomplished in reviving a run-down department than the constant supplying of the workmen with plenty of work and the necessary tools, and having the jobs classified and arranged in logical order, the productive capacity of the department would be considerably increased. Yet, in average cases the foreman gives these matters little consideration, resulting in work being assigned to high-priced workmen that could as well be performed by cheaper men, and in wasted time while the foreman hurriedly chases around looking up jobs for men who are out of work. In this way, work is often assigned and commenced without regard to whether or not it is wanted first, and without ascertaining the fact that all the parts belonging to any particular job are received and ready for the assembler.

It now remains to formulate plans whereby the work can be assigned and distributed with the least amount of attention on the part of the foreman. At the outset it will be necessary to group or classify the parts which are to be assembled. This task can best be accomplished by the assembling department foreman, since no one is as well qualified to successfully carry out this important work as he.

Fig. 8. Part of a Group Index Page from which the Work is assigned

The most convenient way to make the classifications is to take the assembly drawings and thoroughly analyze the operations necessary to assemble the machine. The classification of grouping of the parts and assembly operations will be made with reference to the correlated members, *i. e.*, members which can be assembled or fitted independently of other parts. In making these classifications, it is advisable to make as large a number of divisions or groups as possible; for instance, a large semi-automatic turret lathe easily would comprise 150 to 200 groups.

The primary objects in making such a large number of groups are to provide for a rigid subdivision of labor, and to enable the rate setter to arrive at a more accurate determination of the time required to assemble the various parts. The secondary advantages derived from the system are that exces-

sive time spent on any particular operation can be detected at once and the cause located; there is likely to be less discrepancy between the estimated time and actual time; it enables all the small members constituting each group to be kept in a separate bin in the stock room so that the parts can be delivered to the workman in logical order, thereby avoiding the necessity of sorting over a large number of pieces when giving out the work; and the task of assigning the work becomes a comparatively simple matter, as only a small number of parts are in each independent group; and a subdivision of this character facilitates the assembling operations by permitting different jobs to be started as soon as a few parts are received.

In mapping out this work, effective use can be made of a loose-leaf book, which enables rapid arranging and indexing of the groups. The general classification of the data may be seen from Fig. 6, which shows the tabulation of the friction gear members in Fig. 7. The stud F. 23213, washer F. 17187, 3/8 screw No. 80, and 3/32 pin No. 300, are not included in the form shown as they belong to another group of parts. As will be seen by referring to Fig. 6, the parts are arranged in logical order the same as they are to be assembled, which is the plan that should be followed in preparing the part lists for all the groups. The column marked "Recd." is to be filled in with lead pencil, so that the same page can be used for any number of machine lots, provided no changes in design are made.

After tabulating all the groups belonging to one machine, they should be arranged in logical order, classified, numbered consecutively, and a list compiled for ready reference. From the specimen page shown in Fig. 8, it will be seen that columns are provided for "Wk. Recd." and "Wk. Assem.," which furnish the foreman with a continual record of the condition of the work, and enable him to ascertain instantly just what groups are ready to be assembled, and when the work is ready for the erectors. This record is kept up-to-date from data secured from the stock-room records and piece-work tickets. As occasion requires, the foreman fills in the column marked "Assem. by," from which his clerk is enabled to make out the proper contract, which should accompany the work when it is delivered to the workman. Another index is required giving the pattern and forging numbers in numerical order together with their group number. This is to facilitate putting the work into the proper stock bins. A copy of this index, together with a list of parts belonging to each group, is needed for the stock room, but the loose-leaf record book must always be kept in the foreman's office.

General Requirements for Efficient Work

It is the intention to here but briefly show the practical working of an inspection system in the assembling department for insuring efficient, economical, and accurate production. At the outset it will be necessary to provide the inspectors with the necessary tools and gages for the rapid and accurate inspection of the work assembled and erected. There should be some regular system whereby the gages, both those in use by the workmen and those in the inspector's care, will be examined carefully at certain intervals and compared with the master gages to ascertain whether or not they have become worn. The reference gages or standards of comparison should be kept by the head tool-maker or by some one especially appointed for that work. This person should determine how often a gage must be examined to insure its being in the proper condition; and by arranging the examinations periodically, accuracy of the tools and gages can in this way be very easily insured. In addition to supplying the inspectors with the proper tools and gages, some safe and convenient means must be provided for keeping this equipment and transporting it around the department. This can easily be accomplished by furnishing each inspector with a portable desk, mounted on wheels, and having suitable drawers with lock and key in which to keep the various tools, gages, printed forms, writing materials, etc.

The inspectors' duties on the assembling and erecting floor consist primarily in examining the fit and alignment of the various shafts, gears, slides, guiding surfaces, etc., and to see that every part of the machine functions properly. This, of course, necessitates the constant and watchful attention of the inspectors as the work proceeds, so that faulty workmanship is discovered in its early stages. Even the matter of looking after such seemingly unimportant details as the proper tightening of nuts and bolts should receive attention, for when this point is neglected, it often happens that through carelessness on the part of a workman, a machine "falls apart" after being used a short time, causing trouble and annoyance to the customer, with the result that the next time he is in the market for a similar machine, he in all probability buys another make. Steel stamps bearing a distinctive character should be furnished the inspectors for marking all work passed upon by them—these stamps, under no circumstances, to be out of their jurisdiction. This acts as a check upon the inspector, for if any defective work passes his hands and bears his stamp he is responsible for any future trouble arising therefrom.

In connection with the question of determining just what limits of error are allowable, it is interesting to note that in modern machine tool practice the tendency is to allow greater limits in running fits than was thought advisable a few years ago. Thus, for all rotating members, except main spindles carrying the work or tools, the practice is to allow from 0.002 to 0.004 inch for running fits, for diameters from 3/4 to 3 inches, according to the requirements of the case; to have a lateral clearance, or endwise motion, of 0.005 inch for shafts, gears, or pulleys, running between bearings, sleeves carrying gears, etc.; and to cut the teeth of all gears thinner than standard, so that two gears when in mesh will have a slightly perceptible amount of backlash.

The advantages of this practice are at once apparent; it not only results in ease and quickness of assembling, but the main feature to be considered is the fact that when the bed of a machine is under the severe strains of a heavy cut, the distortion likely to occur may cause the rotating members to bind in their bearings, if fitted too closely, and thereby consume an excessive amount of power, besides overheating in the case of high rotative speeds. Moreover, so much time will be saved in assembling these parts, that an extra amount of time is allowable for obtaining accuracy in the alignment and fit of vital members, such as main spindles, slides, and guiding surfaces.

Conclusion

Turning now to the subject of reports and their uses, it may be stated that much good can be secured from a simple yet thorough system of reports by the assembling foreman, based upon his actual experience in carrying through his department a newly designed product, these reports to contain criticisms and suggestions upon design, and ease and economy of assembling the parts. This will result in establishing comprehensive and business-like cooperation between the designing department and the assembling foreman and assurance will be obtained that when a new or re-designed machine is produced it will operate properly, and will be so designed as to be produced in the most economical manner possible.

The problems involved in reorganizing a run-down department must be solved with an absolutely unbiased mind and a determination to analyze the situation thoroughly and mercilessly. If any superintendent or foreman wants to determine the fact that many of the defects in methods and management mentioned in this article in all probability apply to his own shop, let him, *after ascertaining what should be accomplished make a comparison with his present methods and processes.*

* * *

HIGH-SPEED STEEL FILES

The expert file maker knows full well how easy it is to ruin a new file by a few quick strokes on hard castings. After a file has been used for some time the same treatment perhaps would not appreciably harm it. The delicate sharp edges of new file teeth are easily ruined by impact and heat, whereas after some wear, they are much less likely to be affected by injudicious use. A new file used on revolving work in the lathe, especially cast iron, is quickly worn out unless used with discretion. It would seem that for such purposes files made of high-speed steel would be much superior to the common brands, but, of course, much more costly, although not more expensive, perhaps.

LATHE BURNISHING OF METALS

By WILLIAM A. PAINTER*

The burnishing of metals while not requiring the skill of the spinner, or the multiple operations or tools used in that craft, still is a trade that is separate and distinct from spinning. Metal burnishing can be divided into three classes:

1. Hand burnishing of irregular shapes, such as tableware, jewelry, belt buckles, metal clocks, ornaments and all metal parts that cannot be revolved on the lathe, using steel hand tools of various shapes.

2. The burnishing of small round work in the lathe, such as buttons, ornaments, etc.—mostly plated ware that has already been surfaced and is operated on to brighten only—not requiring the heavy pressure of the tool, and being mostly done with blood-stone burnishers, a natural stone of small size mounted in a steel holder. These stones, some of which are very expensive, last for years.

3. The burnishing of unfinished or rough work in the lathe, which requires smoothing and polishing at the same time; this requires considerable pressure. The blood-stone burnisher would be ruined on this class of work. The tools used are of steel and the handles are short; they are held in the hand only. A strong wrist and muscular arm are required for burnishing, as well as a steady feed of the tool, which is partly accomplished by the movement of the body, in conjunction with the arm and wrist motion; the hand is steadied by being held against the body.

Burnishing may be described as an economical way to finish, polish or brighten the surface of metal, without wasting any of the material. It is also a means of strengthening the

Fig 1. View showing Method of Moistening Work with Finger Pads and also Position and Angle of Burnishing Tool

metal by tempering or hardening it; this is accomplished by pushing the tool over the work, beginning at the front end and pushing always against the chuck. The toolpost is used as a fulcrum and the tool, which is pressed against the work, as a lever. The tool is given a slight rotary motion, and only the thin edge or end is used.

While the pressure against the work does not seem great, still the area in contact with metal is so small, and the speed of the lathe so high, being from 3200 to 5000 revolutions per minute, that the tool leaves a bright mark. The skill of the operator lies in passing the tool over the metal so as to leave a continuous bright surface without any trace of the tool marks; to do this the tool must be fed with regularity and without overlapping or leaving any dull places.

After sheet metal is spun, or drawn in presses, the smooth, even surface which it has when it comes from the mills is changed to a rough, uneven surface having high and low spots which are hardly noticeable to the naked eye, but very easily distinguished under the magnifying glass. The working operations distend or elongate the molecules, and the annealing operation restores them to their original shape. Some shells are annealed several times before the burnishing operation is reached, besides being pickled after each annealing to remove the scale; this leaves the surface of the metal in a pebbly or matted condition, as well as soft and without temper.

A spun shell can be gone over with a planisher, and hardened, but the scale and dirt is crowded into the grain of the metal, and the only way to get a smooth surface is to buff or cut it down until this pitted face is removed, thus wasting about 10 per cent of the metal. The spinner can do this in another way, that is by skimming or shaving the uneven surface, but even more metal is wasted than by buffing, and the shell is also weakened by gouging the high places. This same shell could be left without polish, and the chuck transferred to the burnishing lathe, which runs at much greater speed than one used for spinning. After the shell is dipped bright to remove all spinning dirt and scale, it can then be polished to an even surface, the uneven face of the metal being amalgamated

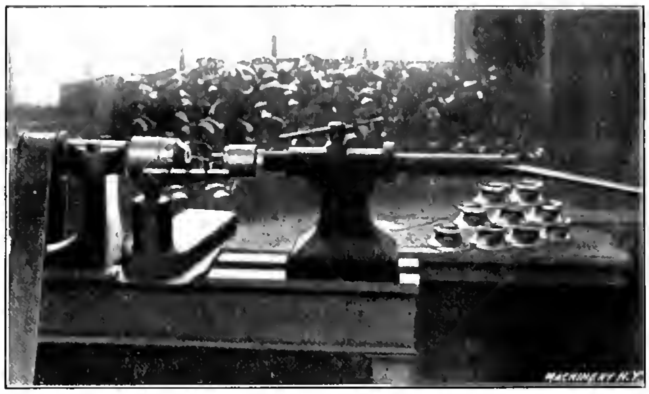

Fig. 2. Burnishing Lathe Equipped with Split Chuck

or smoothed down to a bright surface of the proper temper; it is then colored with a cloth buff to obtain a perfect finish. The gage or thickness remains the same as there is no dirt or scale to buff out.

Burnishing is economical, especially on pressed or drawn work made in large quantities, some work being finished at the rate of five hundred or more an hour. It is necessary to have a metal chuck in burnishing, and where the shell has been spun on such a chuck, the latter can be used for both operations. Some work can be lacquered without coloring on the buff wheel, the only operation after burnishing being to wash in hot water and dry at once in hot sawdust.

A burnishing lathe is smaller than a spinning lathe, and it has only one speed. The countershaft is fastened to the floor under the lathe; this is necessary on account of the great speed, besides a down-pull of the driving belt causes less vibration than the up-pull of a belt from an overhead countershaft. The speed of burnishing lathes is varied for different classes of work. In a group of four lathes in use in our factory one is belted to run at 5000 revolutions, two at 4000 revolutions

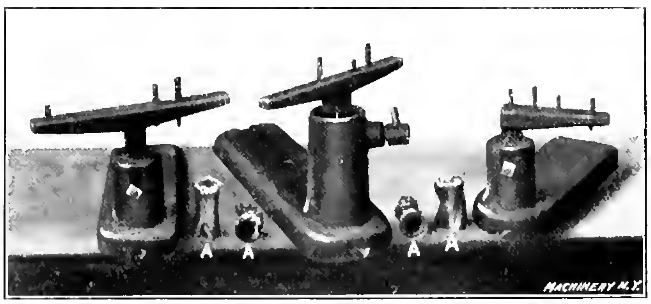

Fig. 3 Burnishing Lathe Steady-rests and Finger Pads

and one at 3200 revolutions a minute. Lathes for very large work of 12 inches and over in diameter have straight babbitted bearings, with a back screw and button to take up the end shake. The babbitt has to be renewed about once a year for continuous service, only the best grade being used. All threads on the spindles are of one standard size, the chucks being interchangeable for the burnishing and spinning lathes.

In some shops it is customary to have a small stream of water running on the work above the chuck, the connections being hinged, so that the stream can be guided above the tool. A back center is used to hold the work against the chuck. The operator wears a rubber apron to protect himself from the flying water, and stands in a shallow trough that has a drain. The great speed of the lathe throws off all surplus water, leaving only a thin film next to the metal all that is necessary.

This article describes a method of burnishing that is used in many shops. The shells are first dipped in a tank of

* Address: 1515 Franklin St., N. S., Pittsburg, Pa.

water, which is on the bench back of the lathe head; they are then held on the chuck by the left hand, the thumb and first three fingers being covered with canvas pads. These pads are dipped in the water and are held opposite the burnishing tool and slightly in advance of it to keep the metal moist, thus leaving no surplus of water to be thrown off. The hand also holds the work against the chuck instead of the back center. Sometimes on large work it is necessary to dip the pads in the water a second time; also where a very fine polish is wanted it is necessary to pass the tool over the work twice, roughing it down on the first pass and finishing it on the second, using the same tool without taking it off the chuck.

Fig. 1 shows the method of using the pads on the fingers and also the proper position and angle of the tool, as well as the height of tool-post or rest. The chuck shown is $8\frac{1}{2}$ inches in diameter and weighs 36 pounds; it runs at 4000 revolutions per minute. The shell has been gone over twice.

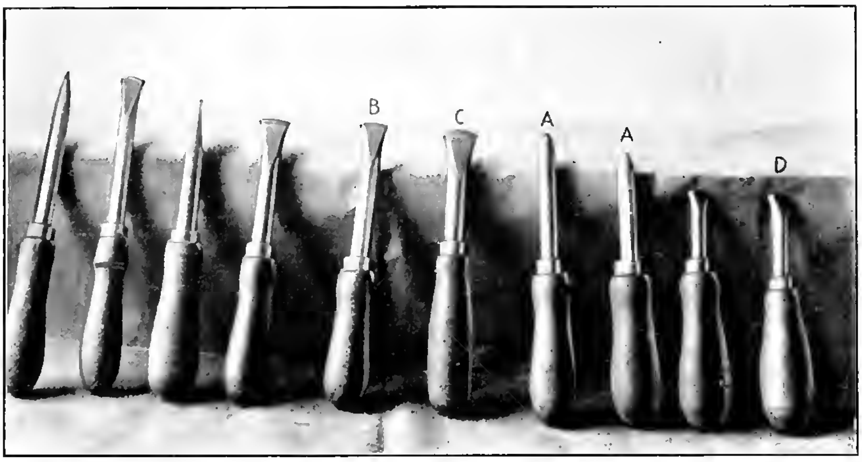

Fig. 4. Group of Tools used for Burnishing

Fig. 2 shows a burnishing lathe equipped with a split chuck, one part being in the tail-spindle and having a roller end bearing similar to the one described in the preceding installment of this article. All chucks for burnishing are like the spinning chucks, except that greater care must be taken in machining them to have them perfectly balanced.

Fig. 3 is a view of the steady-rests that are used on burnishing lathes. These are different from the spinning rests, for while the spinner uses only one pin as a fulcrum, changing it from one hole to another as the work advances, the burnisher uses several pins of much smaller size, inserting as many pins as he needs positions for the sweep of his tool. These pins are about 1/4 inch to 9/32 inch in diameter and are tapered $2\frac{1}{2}$ degrees on the end which is inserted in the cross-bar of the steady-rest, the holes also being tapered and the pins driven in tight. The canvas finger cots that are used on the left hand to moisten the work, are shown at *A*.

Fig. 4 shows a group of burnishing tools, some of which are of high speed steel, and others of regular tool steel. These tools are made extremely hard and no temper is drawn. They project out of the handles from $2\frac{1}{2}$ to 5 inches and are 3/8, 7/16, 1/2, and 5/8 inch in diameter. The handles are 4 to 5 inches long and $1\frac{1}{4}$ to $1\frac{1}{2}$ inch in diameter. The round tools *A* are used on heavy work; also to get in sharp corners and to burnish shells which are part plain and part embossed, requiring the tool to be lifted from one part of the work to another to avoid the embossed area. *B* is a flat tool with a slight curve on the end; it is used mostly on straight work and convex surfaces. *C* is a flat tool with a greater curve on the end, and it is used mostly on concave surfaces, while *D* is a flat tool with a still greater curve on the end, for use on small curved work, such as that shown in Fig. 5. These tools have to be polished when they get coated with metal, the interval between polishings depending on the texture of the metal worked and its temper, a shell that has been annealed several times coating the tool more than one that has not. It is a quick operation to polish the end of a burnisher. A board of soft wood or a strip of leather fastened to a board and to the bench, in a position convenient to the operator, is used. Grooves are worn into the leather or board, and flour of emery and oil, or flint flour and water is used to clean the tools, a few passes of a tool being all that is necessary to polish it.

Fig. 5 shows samples of burnished work; some of these are spun but most of them are drawn in presses. The bright dip which is used to clean work before burnishing is composed of: Oil vitriol (sulphuric acid), 2 parts; aqua fortis (nitric acid), 1 part. This solution should be kept in a crock set in a tank of running water, and mixed 7 or 8 hours before using, as the acids when combined heat up. It is best to mix the acids the day before using. In dipping brass, copper and German silver, the parts are strung on a wire whenever possible. If there are no holes in the metal that can be used for stringing, they can be put in a metal or crock basket, but they cannot be handled to good advantage as it is very difficult to thoroughly wash and dip them. After stringing the work on a stiff brass or copper wire, it should be washed in boiling potash, and then dipped in cold water to clean the potash off and cool the metal.

After cooling in the water, they are dipped for a few seconds in the acids, keeping the work constantly in motion, so that the surfaces will be all exposed equally; they are then shaken thoroughly above the acid and immediately washed in two separate cold-water baths, then in hot soap water, and then in hot water, after which they are dryed at once in hot sawdust. This operation will leave a bright, clean surface free from acid.

Common yellow soap, dissolved to thick paste, is used as a lubricant when burnishing brass. The shells and the finger pads are dipped in clear water, and the tool is dipped in the soap paste before burnishing each shell.

A lubricant for copper is made by dissolving about one ounce of ivory or castile soap in a gallon of water. The shells and pads are dipped in this solution, no lubricant being used on the tool. Yellow soap should not be used on copper, as the action of the rosin on copper is different from that on brass, the metal being so glazed or greased that the tool works badly.

For copper plate on steel, such as copperized steel oilers, etc., about one-half ounce oil vitriol to four gallons of water should be used. The burnishing tool should be dipped in a mixture of mutton tallow that has been melted with 5 per cent of beeswax, and the work and the finger pads should be dipped in the acid mixture. The tool is lubricated in the tallow mixture before burnishing each shell.

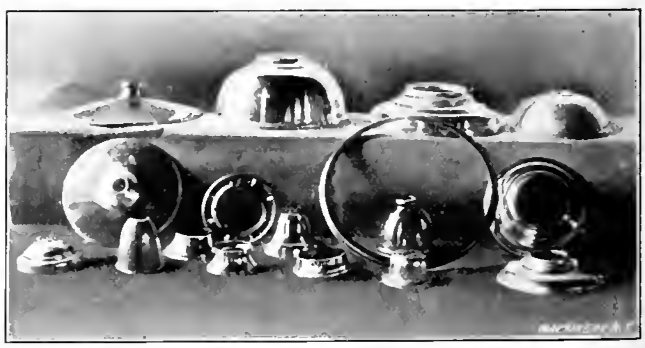

Fig. 5. Samples of Burnished Work

For German silver, the shell should be dipped in clear water, the finger pads in sour beer, and the tool in yellow soap paste.

For white metal or Britannia, use ivory or castile soap in the paste form for the tool, and sour beer or ox gall in water (4 ounces to the gallon) for the finger pads. Wash the work in hot alkali water (a spoonful of cream of tartar, saleratus or soda to a pail of water), and dry in hot sawdust.

For burnished work which is to be lacquered, without coloring on the cloth buff, use thin glue for a lubricant, and also on the finger pads. When the part is burnished put it in saleratus water to keep it from tarnishing; then wash in hot water and dry in hot sawdust. Most plated work can be burnished with the sour beer mixture for the finger pads, and castile or ivory soap paste for the tool lubricant.

THREADING OPERATIONS*—1

PRACTICE FOR THE BROWN & SHARPE AUTOMATIC SCREW MACHINE

By DOUGLAS T. HAMILTON†

The subject of threading on the Brown & Sharpe automatic screw machine forms a very interesting topic for discussion both in regard to the designing of the cams and the setting up of the machine. This is a subject which confuses the beginner on account of the calculations necessary for determining the rise on the cam due to the relation between the speed of the spindle and the driving shaft. The various reversing devices, tripping devices and threading attachments also

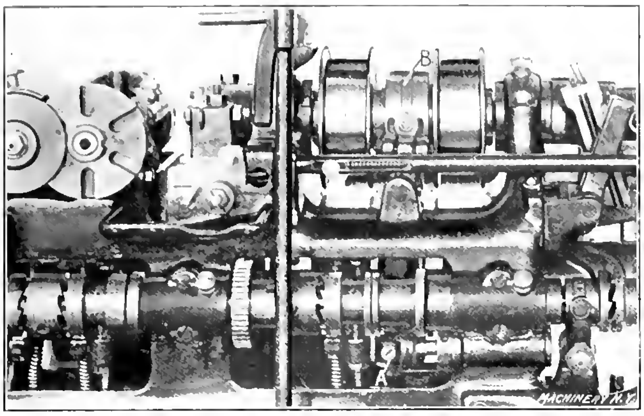

Fig. 1. (Rear View) Number 00 Brown & Sharpe Automatic Screw Machine showing Reversing Mechanism

play an important part in regard to threading. Until the various devices and arrangements used are fully understood, good results cannot be expected. Considering the difficulties encountered, the writer will discuss and illustrate methods and devices for overcoming same.

Reversing the Spindle

On the No. 00 Brown & Sharpe automatic screw machine the spindle is reversed to run backward by means of a spring plunger shown at *A*, Fig. 1; this plunger acting through the medium of the friction clutch *B* reverses the spindle instantaneously. But, to reverse the spindle from backward to forward, onto a slow speed (as is sometimes necessary when cut-

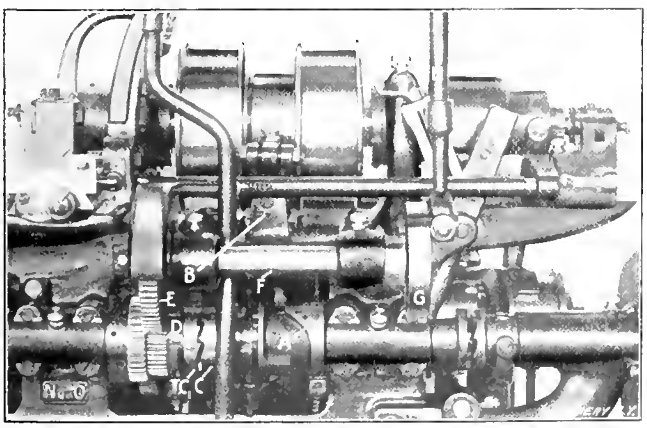

Fig. 2 (Rear View) Number 0 Brown & Sharpe Automatic Screw Machine showing Reversing Mechanism and Belt Shifting Attachment

ting a thread) requires one revolution of the driving shaft, which is equal to 1/120 of the speed at which the spindle is running. For example, let the spindle speed equal 2400 revolutions per minute and the speed of the driving shaft equal 120 revolutions per minute. Then the revolutions required for reversing the spindle $= \frac{2400}{120} = 20$ revolutions. The 20 revolutions used for this purpose is lost time, so to obviate this the Brown & Sharpe Mfg. Co. has provided a speed ratio threading attachment which is used in the turret. This attachment will be described later. On the No. 0 and No. 2 Brown & Sharpe automatic screw machines, the spindle is reversed from forward to backward by means of cam *A* and lever *B*, Fig. 2, which reverses the spindle instantaneously. The spindle is reversed from backward to forward by means of the same cam *A*, situated on the driving shaft, and considering that there are two lobes on this cam, it requires one-half revolution of the driving shaft to reverse the spindle. For example, let the spindle speed equal 1800 revolutions per minute; let the speed of the driving shaft equal 180 revolutions per minute. Then the number of revolutions required to reverse the spindle $= \frac{1800}{180 \times 2} = 5$ revolutions. To reverse the spindle from forward to backward and then forward again (as would be necessary where two threading operations come in succession) requires 4¾ hundredths of the cam surface on account of the tripping dogs on the drum which cannot be placed any closer together. This will be described under the heading "Setting the Tripping Dogs for Threading."

On the No. 2 Brown & Sharpe automatic screw machine, the spindle is reversed in the same manner as on the No. 0, but the ratio between the spindle speed and the driving shaft is different, being 1/240 instead of 1/360 of the speed at which the spindle is running. For example, let the spindle speed equal 1200 revolutions per minute; let the speed of the driving shaft

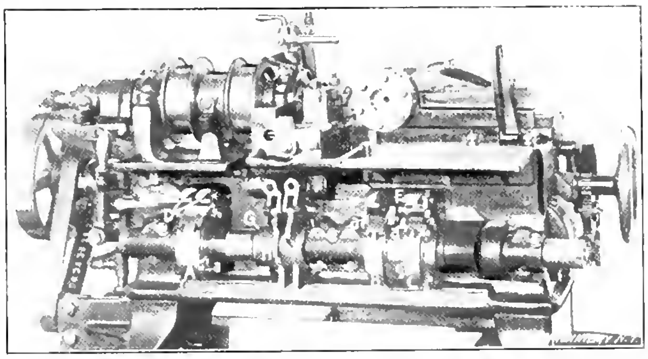

Fig. 3. (Front View) Showing Feeding, Reversing and Revolving Devices

equal 120 revolutions per minute. Then the number of revolutions required to reverse the spindle $= \frac{1200}{120 \times 2} = 5$ revolutions. But to reverse the spindle from forward to backward and forward again (as we explained regarding the No. 0 machine) requires 3¾ hundredths of the cam surface.

Setting the Tripping Dogs for Threading

The tripping dogs *a* which are used for reversing the spindle, feeding the stock, and revolving the turret are placed on the various drums on the front shaft as follows: The dog for reversing the spindle is placed on drum *A*, for feeding

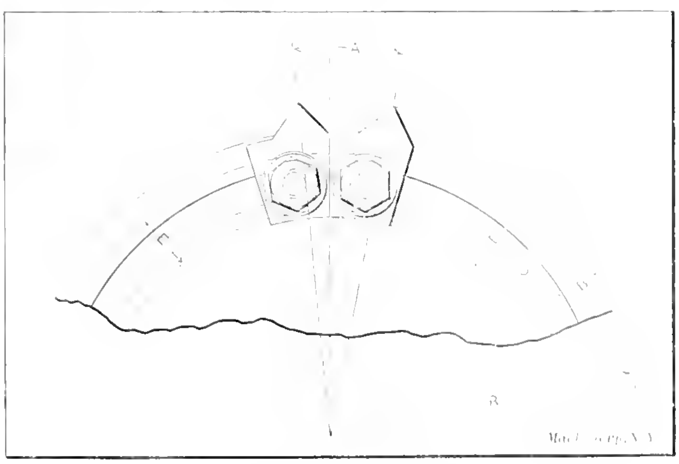

Fig. 4 Reversing Dogs in Position on Drum

the stock on drum *B* and for revolving the turret on drum *C*, as shown in Fig. 3. These dogs operate the levers *D*, *E*, and *F*, respectively, which, in turn, disengage a clutch on the driving shaft on the rear of the machine, thus operating the re-

* For further information on Brown & Sharpe automatic screw machine practice, see "Circular Form and Cut-off Tools," MACHINERY, March and April, 1910, and other articles there referred to.
† Associate Editor of MACHINERY.

versing, feeding and revolving devices. Where two threading operations follow in succession, the time required to revolve the turret is not always sufficient to bring the second tap or die into position. This is illustrated in Fig. 4, where two tripping dogs are shown in position on the drum. To illustrate the method of determining whether extra time should be allowed for clearance, take a practical example. Assume that a set of cams is required to be used on the No. 2 Brown & Sharpe automatic screw machine. Let the spindle speed equal 1200 revolutions per minute; let the time required to complete one piece equal 20 seconds. Then the number of revolutions to complete one piece $= \dfrac{1200 \times 20}{60} = 400$ revolutions.

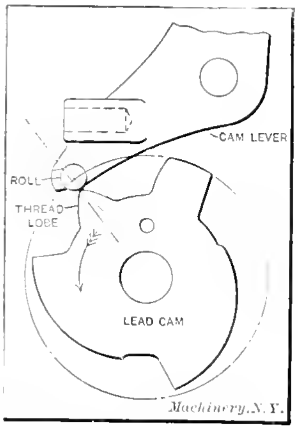

Fig. 5 Position of Roll on Thread Lobe when Spindle is reversed

Referring to the table for laying out cams in the Brown & Sharpe book we find that it requires five hundredths to feed stock, plus one hundredth for clearance. This gives 6 hundredths to revolve the turret. Referring to Table I we find that the angle A is 14 degrees. Then if the number of hundredths of the cam surface utilized in revolving the turret is less than 14 degrees, we would have to add more hundredths for clearance. In this case it requires 6 hundredths to revolve the turret. Then reducing 14 degrees to hundredths $= \dfrac{100 \times 14}{360} = 3.88$ hundredths. Therefore, it would not be necessary to add extra hundredths in this case.

Setting Dies and Taps

Before the reversing mechanism can operate, the clutch G must engage with clutch H. (See Fig. 3). After engaging these clutches, we set the reversing dog a so that the spindle will reverse just as the roll passes over the highest portion of the thread lobe on the rear cam, as shown exaggerated for clearness in Fig. 5. When the spindle is reversing at the exact point as mentioned, the die or tap holder containing the die or tap is placed in the turret, and brought into position as shown in Fig. 6. The cam roll is set on the thread lobe in the position shown. Here a button die holder A (draw-out type) is shown in position ready to start on the work. The face of the die should be set equal to the distance a, which varies from 1/16 to 3/16 inch, depending on the pitch of the thread and the length of the threaded portion. If the die does not travel on the work far enough at the first setting, the holder can be brought further out of the turret. The same procedure can be followed in setting the tap, except that it should be set more carefully, only going into the work a slight distance in starting, and then moving the holder out of the turret until the desired depth is reached. It is sometimes found necessary after setting the tripping dog, to adjust it slightly, especially when using a draw-out die or tap holder. The turret should not be revolved until the die or tap is clear of the work.

TABLE I GENERAL DIMENSIONS OF DRUM AND REVERSING DOGS

No. of Machine	A	B	C	D	E	R
00	20	$\frac{15}{64}$	$\frac{1}{4}$	$\frac{15}{16}$	$\frac{1}{2}$	2
0	17	$\frac{5}{16}$	$\frac{1}{4}$	$1\frac{1}{32}$	$\frac{1}{2}$	$2\frac{3}{4}$
2	14	$\frac{13}{32}$	$\frac{5}{16}$	$1\frac{1}{4}$	$\frac{9}{16}$	$3\frac{1}{4}$

Finding Revolutions for Threading

When calculating the revolutions of the spindle required for threading, a greater number of revolutions should be allowed than the exact number of threads required on the piece, depending on the pitch of the thread (and in some cases on the length of the threaded portion, as when a short thread has to be produced necessitating the threading of a longer portion and then facing it off). This is to allow the die to approach the end of the piece on the rise of the thread lobe. The actual number of revolutions required for threading can be found by the aid of the following formulas:

$$\text{From 14 to 24 pitch } R = \frac{L}{p} + 1.5$$

$$\text{From 28 to 48 pitch } R = \frac{L}{p} + 3 \qquad (1)$$

$$\text{From 56 to 80 pitch } R = \frac{L}{p} + 4.5$$

Where L = length of the threaded portion, p = the pitch of the thread, or $\dfrac{1}{\text{number of threads per inch}}$, and R equals the revolutions of the spindle required for threading.

Converting Revolutions into Hundredths

Owing to the inconvenience of dividing the cam surface into the same number of equal parts as the revolutions required to complete one piece, the Brown & Sharpe Mfg. Co. has adopted the system of dividing the cam surface into one hundred equal parts, the hundredths being obtained by dividing the number of revolutions for each operation by the total number of revolutions required to complete one piece, taking the nearest decimal with two places. For example, if the number of revolutions required for the die to advance on to the work is 10, and the total number of revolutions required to complete one piece is 200, then $\dfrac{10}{200} = 0.05$ or 5 one-hundredths of the cam surface.

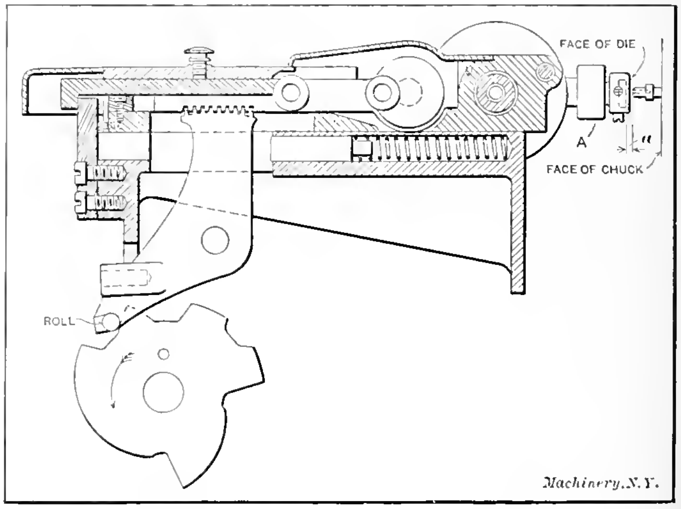

Fig. 6. Position of Roll on Thread Lobe when setting Die or Tap

Constructing the Thread Lobe

The method of laying out the cam lobe as described in the Brown & Sharpe book on the construction of their automatic screw machines, is shown at Fig. 7. The outer circle A indicates the relation between the center of the fulcrum of the lead lever and the cam. This circle represents the path which would be described by the center of the lead lever if it were revolved around the cam. The radius B equals the distance from the center of the roll to the center of the fulcrum on the lead lever. C equals the vertical distance from the center of the cam to the center of the fulcrum on the lead lever, and D equals the horizontal distance. Before constructing the thread lobe, the number of hundredths, the rise on the cam for threading, and the amount that the thread lobe is cut below the outer circle of the cam have to be determined. Then, after having drawn the various circles and lines necessary for the construction, we can proceed as follows: First, from the starting point a, the highest point b and the finishing point c, of the cam lobe, with a radius equal to B describe arcs cutting the outer circle A at the points d, e, and f. Then divide the spaces between the points d, e, and f into the same number of equal spaces as the number of revolutions required

* In the above tables which contain the pitches as adopted by the A. S. M. E., 22 and 44 threads per inch have been omitted, being rarely used.

for threading. With a radius equal to B and with centers where the divisions cut the large circle A, describe arcs cutting the thread lobe as shown. On the arc cutting the point g, describe the roll circle, this being the position of the cam roll when starting the thread. Then proceed in like manner from the center of this roll, laying off an equal number of spaces corresponding to the pitch of the thread and the number of revolutions required for threading. A series of circles of the diameter of the cam roll, drawn on these centers gives the form of the thread lobe. The form thus produced would not give satisfactory results as crowding of the tap or die would occur owing to the spindle speed and the speed of the driving shaft not being constantly in the same ratio. It is, therefore, advisable to cut down the cam lobe after the first couple of threads. This is shown in Fig. 7 as the actual rise required for threading. As will be seen this is a rather long and difficult method of constructing a cam lobe and can be simplified where a circular milling attachment is available for cutting the cam.

Improved Method of Constructing Thread Lobe

In the method just described the rise on the thread lobe was determined graphically, this being a very complicated and tedious method. The advantage of the following method lies in its simplicity, as the lobe is determined mathematically.

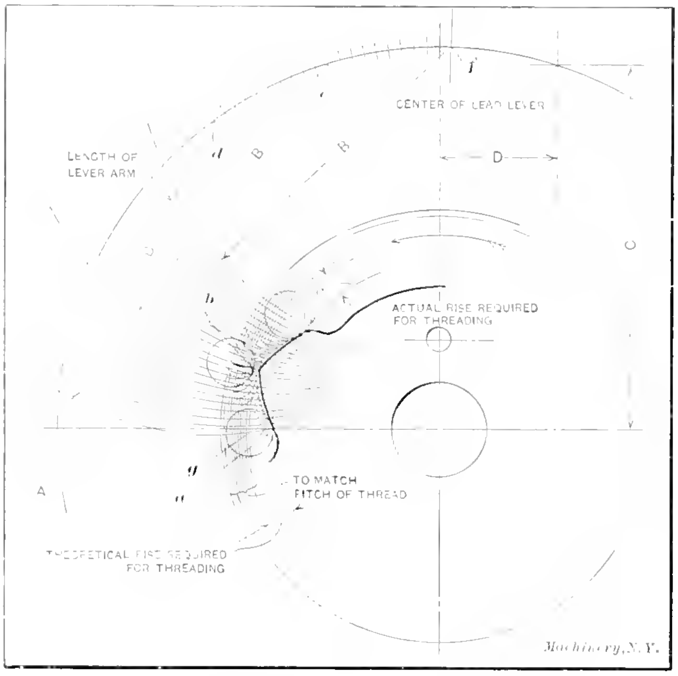

Fig. 7. Graphical Method of Constructing Thread Lobe

Before the thread lobe can be constructed, the length of the threaded portion, the pitch of the thread and the total number of revolutions of the spindle to complete one piece are required. When the number of revolutions for threading and the pitch of the thread are known, the rise on the cam can be found by the following formulas:

$$\begin{aligned}&\text{From 14 to 24 pitch, } r = R \times p \times 0.85,\\ &\text{From 28 to 48 pitch, } r = R \times p \times 0.88, \qquad (2)\\ &\text{From 56 to 80 pitch, } r = R \times p \times 0.90.\end{aligned}$$

Where R equals the revolutions required for threading, p equals pitch of thread, or $\dfrac{1}{\text{number of threads per inch}}$, r equals rise on cam.

In Tables II and III the results as obtained by formulas (1) and (2) for the various pitches are tabulated. To show the advantages of these tables, take a practical example. Assume that a set of cams is required for the No. 00 Brown & Sharpe automatic screw machine. To make the piece as shown at A, Fig. 8, let the spindle speed equal 2400 revolutions per minute, the number of revolutions to complete one piece, 400, time to make one piece, 10 seconds. Referring to A, Fig. 8, the length of the threaded portion is 3/8 inch and the pitch of the thread 1/32 inch, or thirty-two threads per inch. Referring to Table II, we find that the number of revolutions required is 15 and the rise on the cam 0.413. To construct the lobe, convert the revolutions into hundredths, or $\dfrac{15}{400} = 0.0375$ or $3\frac{3}{4}$ hundredths. Then draw the cam circle B, as shown in Fig. 8, and lay off on this circle $3\frac{3}{4}$ hundredths to advance on the screw and $3\frac{3}{4}$ hundredths to withdraw. Cut down the amount C below the outer cam circle B as required. Bisect the rise at E and with OE as a radius and a, b, and c as centers draw arcs intersecting each other at d and e. With d as a center and a radius OE, join the points b and a; with e as a center and radius OE join points c and a. This gives the shape of the thread lobe. For convenience in cutting, when a Brown & Sharpe circular milling attachment is available, the cam surface used by the tools is divided into minutes. Then to obtain the lead (or the number of minutes traversed for each 1/1000 inch rise) divide the number of minutes contained in that portion of the lobe used, by the rise. For example, $\dfrac{810}{0.413} = 1.96$, or approximately 2 minutes. The equivalents of hundredths and minutes are tabulated in Tables IV and V. The information as derived by the various formulas is recorded on the drawing as shown in Fig. 8, being used by the toolmaker when cutting the cam.

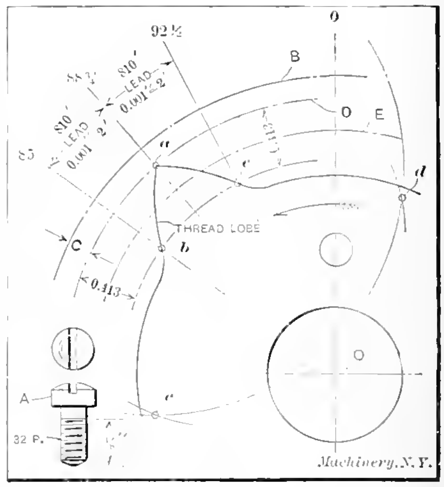

Fig. 8. Improved Method of Constructing Thread Lobe

Speed-changing Device

When threading brass, the spindle speed used for the other tools is generally suitable for taps and dies, but when threading gun-screw iron, Norway iron, machine steel, tool steel, etc., the speed used is too high. As has been previously explained under the heading "Reversing the Spindle," time would be lost in threading if the machine were reversed from forward to backward and then forward again (on the No. 00 Brown & Sharpe automatic screw machine). There are various methods of overcoming this difficulty, some of which are as follows:

One method of accomplishing this for the forming and cut-off operations is to run the spindle backward with the large

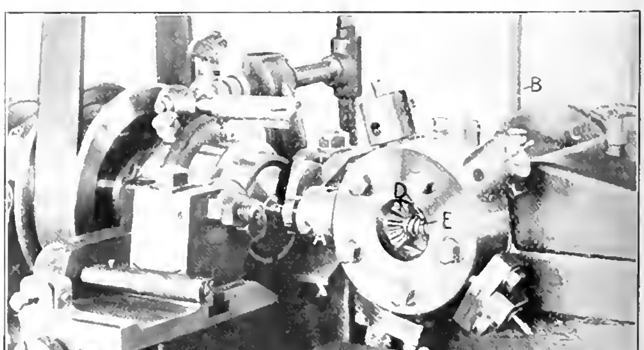

Fig. 9. Ratio Threading Attachment

pulley and forward with the small pulley on the countershaft. There is an objection to this, however, *viz.*, as there are generally other tools in the turret besides the die or tap holder, they would either have to be made to cut left-hand or else run at the same speed as the tap or die. It can easily be seen that in the majority of cases, the tools used in the turret would not be working at their maximum capacity if made to cut right-hand.

Ratio Threading Attachment

The attachment *A*, shown in position in the turret in Fig. 9, serves to revolve the die or tap in the same direction as that in which the spindle is rotating, but at one-half the spindle speed. As before mentioned, it is used where no other slow movements are required except for threading, enabling the spindle to run at its maximum speed for all the other operations. The attachment is driven by a 3/8-inch round belt from the overhead works, the shaft passing through the turret head connecting pulley *C* with bevel gears *D*, thus driving the attachment *A*. The spring *E* acts in the same manner as the spring in the ordinary draw-out die or tap holder. The method of determining the shape of the cam lobe when using this attachment is as follows: Let the spindle speed for the forming and cut-off operations equal 2400 revolutions per minute, then the speed of this attachment will be 600 revolutions per minute. Assume the length of the threaded portion to be 3/16 inch and the thread 40 pitch. Referring to Table II, we find that it will require 10.5 revolutions. But considering that the speed of this attachment is one-half

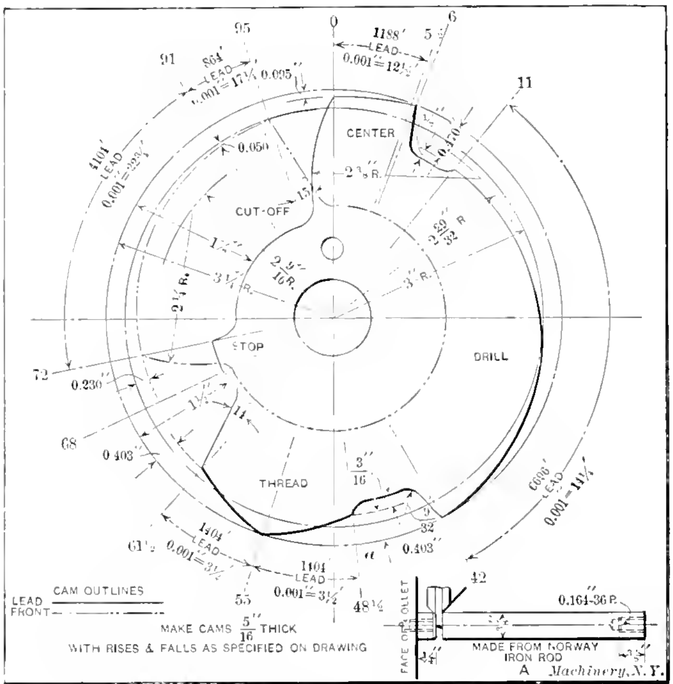

Fig. 10. Example of designing Thread Lobe when using Belt Shifting Attachment

the spindle speed, we would require $10.5 \times 2 = 21$ revolutions for cutting the thread. Again, as this attachment rotates in the same direction as the spindle, the speed of the attachment when backing off the work would be $2400 + 600$ or 3000 revolutions per minute. Then the number of revolutions required for backing off the work would be $\frac{2400}{3000} \times 10.5$, or 8.5 revolutions approximately. The same rise, 0.231, as given in Table II is used for each side of the thread lobe, but the number of hundredths contained in each part of the lobe is different, as it requires 21 revolutions to advance and only 8.5 revolutions to retreat.

Belt Shifting Attachment

The ratio threading attachment as shown in Fig. 9 is only suitable for cutting brass and fine threads on Norway iron, machine steel, etc. This attachment would not be entirely satisfactory for the No. 0 or No. 2 Brown & Sharpe automatic screw machine, as a more positive drive is generally required for these machines. In Fig. 2 is shown the No. 0 Brown & Sharpe automatic screw machine equipped with this speed-changing attachment. The countershaft is supplied with a large and a small pulley which will give the desired spindle speeds. This attachment is operated by the same dog and lever that reverses the spindle. When the dog on the cam shaft trips the lever, the clutches *C* and C_1 engage, thus driving gears *D* and *E*. The gear *E* being attached to shaft *F* revolves the disk *G* on which the eccentric connecting-rod *H* is attached. When the rod *H* is drawn up or down it shifts the belt from the large to the small pulley or *vice versa*. The system of gearing provided shifts the belt twice for every revolution of the driving shaft. Therefore, the number of revolutions required for changing the speed when the spindle is running at 1800 and 900 revolutions respectively would be as follows: When the spindle is running at 1800 revolutions per minute it would require $\frac{1800}{180 \times 2} = 5$ revolutions, but it is obvious that part of the time the spindle will be running at 900 revolutions per minute. Then the number of revolutions required to shift the belt when the spindle is running at 900 revolutions per minute $= \frac{900 \times 2}{180} = 10$ revolutions. Therefore, the actual number of revolutions required to shift the belt would be $\frac{10 + 5}{2} = 7\frac{1}{2}$ revolutions.

To explain thoroughly the method of designing the thread lobe, we will take a practical example. Assume that it is required to make the piece as shown at *A*, Fig. 10, the spindle speed being 1800 and 900 revolutions per minute respectively (using the 900 revolutions per minute for tapping). The cams for making this piece are shown in Fig. 10. The time required to make one piece being 17 seconds, or 510 revolutions, then the number of revolutions for threading found in Table II is 16.5; but as the tap will run at 900 revolutions per minute instead of 1800, we will require 16.5×2 or 33 revolutions for threading. Then the hundredths required equals $\frac{33}{510} = 0.0647$, or approximately $6\frac{1}{2}$, the rise on the cam being the same as that in Table II, 0.403. Referring to the table in the Brown & Sharpe book, we find that it will require 4/100 to feed the stock $+ 1 = 5/100$ to revolve the turret; this equals 25.5 revolutions to revolve the turret. Then the actual number of hundredths between the last operation and the starting of the thread lobe to revolve the turret and reverse the spindle is $25.5 + 7.5 = 33$ revolutions. Converting this into hundredths, we get 6.47 or approximately $6\frac{1}{2}$ hundredths. It is always good practice to allow plenty of clearance for threading, as the die or tap holder intended for the job may have to be replaced by one which would require more clearance.

* * *

In a note recently published in MACHINERY (see the January, 1909, and November, 1905, issues), attention was called to the limitations of sewing machine capacity. It was stated that the heating of the needle in thick goods prevents the needle exceeding a certain number of strokes per minute. On ordinary thin goods such as muslin the strength of the thread is the limitation of the capacity, however. If the cotton thread used on the average run of manufactured goods were of a higher tensile strength, the machines could be run faster. The Wilcox & Gibbs manufacturing machines are tested at about 3825 stitches per minute, and the common speed in use is somewhat less. The tests are made on a circular band of muslin which encircles the bench on which the machine is supported. The band of cloth is driven around and around over and under the bench at a speed amazing to one accustomed only to the work of the domestic sewing machine. If a stitch is 1/16 inch long the speed at 3825 stitches per minute is 239 inches per minute, or nearly 20 feet.

* * *

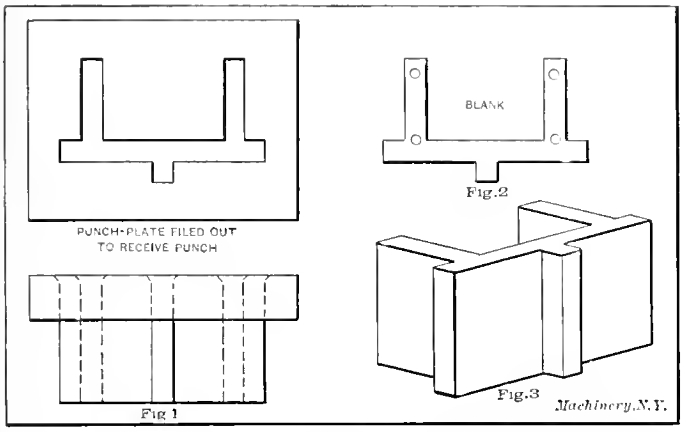
What is the limit of human endurance in handling parts? The answer depends on the shape, weight, and the distance that they have to be moved. Of a certain class of work, consisting of light objects, boys handle an average of one piece a second all day long, or 36,000 in ten hours. The object has to be picked up and mounted on a series of moving pins, the holes in the objects being comparatively small. Boys learn to do the work with ease and do not complain of weariness, but on the contrary seem light-hearted and cheerful. So expert do they become that the work is performed automatically—without thought—the operators being able to converse, laugh, joke and sing at their work. Curiously enough, if they stop to think what they are doing, they bungle and fall behind.

OUT-OF-DATE DIE-MAKING METHODS

By F. E. SHAILOR*

It seems as if die making has been known long enough for everyone engaged in sheet metal work to have found out the best methods and to use the best, instead of clinging to the original ideas such as filing out the punch holder to exactly fit the punch, making a large die (having many piercing dies in it) solid, and many other methods that have proved to be a source of trouble, extra expense for maintenance, etc. The following suggestions will be put in the form of comparisons and the reader can judge for himself which are the better:

First, let us take up various methods of forming the punch, and of securing it to the punch-plate. If we were to explore the junk boxes in the cellars of some of our best and oldest factories in which punches and dies are used, we would be very likely to find punches made as shown in Fig. 1, but long since discarded. Let us assume that we are about to make a punch and die to produce the blank shown in Fig. 2. The



Figs. 1, 2 and 3. Objectionable Method of Attaching Punch to Plate

method in vogue fifty years ago and still used by some large up-to-date (?) factories, is to machine the entire length of the punch as shown in Fig. 3. The punch-plate is then drilled and filed to fit the punch as tightly as possible and the back of the punch is upset as shown to prevent it from pulling out. Every die maker knows that it is "no cinch" to file out a die so that a templet fits absolutely even, though we have the advantage of the clearance in the die which makes it possible to enter the templet before the die is filed to size. This is not

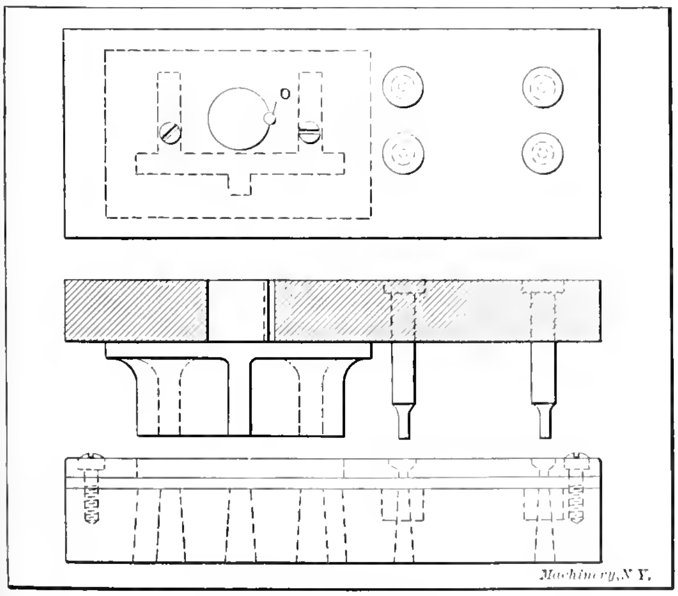


Fig. 4. Punch Attached to Die so as to obtain Greater Rigidity and Durability

the case, however, with the punch-plate shown in Fig. 1; this must be filed absolutely straight in order to secure a good fit.

The greatest objections to making a punch and punch-plate in this manner are the weakening of the punch and the difficulty experienced in making the fit good enough to rigidly hold the punch. We know that a plug and ring gage will "shake" if there is a difference of 0.0001 inch; can we expect to file perfectly straight and within one-tenth of a thousandth? After a greater length of time has been spent making the punch-plate than was necessary for making the die, we find we are obliged to peen the punch-plate in order to have it fit the

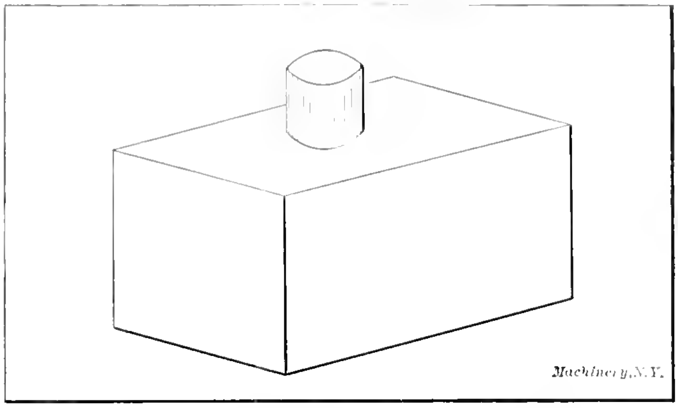

Fig. 5. First Step in Making Punch shown in Fig. 4

punch tightly. Then after the press operator makes one mis-cut, or a "half cut," the punch which is not sufficiently rigid, springs to one side, shears, loosens the peening effect, which causes the punch to "shake" in the punch-plate and this continues to cause trouble until the die is worn out.

Again, fitting the punch in the plate, necessitates fitting the entire length in the die, in order to allow the plate to come in contact with the die so that the holes for the piercing punches can be transferred from the die with some degree of accuracy. This latter method is a poor way to transfer, first because the piercing dies have clearance and the smallest diameter is in

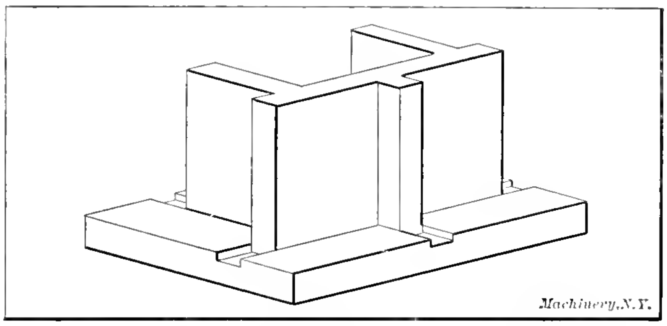

Fig. 6. Another Objectionable Method of attaching Punch to Plate

contact with the punch-plate so that whatever is used to transfer does not, of course, fit the dies. On the other hand, if the punch-plate is away from the die there are chances of error in transferring, one chance being in the truth of the parallels used and another and greater in the taper hole which is being used to guide a straight transfer point.

The style of dies referred to in the foregoing can be found in the cellar of the New Haven Clock Co. with forty years of rust thereon. Messrs. Thomas N. Gierding and T. Grady of the New Haven Clock Co. have done considerable toward bringing die making out of its infancy, as it were, for which they deserve due credit. The writer has seen in numerous shops types of dies and methods of making them that originated with these men.

An improved method of holding a punch is shown in Fig. 4. The way this punch and die is made will be described, so that the reader can judge which is the more practical, easier to make, and more durable. As there are piercing punches and dies, the punch-plate, stripper, and die would be doweled together, laid out, indicated, and the holes for the piercing punches drilled and bored, assuming, of course, that the die has been filed out for the blanking punch. The outline of the hole in the die for the blanking punch is then transferred to the punch-plate (a lead pencil is good enough for this purpose). A point approximately in the center of this outline is found, marked and indicated approximately true, drilled and bored, and at the same setting a light cut is taken to insure a perfect seat for the punch. The latter is turned up as shown

* Address: 796 Lincoln Ave., Detroit, Mich

in Fig. 5. The piercing punches are left 1/16 inch longer than the blanking punch so that the outline of the die may be accurately transferred to the punch. A dowel pin hole *D* is drilled and reamed in the shank and plate so that it will be possible to place the punch back in the same position after removing it. After the punch is milled to the scribed outline, the edge is slightly beveled. The punch is then returned to its seat in the plate and the piercing punches are entered and used as a guide to shear the blanking punch. It will be seen that the lead pencil was good enough for transferring the outline as the punch is guided entirely by the piercing punches when being sheared. Compare the simple and efficient method

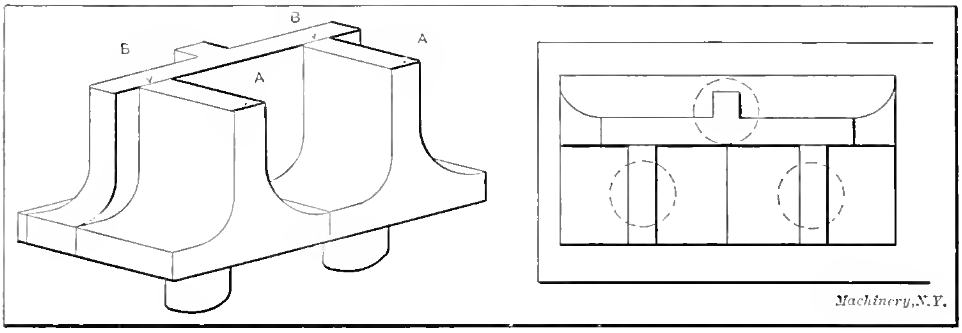

Fig. 7. Sectional Punch for Producing the Blank shown in Fig. 2

of securing the punch to the plate illustrated in Fig. 4 with that shown in Fig. 1; note in the former the rigidity of the punch, the absence of the possibility of springing on a "half cut," the strength of the punch-plate, and the reduced chances of the punch springing out of shape when being hardened. The method illustrated in Fig. 4 is the best that has come under the writer's experience of sixteen years for easily making a rigid, altogether satisfactory punch and die. If any reader knows of a better method we would all like to know of it, and I, for one, will adopt it.

Fig. 6 shows another method of making punches and securing them to the holder, which has several bad features: First, there is not sufficient seat. Imagine a punch one inch long by one-half inch wide, made in this way. A movement of 0.001 inch at the seat means enough at the cutting edge to cause it to shear. Then after the punch is hardened, will it fit the recess planed for it? Not much! But if it had a wide seat or flange, even though it was merely set on the plate, it would be far better as the flange helps wonderfully towards holding the punch in shape when hardening. A good way to make the punch shown in Fig. 1 is to make it in parts, as in Fig. 7. If the punches spring open or together, we have a means of bringing the ends back by rotating them about the shank. In this way quite a movement can take place at points *A* and what little the punch opens at *B* will not materially affect the cutting action.

Oftentimes the die to be made is, say, eight inches long and

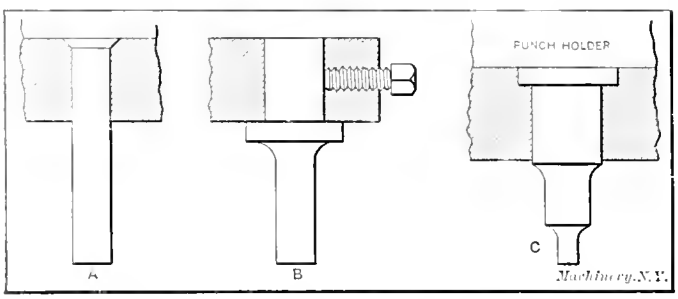

Fig. 8. Three Ways of Securing Piercing Punches

contains several piercing dies besides the blanking die. The writer has made such dies solid, but finds it better practice to make the die in halves, the blanking die being made of tool steel and the part containing the piercing dies of machine steel with tool steel bushings. It is much easier to harden a small die without perceptibly changing its shape than it is one eight inches long; besides, if the piercing dies demand accuracy between the centers, it is necessary to grind the holes after hardening, with a solid die, whereas with one having a soft machine steel block, changes in the center distances of the holes are eliminated. Another good feature of the sectional die is that if some change is made after the die is complete, whereby a smaller or larger hole is needed, a new bushing can easily be inserted; but not so if the die is solid and of tool steel, hardened. This same scheme can be employed on the punch-plate. [A die built on the plan referred to in the foregoing, is shown in Fig. 10. As the illustration shows, the piercing dies are independent of the blanking die, being in the form of bushings. This engraving was taken from one of the advertisements of the Firth-Sterling Steel Co.—Editor.]

The writer has found it good practice always to bore the punch-plate, stripper, and die together, when possible to do so. Some die makers insert the blanking punch as far as possible in the die, put parallels between the plate and die, and then, with a twist drill, "soak" the holes into the plate from the die. After the piercing punches are in the plate, they are knocked this way and that to line them up; but suppose those piercing punches were 1 inch in diameter or even ⅝ inch; such sizes are not knocked around so easily and this is a poor job at best. Peening is resorted to on punches that do not move easily; that is, the stock near the punches is indented with a blunt cold chisel, sufficiently to cause it to "flow" and force the punch over. But only a very few strokes in the press are

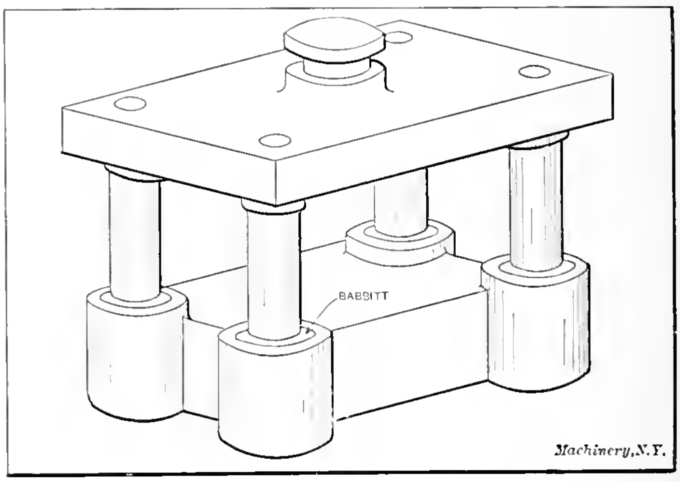

Fig. 9. Die with Guide Posts inserted in Babbitt Bearings

necessary to cause the stock to flow back again, and then there is a sheared punch, and a burr on the work. The die is then taken out and the stock peened again just to make the punch line up until it is off the maker's hands. A few dollars extra, expended in properly making the die, is a mighty good investment. The first cost of a die may be low, but it does not necessarily mean that it is a cheap die; it is a mighty expensive one in the long run, and a toolmaker that will knock punches, peen the punch-plate, or other "after-me-the-deluge" methods, ought not to be classed as a toolmaker—he's a "butcher" and should be treated as such.

The method of securing piercing punches varies in different shops. Some make a straight punch as at *A*, Fig. 8, and hold it in the plate by riveting; others make it as at *B* and secure it to the plate by means of a set-screw on the side; but the ideal method is shown at *C*. This punch has an excellent seat, it is easy to make, cannot be pulled out and is reinforced to eliminate all spring as far as possible. If this is the ideal method of making piercing punches, why is it that supposedly modern shops cling to set-screws that tend to displace the punch, to riveting the head, and to making punches the same size the entire length—the weakest construction of all.

When making dies having guide posts, as in Fig. 9, which shows a sort of sub-press construction, it is almost universally customary to bore the holes to fit the guide-pins. It is a long,

expensive, and difficult job to bore four one-inch holes in the top plate and four one-inch holes in the bottom plate and have the four pins line up with and travel freely in the holes. I have found it good practice to bore the holes in the plate to hold the pins, but the holes in which the pins are to travel can be drilled say 1/4 inch large and anywhere within 1/16-inch of the correct location. The punch is then entered into the die (the pins being first treated to a light coating of graphite and oil) and the holes are babbitted. This method insures absolute alignment, the work is easily done and no great attention need be paid to center distances or to the diameter of the holes. When bored holes are employed, it means absolute accuracy between the centers of the top and bottom plate; it means that the holes must be bored to fit exactly the pins which travel in them, as otherwise the die will shear; it means a lot of unnecessary work on the part of a skilled mechanic, because four one-inch pins will not spring here and there just to be accommodating, and, besides, the fit obtained by boring must of necessity be a trifle free in order to work easily when shearing the punches. With babbitted holes, however, the fit is excellent but it is not made until after the punch and die are entered, and the press can take care of a tight fit or, rather, perfect alignment.

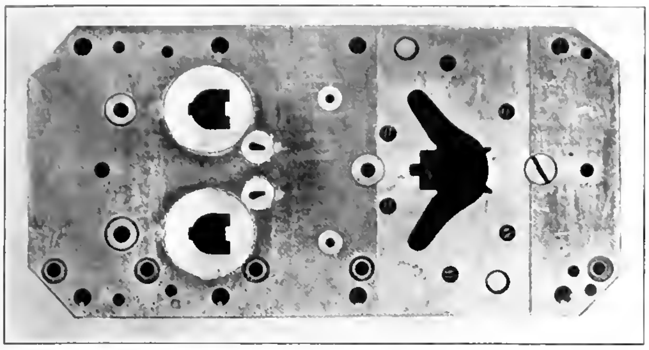

Fig. 10. Die Construction in which Piercing Dies are in the Form of Bushings and Independent of the Blanking Die—Taken from one of the Advertisements of the Firth-Sterling Steel Co

"DON'TS" FOR PLANER MEN

By DONALD A. HAMPSON

Don't cut into parallels.

Don't run a planer with a loose rack.

Don't put greasy fingers on finished work.

Don't brush dirt off the table into the ways.

Don't forget that a little grease is good for gears.

Don't let chips accumulate around the bull wheel.

Don't use a finger-clamp when a U-clamp can be applied.

Don't finish a piece of cast iron with anything but a broad flat tool.

Don't try to cut a keyway in a shaft without some positive stop for it.

Don't stick wrenches, tools, or hammers in the post holes in the table.

Don't try to true up the top of a badly worn planer table with just one cut.

Don't tighten on a clamp unless the bolt enters the nut for its full thickness.

Don't forget to bevel slightly both ends of a casting before taking a finish cut.

Don't leave a rough surface when that surface has to be used later to line up by.

Don't "clear a space" to put on a new job; a live man never has a littered-up planer.

Don't consider a job of angular cutting completed until you have set the head back to "zero."

Don't forget that an occasional drop of oil on bolts and nuts prolongs their life considerably.

Don't take a long "wind chip" because you are too lazy to set the dogs up for the short cuts at each end.

Don't forget that a spring tool, or a modified form of one, is best to finish a cast iron surface accurately.

Don't clean out T-slots without first running the table out so that no chips can fall into the oil drip cups.

* Address: 31 Hanford St., Middletown, N. Y.

Don't put a clamp on a piece of finished work without a piece of heavy paper between the clamp and work.

Don't tighten a chuck so that a light piece is distorted and expect the planed surface to be true when taken out.

Don't set a tool to a height gage for any but the very lightest cuts, without allowing for the spring of the tool.

Don't neglect a belt that shows signs of coming apart; if you do you may get an ugly cut from it when it gives way.

Don't do all or half of your short work in the middle of the planer; let the wear be distributed to the ends as well.

Don't fail to look under the cross-rail and saddle for drops of oil and to wipe them off before finishing a cast iron surface.

Don't trust to the base and jaws of a chuck to make your work parallel and square unless you *know* that the chuck is right.

Don't throw away good wooden wedges and blocks; you can never tell how soon the same job will come up again and you may need them.

Don't do any unnecessary hammering on the planer; if clearances have to be cut, do that before placing the work on the machine.

Don't use any but a solid wrench, and one that fits, to set dogs; an adjustable one makes rounded nuts and may prove dangerous as well.

Don't work one head on a job simply because "it wouldn't pay to set the other head for just one piece"; do a little hustling and make it pay.

Don't fail to put bolts as near the work as possible, and in any case give yourself the benefit of 2 to 1 leverage when setting bolts, clamps and packing.

Don't stop the table by half shifting the belts without locking the shifting mechanism; many a man has been maimed by neglecting to do this.

Don't think that the elevating screws and their bearings never need oil; the top of the arch is too often thick with dust and the bearings completely dry.

Don't let the rear oil pockets fill up with chips, blocks and tools; the chips jar out on the ways and the tools may fall inside and "short circuit" the stroke.

Don't fail to try the ways of a planer at least once a year; no matter how carefully the machine may have been set, settling of the floor or foundation may have occurred.

Don't start a side cut downward without first making sure that all interferences in the way of work or bolts are below the plane of the head at the bottom of the cut.

Don't lubricate the cross-rail of your machine with a squirt can; saturate a piece of clean waste and oil with this; a film of oil on the sides is better than many drops on the table or work.

Don't pass a job lined up with the cross-rail as being square without proving it, unless the cross-rail and housings have been tested and found correct, within a reasonable length of time.

Don't be too particular about packing up a rough job, but remember that on a "perfect" one the minutes spent in shimming up and papering will save the hours that would have to be spent in fitting or recutting.

Don't forget that a box containing short lengths of drawn steel makes a valuable and handy set of gages for the planer; have, if possible, all sizes, by sixteenths, up to one inch, and larger sizes varying by one inch.

Don't forget that a man with an indicator can line up a job absolutely correctly, quicker than with a paper feeler; with the indicator there is the satisfaction of knowing at all times just how accurately the work is set.

Don't loosen bolts preparatory to raising or lowering the cross-rail before you have carefully wiped or scraped off all dirt on the face of the housings; the machine is often blamed for inaccuracies resulting from dirt behind the rail.

Don't forget that two straps and eight posts—two on each side—will allow you to take as big a cut on a heavy casting without its shifting as ten straps and no posts; the posts can also be set up quicker and their use gives more working surface on the top.

MAKING THE DeVILBISS PLIERS—2

By ETHAN VIALL*

The Cam Operations

The process through which the cams of the DeVilbiss pliers go, from the cold rolled steel strips to the finished article, is comparatively simple, the steps being:

1. Blanking.
2. Flattening.
3. Trimming.
4. Drilling and reaming.
5. Burring on the disk wheel.
6. Tumbling.
7. Assembling.

The first four steps are illustrated at *A*, *B*, *C* and *D*, Fig.

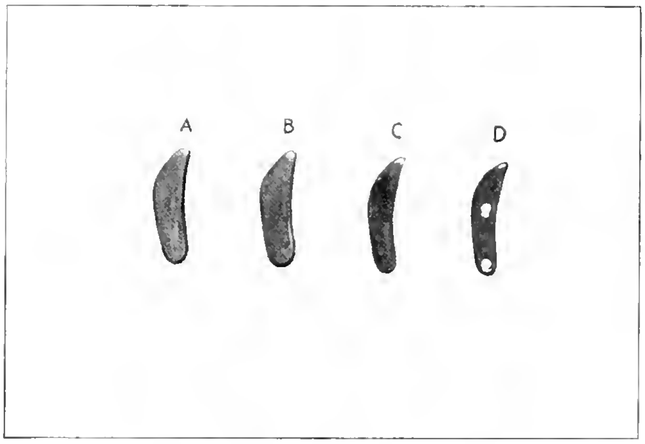

Fig. 24. The First Four Steps in the Making of a Plier Cam

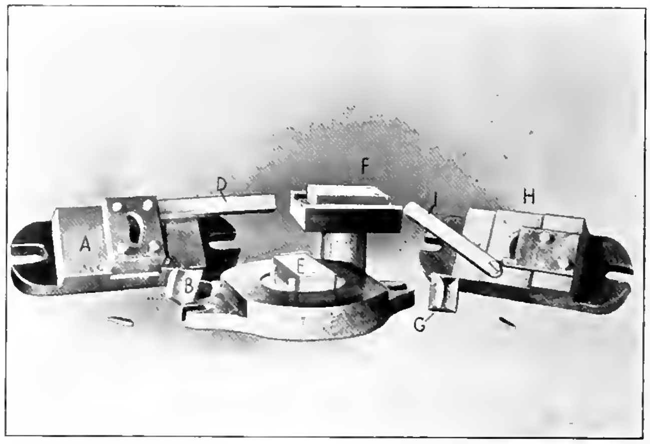

Fig. 25. The Blanking, Flattening and Trimming Dies

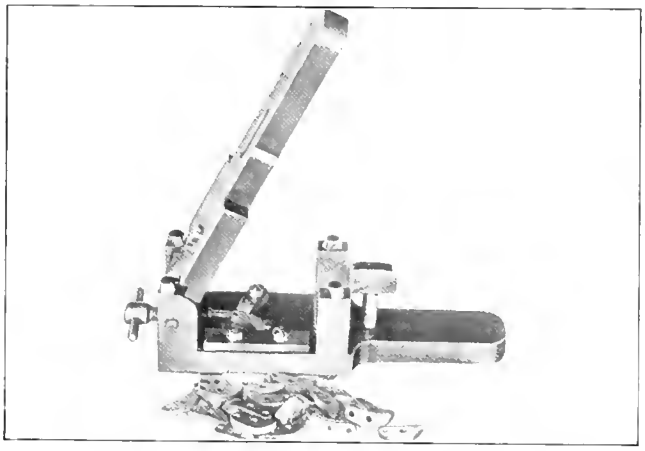

Fig. 26. Cam Drilling and Reaming Jig (Open)

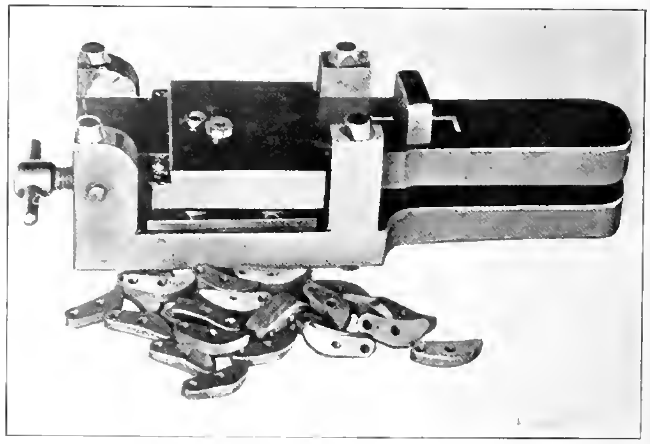

Fig. 27. Cam Jig Closed, Ready for Drilling

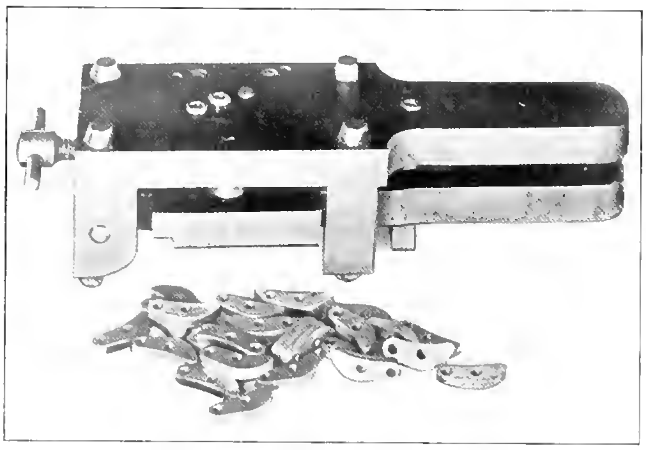

Fig. 28. Cam Jig Reversed, Ready for Reaming

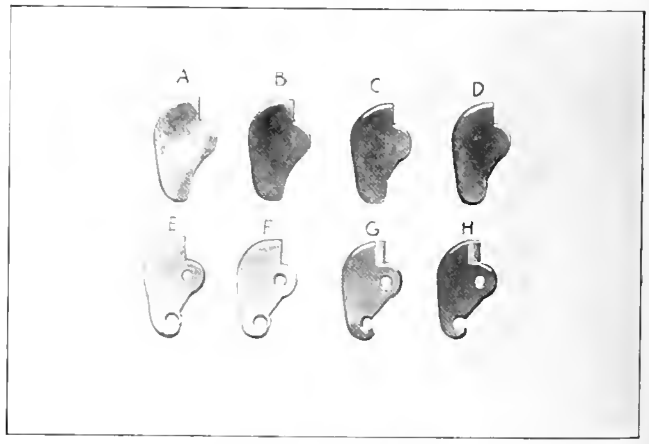

Fig. 29. Eight Steps in Making a Moving Cutter Blade

24, while at *A*, Fig. 25 is shown the blanking die, and at *B* the blanking punch; *D* is the stock guide, and a simple pin acts as a spacing stop. *E* and *F* are the flattening punch and die and *G* and *H* the trimming punch and die. In using the trimming die, the punch is not, of course, set to enter the die on the stroke, but is set about the thickness of thin paper above it, so that one blank pushes the previous one through, and in this way the keen edge of the die is preserved much longer. The lever *I* on die *H*, is used to press the cam blank firmly against the stops; the pin on the lever really forming one side of a triangle of stops.

Combination Drilling and Reaming Jigs

The practice of drilling and reaming flat pieces in the same jig, is not uncommon, yet the methods differ considerably and as there is no simpler method than the one here shown, the jigs will be described in detail. Fig. 26 shows one of these combination jigs open with the drilled cam in position. It will be noted that the cam is located in the jig by stops in contact with the point and rolling side, and that the clamping-screw point comes in contact with the rounded end in such a way as to wedge the cam in firmly. The hinged cover also has a pin in it that presses the cam down firmly onto the lower plate as the locking thumb-screw is turned. The thumb-screw just mentioned has the head slightly beveled on the underside and this together with the threaded end that screws into the lower plate, takes care of any possible difference in the thickness of the cams and produces a firm contact. An objection might be raised here, that this would throw the drilling bushings out of line, but the cams are flattened to such uniform thickness that the error is too

* Associate Editor of MACHINERY.

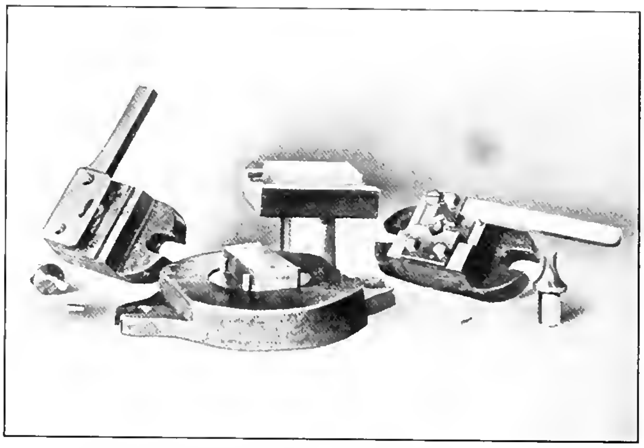

Fig. 39. Link Blanking, Flattening and Trimming Dies

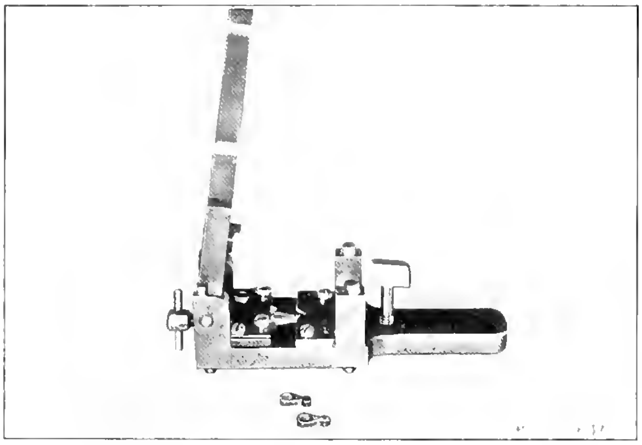

Fig 40. Link Drilling and Reaming Jig

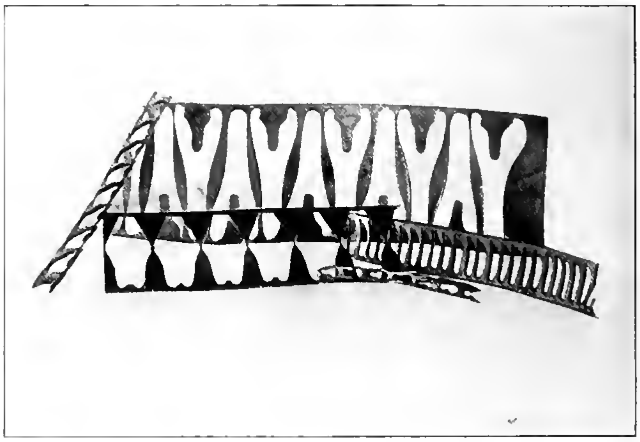

Fig. 41. Samples of Punched Scrap

slight to be reckoned with; indeed considerable variation can be allowed without causing any serious trouble. Fig. 27 shows the jig closed ready for drilling, and Fig. 28 shows it turned over ready for reaming. It will be seen that in the reaming operation, the jig rests solidly on its legs; there is no tendency for the bushings to be sprung out of line and the pin in the cover which holds the cam in place, allows enough space between the cam and the cover for end clearance as the reamers feed through.

After drilling and reaming, the cams have the burrs ground off by holding them on a disk grinder; they are then tumbled and sent to the assemblers.

Shop Operations on Moving Cutter Blades

The shop operations on moving cutter blades are as follows:

1. Blanking.
2. Flattening.
3. Trimming.
4. Shaving.
5. Drilling and reaming.
6. Burring on disk wheel.
7. Cutting edges milled.
8. Link hole slotted out.
9. Hardening in oil.
10. Tempering in oil.
11. Grinding cutting edges.
12. Grinding and polishing edges.
13. Polishing sides.
14. Assembling.

Fig. 29 represents these operations on each piece, as follows: *A*, blanked; *B*, flattened; *C*, trimmed; *D*, shaved; *E*, drilled and reamed; *F*, cutting edges milled; *G*, link hole slotted, and *H*, hardened and tempered.

Both the moving and fixed cutter blades are made of tool steel 15/64 inch thick, and after being blanked in the die *A*, Fig. 30, the moving jaws are flattened from 15/64 to 0.223 inch, which takes out the unevenness around the edges ready

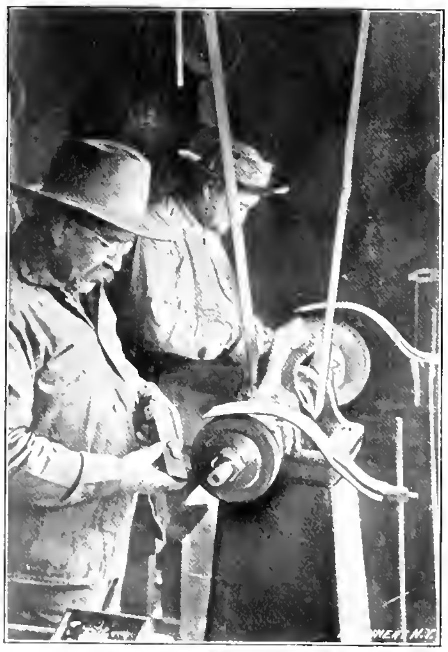

Fig. 42. Polishing the Sides of the Cutter Blades

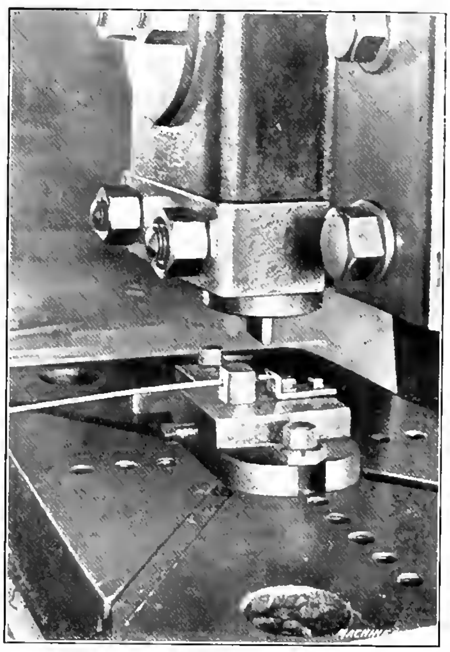

Fig 43. The Way Rivets are sheared in the Punch-press

Fig 44. Assembling the Cams and Jaws and Setting the Rivets

for trimming and obviates rough polishing, with a considerable saving. Next the flattened blanks are trimmed and then shaved to exact size in dies *A* and *B*, Fig. 31, respectively. As these dies are similar to those already shown, they will not be described. After the shaving operation, the blanks are drilled and reamed in the combination jig *A*, Fig. 32,

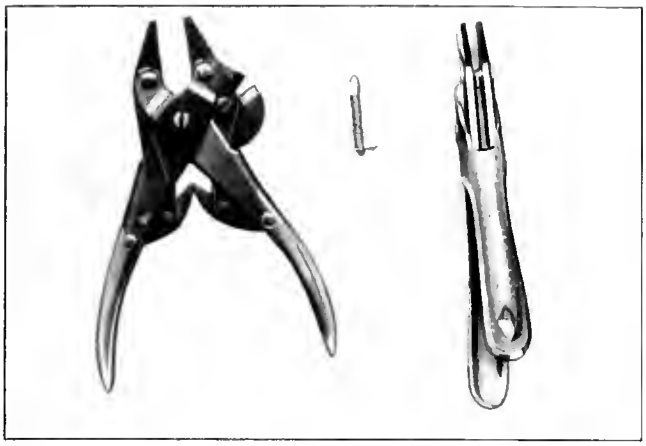

Fig. 45. View showing Position of Spring in a Spring Plier

which shows the retaining pin in the cover plainer than in the previously illustrated jigs for cams. Now the burrs are taken off on a disk wheel and then the blades are put in the milling machine vise jig *B*, and the cutting edges milled. In using this jig, four blanks are put in it, and with the clamping blocks *C* and *D* in place, it is put in the vise

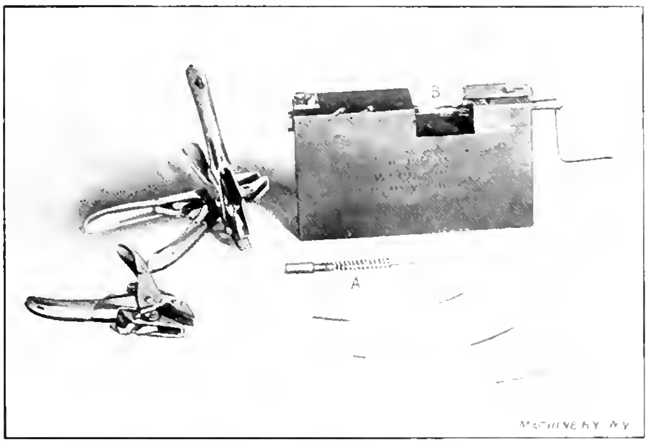

Fig. 46. Device for Winding Springs

and the vise tightened; then, using a small side cutting mill, one cut is taken which finishes the bevel for the cutting edge on one side of each blank, and then the blanks are switched in pairs and the final cut taken.

The link hole is slotted out, while the blank is held in the vise jig *E*, with an ordinary ½-inch milling cutter, the shape

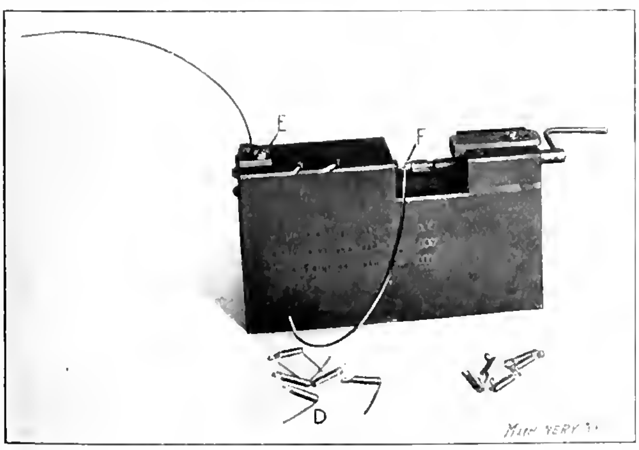

Fig. 47. Method of Starting a Spring

of the slot wanted and the position in which the blank is held making this possible. When the blades have been hardened and tempered, the cutting edges are ground by hand on a thin emery wheel, using the little slotted V fixture, Fig. 33, for a guide. The edges are next ground and polished and then the sides are polished as in Fig. 12, after which they are ready for assembling.

Cutter Blades (Fixed)

The fixed cutter blades differ not only in shape but also in many of the operations which are:

1. Blanking.
2. Flattening to size.
3. Trimming.
4. Drilling and reaming.
5. Reaming out circle for inset of moving jaw.
6. Burring on disk wheel.
7. Cutting edges milled.
8. Drilled hole slotted out.
9. Hardening.
10. Tempering.
11. Grinding and polishing.
12. Assembling.

A, Fig. 34, is the blank; *B*, the flattened blank; *C*, trimmed; *D*, drilled and reamed; *E*, inset reamed; *F*, cutting edge milled; *G*, slotted, and *H*, hardened and tempered. In Fig. 35 *A* is the blanking die, *B* the flattening die, and *C* the trimming die. It will be noted that this blade is only trimmed once and not shaved, which is all that is necessary,

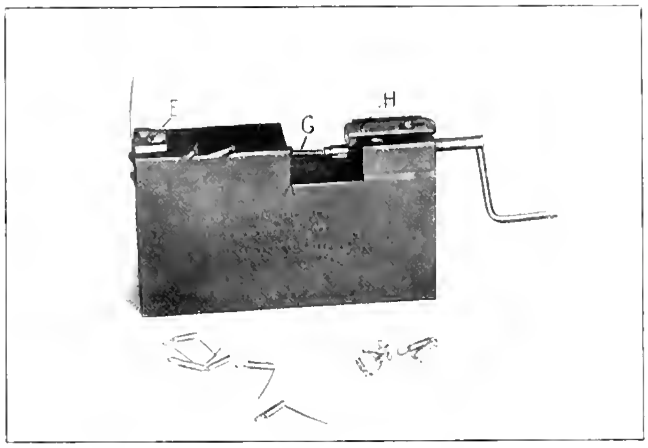

Fig. 48. View showing Device with Wound Spring in Place

as the parts that have any important bearing surface are reamed.

After drilling and reaming in the jig *A*, Fig. 36, the blades are put in the jig *B*, two at a time as shown, and the circle for the inset of the moving jaw is reamed out with the rose reamer *D*. The two jigs in this halftone are shown closed in Fig. 37.

The fixed blades are now burred on a disk wheel, the cut-

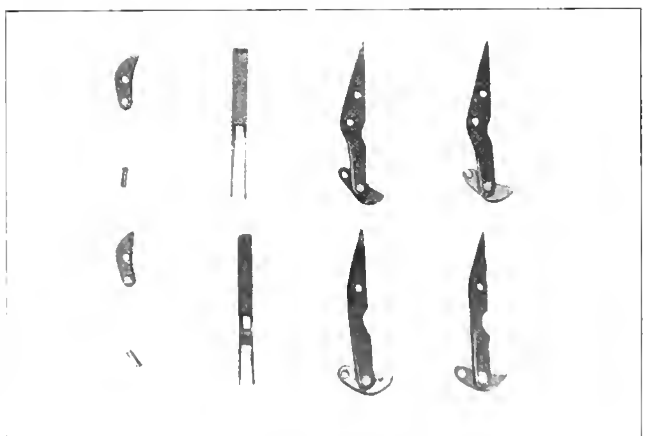

Fig. 49. Cams Assembled in the Jaws

ting edges milled as shown for the moving blades and the drilled hole slotted out as illustrated in the parts *G* and *H*, Fig. 34, by holding them in the vise and using a suitable mill. These blades are slotted out in this manner so that they can be removed from the pliers when dull or damaged, without removing the rivet or using a screw in place of the rivet, which would be unsatisfactory for a number of reasons. The blades are next hardened, tempered, ground, polished and assembled.

Links

The operations on the links in the order in which they follow are:

1. Blanking.
2. Flattening.
3. Trimming.
4. Drilling and reaming.
5. Carbonizing.
6. Burring.
7. Drawing to a blue color.
8. Assembling.

The seven shop steps are shown in Fig. 38 and the tools used are shown in Figs. 39 and 40. After carbonizing, the burring operation serves to rough polish the parts sufficiently to show the blue color in the drawing.

Fig. 41 shows some of the scrap from which the various blanks were punched, which will show the way the metal was economized. The harder metal requires more waste space between the blanks than the soft and in the case of the handles, the strip is run through one way and then reversed in order to save metal, without using a double punch and die.

Screws, Rivets and Springs

The screws used in the center of the pliers to hold the moving cutter blades, are not made in the shop but are purchased from a specialty firm, though the hardening is done

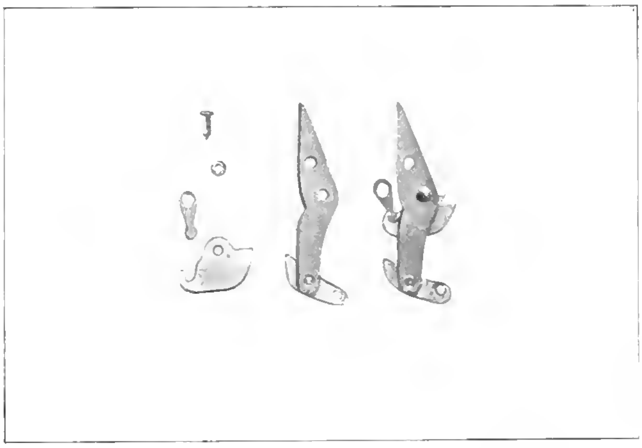

Fig. 50. Cutting Jaw with Cam, Blade and Link in Place

in the shop. The screws for the cutter blades are carbonized all through and then drawn just enough to prevent brittleness. An ordinary unhardened screw used in this place would be of no use whatever, as it would shear or wear out in no time.

The regular rivets used are cut from rods as shown in Fig. 43, though the rivets used in the spring pliers, have a groove

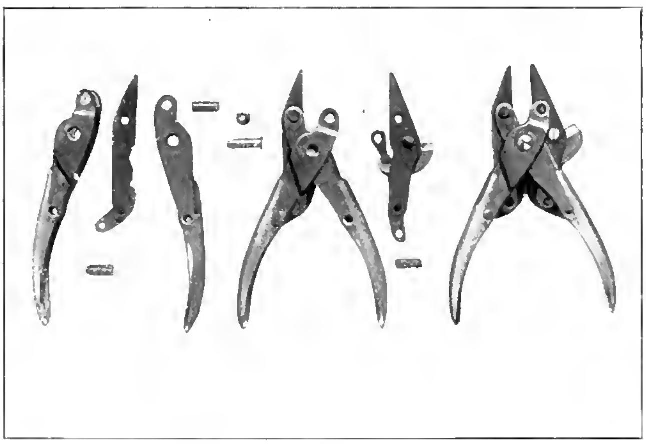

Fig. 51. Steps in the Assembling of Cutting Pliers

in the middle and so have to be cut off in a screw machine. The position of the rivet and spring is shown in Fig. 45.

Winding the Springs

A unique little spring winding device designed by Mr. DeVilbiss, by which a boy may easily wind accurate springs, is shown in Figs. 46, 47 and 48. Three different sizes of springs are wound with the device, a different sized winding mandrel being inserted for each size. One of the winding mandrels with its returning spring is shown at *A*, Fig. 46, and the projecting point of another, inserted and ready for use, is shown at *B*, while at *C* is a guide pin for the wire. A loop is first bent on the spring wire, like that shown on the springs in group *D*, Fig. 47, by bending in the little jig *E*. This loop is then inserted in the slotted end of the winding crank, as at *F*, which is pushed in far enough for the end of the winding mandrel to enter. The crank is now turned, winding the spring as shown at *G*, Fig. 48, the mandrel being drawn out by the tension of the spring coils as it is wound; but the instant the tension is released on the coils of the spring just wound, the mandrel flies back into its socket out of the way, allowing

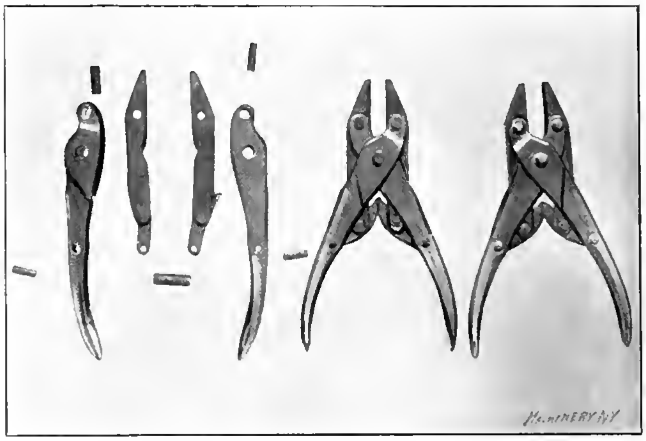

Fig. 52. Steps in the Assembling of Plain Pliers

the spring to drop down. The length to wind the various springs is gaged by the piece *H*, which points to a mark on the crank. The little loop on the opposite end of the spring is easily made by winding around a pin, when the small amount of superfluous wire is snipped off with a regular cutting plier the cutting blades of which have been left a little

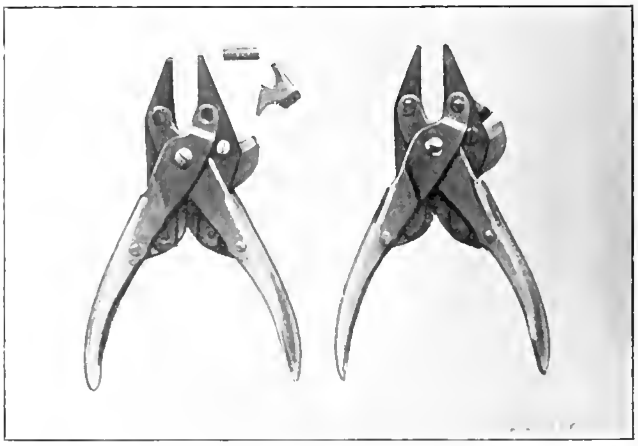

Fig. 53. The Fixed Blade before and after being placed in Position

harder than usual, which is necessary on account of the hardness of the wire used.

Assembling

The order in which the various parts of the pliers are assembled and made ready for shipping is as follows:

1. Putting cams in jaws.
2. Inserting moving cutter blade and putting in screw.
3. Putting in link.
4. Assembling complete, except fixed jaw and its rivet.
5. Fitting fixed jaw.
6. Spinning both ends of all rivets.
7. Inspecting, loosening, and testing cutters.
8. Burring center screw.
9. Polishing ends of jaws, screws and rivets.
10. Plating.
11. Buffing.
12. Washing.
13. Tumbling.
14. Inserting springs in the spring pliers.
15. Wrapping and packing.

Fig. 49 shows cams, jaws and rivets, separate and assembled, for both plain and cutting jaws, the parts being put together by a boy as in Fig. 44. The moving cutter blade and link are next put together as shown in Fig. 50, and then the cutting plier is assembled complete, as shown in Fig. 51, all except the fixed blade.

The plain plier having no cutter blades to fit, is assembled and the rivets spun down as illustrated in Fig. 52, but on the cutting pliers the fixed blade must be fitted as in Fig. 53, and the cutting edge brought perfectly in line with that of the moving jaw, which is done by inserting a pin in the hole in place of a rivet and then touching up the edge of the blade

on the little disk wheel, Fig. 54, which has one safe side. After the blades have been satisfactorily fitted and lined up, the rivets are spun down with a Grant rivet spinning machine Fig. 55, the plier as it looks before and after spinning being

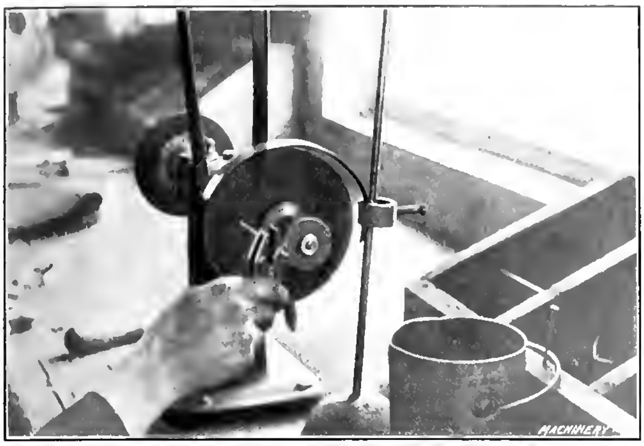

Fig 54. Lining up and Sharpening the Cutting Edges

shown in Fig. 56. Fig. 57 shows a group of assemblers at work. The inspecting consists of seeing that the plier looks and works perfectly and cuts properly.

Burring or slightly riveting the center screw, is done to prevent the nut from working loose, and after the ends of the jaws, screws, and rivets are polished, the pliers are plated for one-half hour open and one-half hour closed, in the plating room, one corner of which is shown in Fig. 58. When the pliers have been buffed they are washed in a mixture of kerosene and paraffine oil to cut and remove the polishing compound, and they are then tumbled in sawdust. In packing, the pliers are wrapped in a special rust-proof paper and placed six in a box ready for shipping.

Fig 55. Spinning down the Rivets on a Grant Rivet Spinning Machine

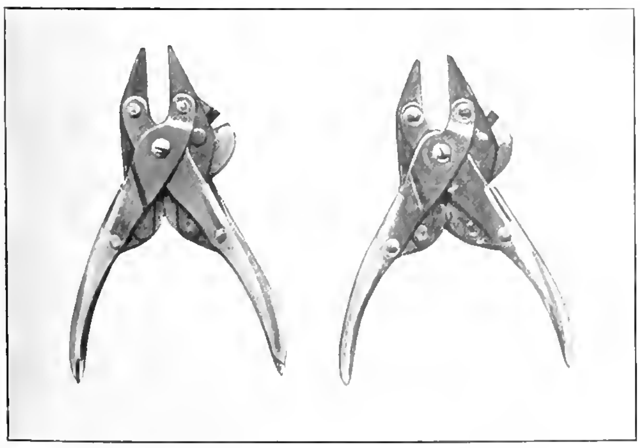

Fig. 56. Cutting Pliers with Rivets before and after being spun

In the general shop practice, high speed drills, reamers and tools of all kinds are used, and in the plier itself there are a few good points that it may be well to bring out, one of which is the making of the jaws of pressed steel instead of solid metal, which allows the cutters to be set in the middle where they belong, and it also allows the use of a high grade of tool steel for the cutters and a steel that can be carbonized, for the jaws, thus giving hard, but not brittle, serrations and edges.

* * *

THE CRACKING OF ALUMINUM CASTINGS

A few valuable hints regarding the prevention of the cracking of aluminum castings are given in *Castings*. To secure best results only new metal should be used. The aluminum should be melted rapidly, but the heat of the furnace should be kept low as compared with the heat of a brass-melting furnace. Just as soon as the metal is thoroughly melted, the crucible must be pulled, stirred, skimmed and the metal poured. If the metal is overheated or is allowed to soak in the furnace it will absorb gases which will fill the casting with pin holes. New graphite crucibles ought to be used, or such as have been used only for aluminum. When the crucible is pulled from the furnace, a small lump of sal-ammoniac or of chloride of zinc should be thrown on the surface of the metal before stirring and skimming. The pouring, at as low a heat as possible, should be rapid and through large gates, because aluminum chills with exceeding rapidity. The cores for aluminum castings should be either of green sand or, if made up with a binder they should be thoroughly baked and as soft as possible. Aluminum shrinks a great deal when cooling, and if it cannot compress the cores internal cracks are likely to result.

Fig. 57. Group of Assemblers at Work

* * *

The Verein Deutscher Eisenbahnverwaltungen (Association of German Railway Administration) has offered a total of 30,000 marks ($7,500) in prizes for inventions and improvements of special importance in railway traffic as well as for writings of exceptional merit relating to railway matters. The inventions and improvements must have been carried out practically and the written works to be considered must have been published between July, 1905, and July, 1911. The amounts of the individual prizes vary from $400 to nearly $2,000

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on.

JUNE, 1910

PAID CIRCULATION FOR MAY, 1910, 26,349 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 700 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 300 pages a year of additional matter, and forty-eight 6 x 9 Data Sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. The Railway Edition, $2.00 a year, is a special edition including a variety of matter for railway shop work—same size as Engineering and same number of Data Sheets.

THE PISTON RING PROBLEM

Notwithstanding our conceded ability to solve problems in the manufacture of machinery, there seems to be no generally-known, first-class method of cheaply making piston rings for gas engines. By that we mean a method that can be depended on to turn out truly circular, well-finished, even tension rings at low cost.

The commercial methods in vogue are inaccurate, costly and unsatisfactory in result. The makers are not able to control all the factors entering the problem, and must follow more or less happy-go-lucky processes quite repugnant to the ideals of mechanics accustomed to precise methods of production. A practice that will turn out perfect rings, interchangeable and of uniform tension, is yet to be described.

* * *

FACE GRINDING

The grinding machine using a cup wheel is a machine tool of great present performance and of even greater possibilities. Already it has shown such marked superiority on certain classes of machine work that the milling machine is being discarded in its favor. It has some of the advantages over the axial grinding wheel that the face milling cutter has over the axial milling cutter. The power consumption is less and plane surfaces are produced with fewer passes of the wheel. There is also the advantage that the mean radius of the face grinding wheel remains unchanged until worn out. The economy of wheel material is high, inasmuch as a comparatively small part is wasted when the wheel is worn out, and moreover the cup wheel can be reinforced so that it is practically proof against bursting. For such work as machining the ends of machine legs, columns, joining the boxes of grinder frames and similar parts, the face grinder having a horizontal spindle with power-actuated table is unexcelled. The work is done quickly and with almost any required accuracy. If it should be of a comparatively rough nature, the grinder can be forced and the number of passes cut down to suit the most economical-minded manager. On the other hand, the finest class of work is performed with precision obtained only at much greater expense on the milling machine.

MAKING MACHINE PARTS WITHOUT WASTE

Mechanical progress is generally in the direction of saving labor, time and material, and improving the quality of finish and the durability of the product. Sometimes practice apparently moves backward as regards one factor, in order to gain greater advantage in another; and it is often hard to determine whether or not a new process has advantages in general. This is not the case with the process for making machine screws without waste, briefly described in the April number. The speed of production is unparalleled, the physical characteristics of the product are improved, practically no oil is used, there are no cutting tools to grind and set, except a cutting-off shear, and there is absolutely no waste of material. There is, however, a lack of desirable finish, which defect doubtless will be corrected when commercial machines are perfected. While now limited to small machine screws, the process will soon be applied to the manufacture of all ordinary commercial sizes of machine screws and wood screws. The possible saving of material and oil on all the machine and wood screws manufactured would amount to millions annually. It apparently means a revolution in the methods of manufacture of parts in which much capital is invested.

In the November number of MACHINERY, engineering edition, we referred editorially to the making of steel machinery chain without waste. The conclusions there drawn apply even more forcibly to the present development than to the manufacture of chain, and the saving of material and labor in the machine screw industry should add materially to our national wealth. The possibilities of cold forming machine screws, studs and similar products from wire and rod seem to be limited only by the ability of engineers to design and build machinery that will stand the stresses.

* * *

CLOSER RELATIONS BETWEEN DEPARTMENTS

As a manufacturing business grows, greater and greater difficulty is almost invariably experienced in keeping the various departments in harmony with the general spirit of the business and fully informed of one another's needs and activities. Unless an excellent system exists, deplorable differences in policy will develop, making it exceedingly difficult in some cases for other concerns to transact business satisfactorily with the purchasing department.

Take the case of an automobile manufacturing concern for an illustration: Certain parts are made by outside concerns to specifications furnished by its engineering department. These specifications state the character of materials, and are accompanied by blueprints giving dimensions, shapes, etc., some of which must be exactly as specified; but it is immaterial whether certain others be exactly reproduced or not. In making up their estimates, the engineers of the bidding concerns usually take into consideration the parts that must be made carefully and those on which less work is required, and figure the cost accordingly. If the work is to be strictly interchangeable throughout, using elaborate jigs and fixtures for all parts, immaterial dimensions would be faithfully reproduced; but in the class of work which is done in lots of a few hundred it is generally out of the question for the jobbing shops to build complete sets of jigs and fixtures. Everyone is familiar with the result of this system of manufacture—the essentials are right while the non-essentials are not wrong, although their dimensions may vary a sixteenth or an eighth inch one way or another; but when a shipment of parts made in this manner is received by an "unintelligent purchasing department" whose inspectors are held to a strictly literal interpretation of the specifications, trouble develops quickly. Cases are not unknown where goods have been rejected without consulting the engineering department, causing heavy losses to both the makers of the parts and the buying manufacturer. If a practical mechanic in authority had been shown the work it would have been accepted unhesitatingly, and every essential requirement would have been satisfied. The moral is that closer relations should exist between the purchasing and engineering departments, or that wide limits should be specified for immaterial dimensions so that work done in accordance with the spirit of the specifications will not be rejected by literal-minded inspectors.

THE HARDENING OF CARBON STEEL

The hardening of steel has always been considered an operation for which definite rules could not be laid down, but in which the experience and judgment of the hardener would almost exclusively have to be relied upon. Practically the only definite rules that have been laid down are that steel should be hardened at as low a heat as possible, and that there is a definite temperature for each kind of steel above which it must be heated to harden at all.

Apart from this meager information, a few generalities only have been furnished for the guidance of men doing this work, including directions for cooling, so as to minimize the risk of cracking; but definite information on the process of hardening is singularly lacking, and many have considered it impossible to shape rules for this operation, even as the result of careful experiments.

For this reason the experiments conducted by Mr. Shipley N. Brayshaw of Manchester, England, the results of which are recorded in detail in another part of this number, are all the more remarkable and of great interest to everyone engaged in mechanical work. These experiments appear to have been made with extraordinary care, and two of the points brought out in his investigations deserve to be particularly mentioned. One of them relates to the shortening or lengthening of steel in hardening. It has often been stated that steel is unreliable and not uniform in this respect, and that the same kind of steel has sometimes been known to shorten in hardening, and sometimes to lengthen. This phenomenon has been attributed to defects, or, at least, to special conditions in the steel, over which the hardener has no control. Mr. Brayshaw's experiments, however, show that the shortening and lengthening of steel in hardening follows a uniform law and that steel hardened below a given temperature, which he calls the "change-point," will shorten when quenched; whereas the same steel, if heated above this change-point before quenching, will lengthen. He also shows that by heating the steel in two furnaces, first bringing it up to a certain temperature in one, and then soaking it for a given time at a definite temperature in the other, it is possible to harden steel so that it will neither lengthen nor shorten when quenched. So far as we know, this is the first definite information that has been published on the change in the length of steel in hardening, the uncertainty of which has caused considerable difficulty in making accurate taps, dies, etc.

Another interesting point brought forth by Mr. Brayshaw's experiments relates to the proper hardening temperature. While it is possible to harden steel within a temperature range of about 200 degrees, and obtain what to the ordinary observer would seem to be good results, the *best* results are always obtained within a very narrow range of temperatures, approaching closely the decalescence point, or the temperature at which steel changes into a condition when it can be hardened by quenching. It is interesting to note that this result agrees with the old theory that steel should be hardened at as low a temperature as possible. In a number of cases certain tools are found to last exceptionally well, while other tools in the same lot show only ordinary durability, although no difference can be detected in the grain of the hardened steel. Such differences can now be accounted for by the slight variations in the temperature at which the various tools have been hardened.

These experiments open up an entirely new field for investigation and new possibilities in the hardening of tool steel. They indicate that in cases where it is important to prevent the cracking of tools in hardening and the deformation of tools due to internal stresses, they should be hardened at a temperature higher than that which gives the best results as regards hardness only. Thus we find that certain of the desirable qualities in a hardened tool are antagonistic; that is, we are unlikely to obtain a tool having extreme hardness and elastic limit and which at the same time is not likely to crack or lose its shape. Under these conditions one of the necessary qualities must be partly sacrificed to another, and a tool must be hardened so as to obtain good general results rather than the best specific one.

The influence of previous annealing on hardening is also of interest; and many of the points brought out in the abstract of the original paper are well worth considering. Those who are giving especial attention to the hardening of steel will find it worth while to obtain a copy of the original paper of 160 pages read by Mr. Brayshaw before the Institution of Mechanical Engineers of Great Britain,* which records his experiments in minute detail.

* * *

THE MANUFACTURE OF FROGS AND SWITCHES

By J. B. HASKELL†

The description of frog and switch manufacture which follows is taken from the methods used by some of the best known firms in this country engaged in the manufacture of this line of work, and is especially based on the practice of the American Frog and Switch Co. of Hamilton, Ohio.

The rails as they come from the mills vary somewhat in length and size, and a great deal in quality, some of them

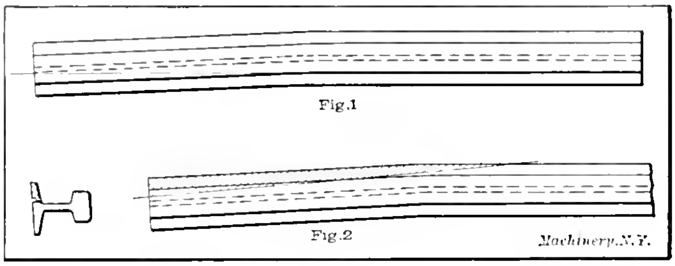

Fig. 1. Bent Rail for Switches Fig 2. Amount cut off Flange of Rail for Switches

being exceptionally hard; it often happens that a high-speed steel drill of good quality has to be reground for every two or three holes or even two or three times for one hole.

Switches

In the manufacture of switches, the rails are first cut to length by means of either an ordinary circular cold saw or a high-speed saw. When cut with a high-speed saw, the rail ends are made very hard by the action of the saw—often too hard for a tool to cut successfully if no means are employed to prevent the hardening. It is best prevented by running

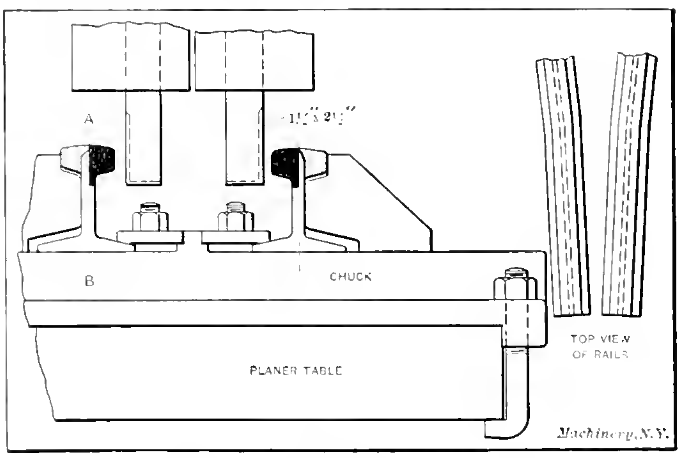

Fig. 3. Planing off Rails for Switches

the saw in water, the under side of the saw being covered to a depth of from two to six inches. Next the rails are drilled for the switch lug bolts and for the reinforcing bar rivets or bolts, if any reinforcement is to be used. The drilling is done in jigs or by means of templets. If the switch is to be reinforced the reinforcing bars are next riveted on.

In the next operation the rails are bent, as shown in Fig. 1, an amount sufficient to bring the side of the web at or near the gage line, the practice of different manufacturers varying somewhat; some place it at the gage line and others from $\frac{1}{8}$ to $\frac{1}{4}$ inch from it. The bend is made of such a length that the point of bend occurs at the intersection of the line of the stock rail and the line of the back of the switch point railhead. This length is usually increased by an allowance of

* Address: The Institution of Mechanical Engineers, Storey's Gate, St. James's Park, Westminster, S. W., London, England.
† Address: 345 E. Millville Ave., Hamilton, Ohio.

½ inch for each foot of bend length, which allowance has the effect of giving a slight clearance between the two rails at the bending point, thus allowing the end of the point to close tight before the point further toward the heel closes. Some makers then shear the part of the flange shown sectioned in Fig. 2, while others place it base up on a planer table, and after cutting a groove in it as shown, break off the flange.

The rails are then placed on a switch planer in special adjustable chucks, as shown in Fig. 3. The chucks are so made that their position may be adjusted both vertically and horizontally. The means for this adjustment are shown in Fig. 4, where the chuck is illustrated in detail. The rails are held quite rigidly, but owing to the spring of the rail and the shape of the tool there is some chatter. The portion of the rail-head shown in black, Fig. 3, is planed off by feeding each tool out separately by hand, two tools being used at once. The feed is by hand chiefly because the widths of the cuts vary so much on the same switch.

The line *AB* of the planing is arbitrarily determined, some making it at the center line of the web and others even with the side. The widths of the cuts vary according to the depth of rail-head, but usually run from one inch to two inches, the total depth being taken in one cut, as the tools are fed in from the side. The average cut is from 1½ inch wide by 3/32 inch feed to 2¼ inches wide by 1/16 to 3/32 inch feed. The speed of the planer which has been found to give the best results is 30 feet per minute, the return of course being considerably faster—usually from 40 to 50 feet per minute. The tools are of the shape and size shown in Fig. 3 and are of Novo steel. These tools when taking these cuts sometimes break off at the bottom of the holder.

The rails are now moved to such a position that the line of the unbent portion of the rail is in line with the planer. Both tools are then fed, thus planing off the portion shown in section lining in Fig. 3. The rail is planed on top in such a manner that the point will be from ¼ to ¾ inch below the top of the stock rail when it is in position on the friction plates, the amount varying according to the practice of the maker or the railroad. This planing is accomplished by setting the chuck vertical in such a way as to bring the required line horizontal. The tools are then fed down, for as the point is narrow, feeding sidewise would bend it. The gage line corner is rounded off to a radius corresponding to the radius of the corner of the rail-head. When this planing is finished, the rails are moved by a trolley and hoist to the next planer, which is equipped with chucks as shown in Fig. 5 for holding the rail in the position shown.

The tools on this planer are set at the proper angle to plane the flange so that it will agree with the angle of slope of the stock-rail flange, this angle being 13 degrees for all A. S. C. E. section rails. The portion of the flange shown in section lining in Fig. 5 is then planed off. This amount varies with the thickness of the riser to be used and with the thickness of the flange of the stock rail. The in-and-out adjustment of the chucks allows for this difference in the planing. On this cut the width runs up to 3 inches; on the widest part of the cut the feed is 1/16 inch. A broken chip is produced, which drops off in pieces of the width and depth of the cut and from ¼ to ¾ inch long on Bessemer rail, but on open hearth rail it is a long spiral chip. This cut finishes the

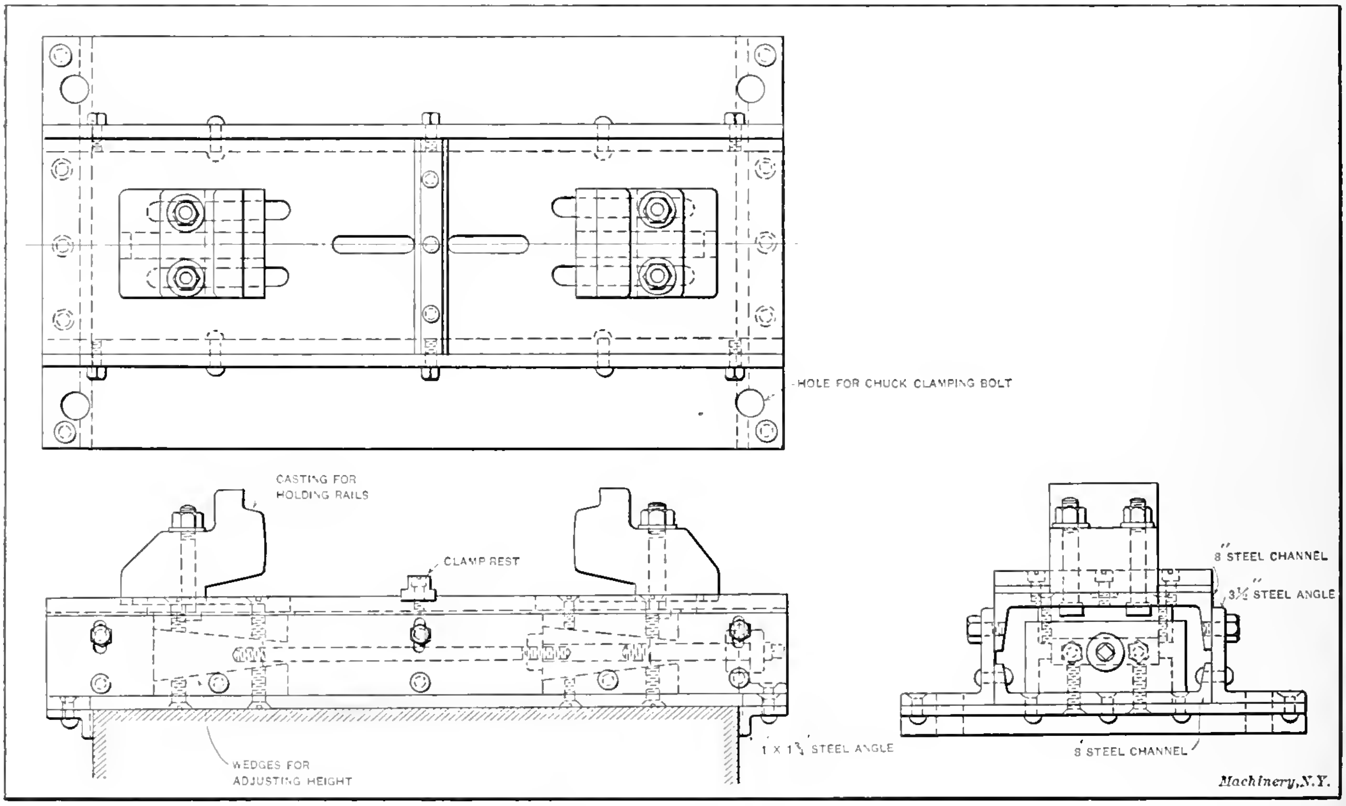

Fig. 4. Chuck for Holding Rails while Planing

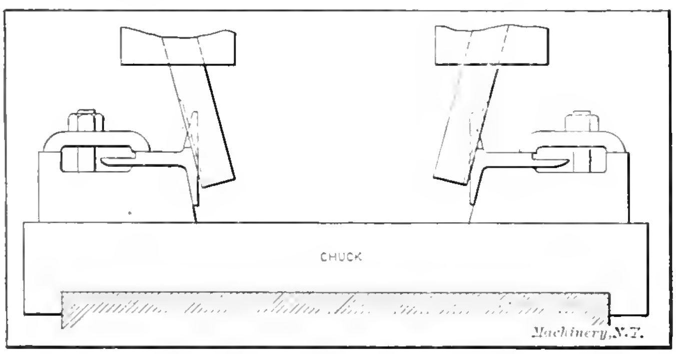

Fig. 5. Planing off Flanges

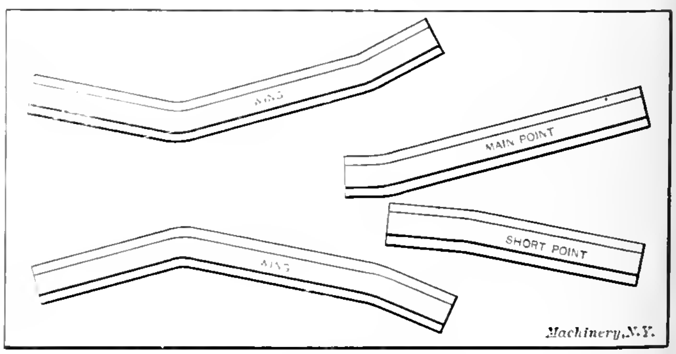

Fig. 6. Frog Parts Bent, ready for Planing

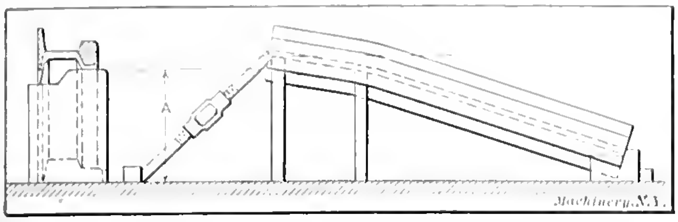

Fig. 7. Method of Setting up Main Point of Switch for Planing

switch except for grinding the top of the point end to a round corner.

Frogs

For the frogs as for the switches the rails are first cut to length. They are then heated and bent to the proper angle and shape. Each bend is made according to a templet, each

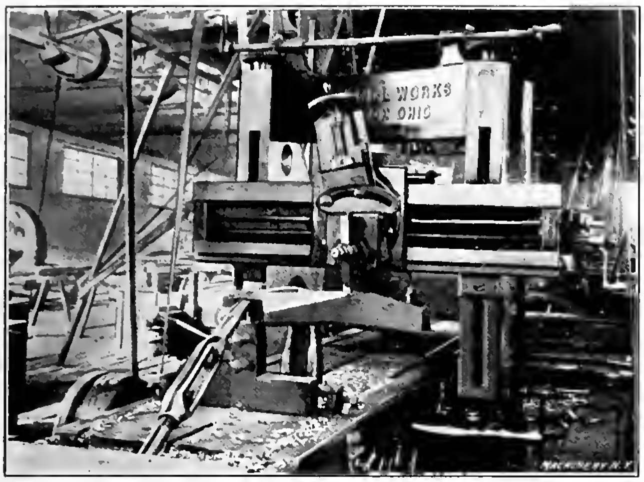

Fig. 8. "Balling out" Short Point of Frog

frog angle having its own set of templets. After the bending the rails appear as shown in Fig. 6. The wing flanges are then planed off the amount necessary to clear the flanges of the point rails. In doing this they are placed on the planer, base up, and two wings are planed at the same time. The short point is next planed out, the operation being called "balling out," to fit against the main point. The point is set up on the

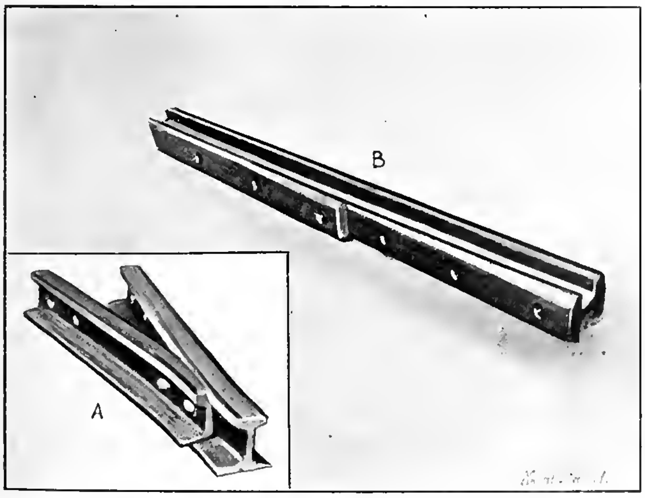

Fig. 9. Frog Point before Final Planing, and Frog Filling after Planing and Drilling

planer table as shown in Figs. 7 and 8, the distance *A* being governed of course by the frog angle. The planing line is marked on the end of the rail and it is then planed to this line. The cut in this case is not very heavy, it being 5/8-inch, with 1/32-inch feed. The two points after being drilled for two rivets and riveted together, as shown in Fig. 9 at *A*, are set on the planer and the bent part shown sectioned in Fig. 10 is cut off, thus forming the two intersecting gage lines.

Considerable planing is done on the filling, the approximate amount for an average standard frog being shown at *B* in Fig. 9, and in Fig. 11. As many pieces of a kind as there are, up to the capacity of the planer, are placed on it, set to the proper slope and are all planed at once as shown in Fig. 12. This work is done at a cutting speed of 25 feet per minute with a cut about 3/4 inch deep and a feed of 3/8 inch per stroke. The tool is 1 1/2 inch by 2 1/2 inches in size with a round nose. It is given a rake of from 5 to 8 degrees and a clearance of 2 degrees. Some makers instead of planing the filling do the work on milling machines.

The whole frog is next clamped up including filling, heel

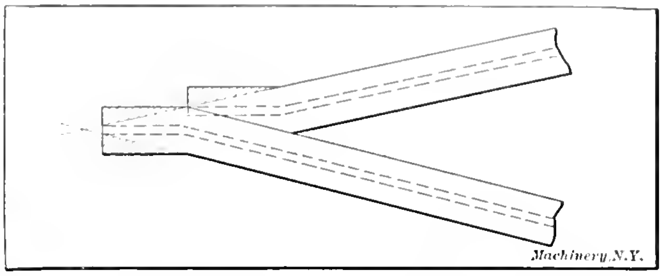

Fig. 10. Diagram showing Amount planed off Frog Point

risers and point fillers, if there are any, care being taken to secure proper alignment and length over all. It is then taken to a multiple spindle horizontal drill, whose spindles are set to the proper center distances for the frog being built, and the whole frog is drilled at once. This method avoids the reaming which is almost always necessary when the holes are drilled singly in the rails. Quite often when using an ordinary lubricant, the drills need considerable grinding when the rails are running hard. A mixture of camphor gum, turpentine and soft water may be used to avoid this trouble with

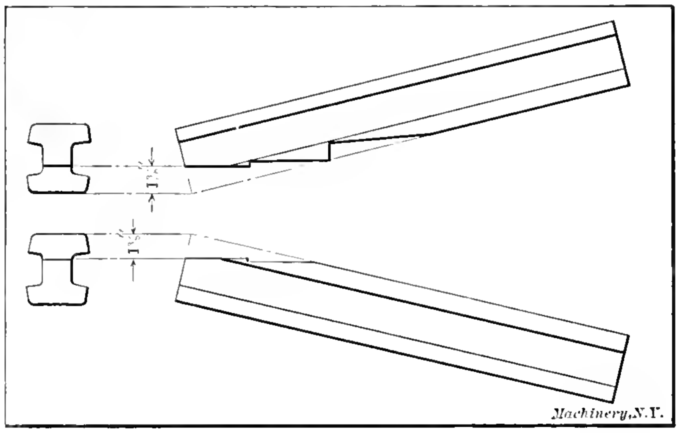

Fig 11. Frog Filling when Planed

hard rails. After being drilled the frog is bolted up. In frogs having foot guards, etc., the extra holes are drilled at the same time as the frog bolt holes. The foot guards, plates, etc., are next bolted or fastened in place, completing the frog.

Crossings

The rails in crossings are first cut to lengths given on the drawings. They are then bent as required and the flange of the guard rail planed off if necessary. They are then assem-

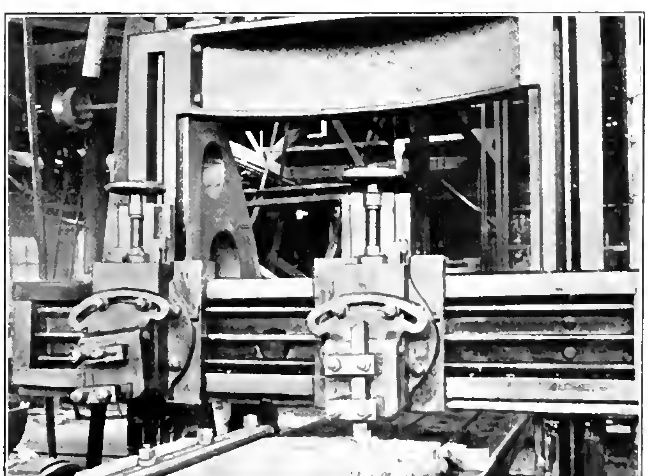

Fig. 12. Planing Frog Fillings

bled and clamped up in sections as shown in Figs. 13 and 14. Each section is drilled separately on a multiple spindle horizontal drill, all bolt and fishing holes being drilled at one setting.

The planing is next done, such as grooving out the flangeways, shaping the ends of the abutting rails, notching the backs of the heads, etc. This work is usually done on a drawcut shaper. The cuts are quite heavy, and even on the heaviest kind of shaper there is considerable spring in the table. The ordinary shaper has a brace supporting the outer side of the table, but it usually is so made that it has no holding-down power. When the heavy cut starts in on the rail it tends to raise the table. By altering this brace so that it also holds the table down, a big improvement is effected.

In setting rails to have the flange-way cut at an angle on the shaper, it is difficult to hold the rails properly, the cut

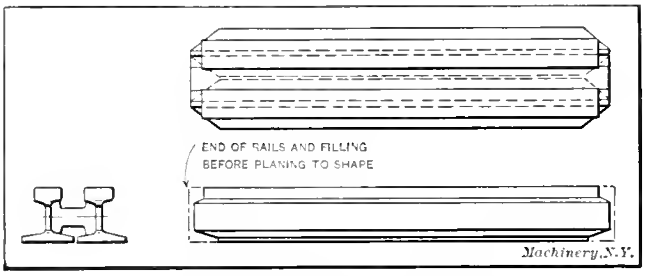

Fig 13. Rail Section for Crossings

tending to turn the rail and holder and thus throw the angle out. The flange-ways are grooved out by means of a broad round-nosed tool. On curved crossings, where all the angles vary, each one is determined by calculation and the groove is then cut to the required angle. In shaping the ends of abutting rails, it is necessary to make two settings of the rail to properly plane both top and bottom. The cutting of the slope on the top of easer rails is performed on the planer by setting up the rail to the proper slope to give the needed rise.

The crossing is then assembled, the straps, after forging to the proper angle, are put in place, marked off and drilled, and the crossing bolted up. The plates, foot guards, etc., are fastened on and the crossing is complete. All dimensions such as diagonals, etc., are carefully checked. Of course, in some details the practice of different makers varies considerably; the principal operations, however, are performed in much the same manner.

Use of Manganese Steel

Manganese frogs as now made consist of a manganese casting that forms the parts of the frog subject to the most severe wear. The wing and point rails are bolted to this casting. The bolt holes in the casting are cored 1/4 inch larger than the bolts to be used. The rails are drilled by jig and are then bolted to the casting. The space around the bolts is then filled by spelter poured in through holes cored in the casting for the purpose. The entire top of the frog is then finished to a true surface by grinding. The manganese steel can be cut by a planer tool, but it is very slow work and the tools will not stand up well to it, making it cheaper and more satisfactory to do all fitting and finishing by grinding.

Rolled manganese steel is coming into some use in track work in the shape of full-length rails where the service is extremely severe. But for frogs, crossings and switch points the cast manganese steel is used altogether.

The regular types of cast crossings require no fitting at all, as the crossing is cast complete in two parts with fish bolt holes cored in the ends, which are made to correspond with the rail section.

THE MAINTENANCE, CARE AND UP-KEEP OF PNEUMATIC HAMMERS

By GEORGE H. HAYES*

Having been connected for a number of years with the manufacturing end of the largest pneumatic tool company in the world, I have been asked to write a few words concerning the maintenance of pneumatic hammers and the abuses which they receive at the hands of the men on the job.

The material used in the construction of pneumatic hammers is the very best that money can buy and is the result of long periods of experimenting at an outlay of a great deal of time and money to get material that is best able to withstand the vibrations, jar and wear which pneumatic tools are called upon to withstand. The treating of the material, fitting up, and testing, must be done by experienced and competent men. Pneumatic tools are made with the most extreme care, the moving parts are accurately and closely fitted, and when the proper lubrication is neglected, which is the most unpardonable offense to which a piece of fine machinery can be subjected, the moving parts of a pneumatic hammer will wear rapidly and in a very short time refuse to work.

Another source of trouble is sometimes located in the pipe line. Moisture carried in the air will rust the pipes and if a hammer is connected up without first blowing out the pipes a sediment is liable to be blown through into the tool, causing the valve or piston to stick. Rubber deteriorates very fast and particles of the hose may blow into the valve box and stop up some of the parts. Many times we have had hammers that would not operate, sent in to the factory, and on dismantling them found the port holes plugged up with pieces of rubber, or sediment from pipes, which when thoroughly washed out with gasoline, reassembled and properly oiled, would operate perfectly.

Another abuse is practiced in taking a hammer apart and putting it together again. Some repair men, instead of using a wrench or soft hammer in loosening or tightening the handle, use a hard steel hammer, battering the parts badly and in many instances breaking them. The finished parts should never be struck with anything but lead or copper hammers, and even when this is done, good judgment should be used as to the strain put on the threads of the handle and the cylinder.

There are many abuses practiced in connection with the operation of pneumatic hammers which are hard to locate, one of the most flagrant being the use of short pistons in riveting hammers. The manufacturers, after long and careful experimenting, have decided on a piston of proper length to perform satisfactorily the work for which the tool was designed, and all parts are made in proportion to withstand the strain. Workmen who are anxious to perform their day's task in the shortest possible time, or to increase their volume of work where they work on a per-piece basis, have little or no regard for these labor-saving devices. Having discovered that a piston a fraction of an inch short will do the work more rapidly, they resort to all manner of means to secure them, even having them made in outside machine shops. They carry them in their pockets and when they take a hammer from the tool room, they substitute the short piston for the one of proper length, again making the exchange before returning the hammer to the tool room. The result is, sets and handles are broken and cylinders frequently split. Where these breakages are occurring at short intervals, it would be well to detail someone to go through the shop and examine the pistons while the hammers are in use, otherwise the cause of the breakages will not be definitely located.

Some of the large plants using pneumatic tools, have adopted the practice of issuing a given tool to the same workman con-

*Works Manager of Chicago Pneumatic Tool Co., Detroit, Mich.

tinually, which has had a tendency to cause better care to be taken of the tools. If breakdowns occur frequently, it enables them to compare the amount of work being accomplished by different tools, and the more careless workmen are located and disciplined. Where this practice is followed, many times when the output of the shop is being forced to such an extent as to require all tools in service, and a workman is delayed in completing his work, while the men who are more careful of their tools finish in good time, it has a tendency to cause others to exercise greater care, which accrues to the benefit of all parties interested, even back to the manufacturer.

A great majority of men who operate pneumatic hammers in the shops, know very little, if anything, about the construction of the tools, and it pays any large institution using pneumatic tools to employ a competent man to look after them, see that they are properly lubricated and returned for cleaning when through with their work. I have been in foundries using large numbers of hammers in cleaning and chipping castings, where, at the sound of the whistle the hammers would be thrown down, generally in the sand, and enough sand or grit would get into the tool, so that when the air was again turned on the piston would stick fast after one or two blows. This necessitates a cleaning of the tool causing a loss of time in its use of from twenty to thirty minutes.

In starting to drive rivets in cold weather, especially on structural or out-of-door work, the hammer should be warmed up enough to take the frost out of the steel, as a hard piece of steel full of frost is liable to break at the first blow; after a few rivets have been driven, there will be enough heat from the rivets to keep the frost out. On the other hand, never allow the temper in the rivet set to be drawn too low, as a soft set will break very quickly. When driving rivets rapidly, have a pail of water handy and put the set and end of the hammer cylinder in the water occasionally to keep from drawing the temper, or change the set occasionally.

The wearing of parts in a hammer will always take place, but the life of the tool can be prolonged greatly by proper care and attention. Crystallization of the steel takes place owing to the rapid blows of the piston and the vibration. The life of the hammer depends mostly on the care which it receives and the character of the work being performed with it. A piece of fine machinery, such as a pneumatic hammer can be ruined in a few minutes by ill usage and neglect.

It has been proved conclusively during the past few years, that pneumatic tools are invaluable in shop practice wherein they are adaptable. Either a small or a large installation of pneumatic equipment is the most economical in maintenance cost. The small installation does not require a special attendant, but can be looked after by the regular mechanical force, reducing the labor charge to a minimum. With an equipment consisting of forty tools or more, it should be put in charge of a special machinist whose duty it is to follow the equipment closely and to keep it in good repair. It has been clearly proved that one man can care for one hundred tools where the proper attention is given by the men handling them. We have recently had our attention directed to tools in service which have been working regularly for a period of seven years. These tools, of course, have been well cared for, and the workmen using them appreciate their value in aiding them in their labors and handle them as they should be handled.

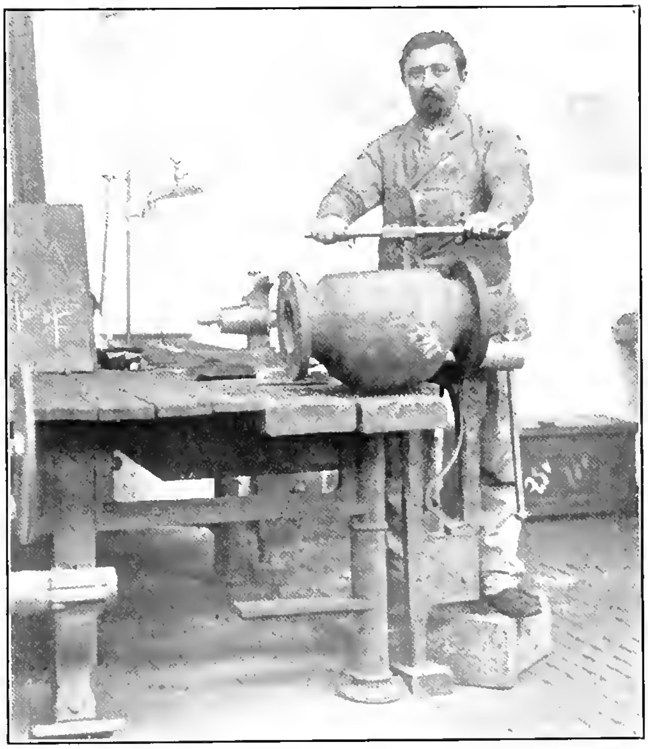
Pneumatic tools are outrageously abused in many cases without the knowledge of the management, and, at other times with their sanction, the latter being on account of these tools having such a large earning power that they are considered an economical investment even though their life be but three months. This latter remark may seem an exaggeration; however, it is borne out by actual knowledge. One of the largest steel concerns in the world is using chipping hammers where nine hammers in the hands of men skilled in their operation easily perform work which would require ninety unskilled men with mauls and cutters. The tools in this case are appreciated by both the management and the workmen and are well cared for. Even when the tools have a short life, a great many concerns having adopted them, state that the saving in wages and increased output make them an extremely economical investment.

Modern labor-saving machines are sometimes blamed for lowering the standard of skilled workmen by transferring him into a mere automaton a droning machine tender. Undoubtedly in some crafts there is less call for men of manual dexterity than there was before the invention of labor-saving devices, leading to a decreased demand for all-around mechanics, and an increased demand for men of only sufficient intelligence to guide an almost sentient machine. On the other hand, many types of labor-saving devices have counteracted this tendency by offering mechanical means for doing the drudgery of a shop, making necessary a higher average of intelligence than before. Pneumatic hammers and drills, portable electric drills and hydraulic riveters are in this class, as skill and judgment rather than mere brute strength and endurance are called for in their operation.

* * *

RATCHET TAP WRENCH

In our shops those holes which we cannot tap by power on the Pearn drill press are tapped by the method shown in the accompanying photograph. The tool consists of a ratchet tap wrench so made that the workman cannot turn the tap backwards, or to the left. From this there results the advantage of a greater rapidity of work as well as the obviating



Ratchet Tap Wrench used by Societe Anonyme des Ateliers de Construction H. Bollinckx, Brussels, Belgium

of the back and forth movement of the tap, which deteriorates the cutting edges; the workman is inclined to habitually give this objectionable movement. The ratchet wrench is reversible so as to permit the tap to be withdrawn with facility.

Société Anonyme des Ateliers de Construction H. Bollinckx

Brussels, Belgium.

* * *

Many problems in mechanism are best solved by avoiding them; that is, by resorting to other expedients that eliminate the troublesome feature. For many years various devices were tried in certain textile machinery to overcome the momentum of spools which caused them to over-run when winding was stopped. The consequent double reversal of motion when winding started again would often snap the thread before the inertia of the spool could be overcome. Thousands of dollars were spent on many devices designed to overcome the trouble, but with little success. At last the problem was solved by getting around it. In winding nowadays the spool does not turn. It is mounted with its axis parallel to the direction of the thread travel, and the thread unwinds from the end of the spool without rotating it. In this simple manner the effect of inertia is eliminated.

MAKING WALSCHAERTS VALVE GEAR PARTS

By RALPH E. FLANDERS*

Every mechanic really interested in mechanics, who chances to live near one of the great trunk line railroads, must have noticed a remarkable change in locomotive design which has taken place in the last three or four years. We refer to the increasing use of the Walschaerts valve gear. A locomotive equipped with this gear, as shown in Fig. 1, presents a distinctly different appearance from one furnished with the old-style Stephenson link motion, which is mounted out of sight between the frames of the engine. This difference in appearance is especially noticeable with the engine running at high speed when the lines of flashing light made by the flying steel work of the rods and links give a decidedly mazy and complicated appearance to the mechanism.

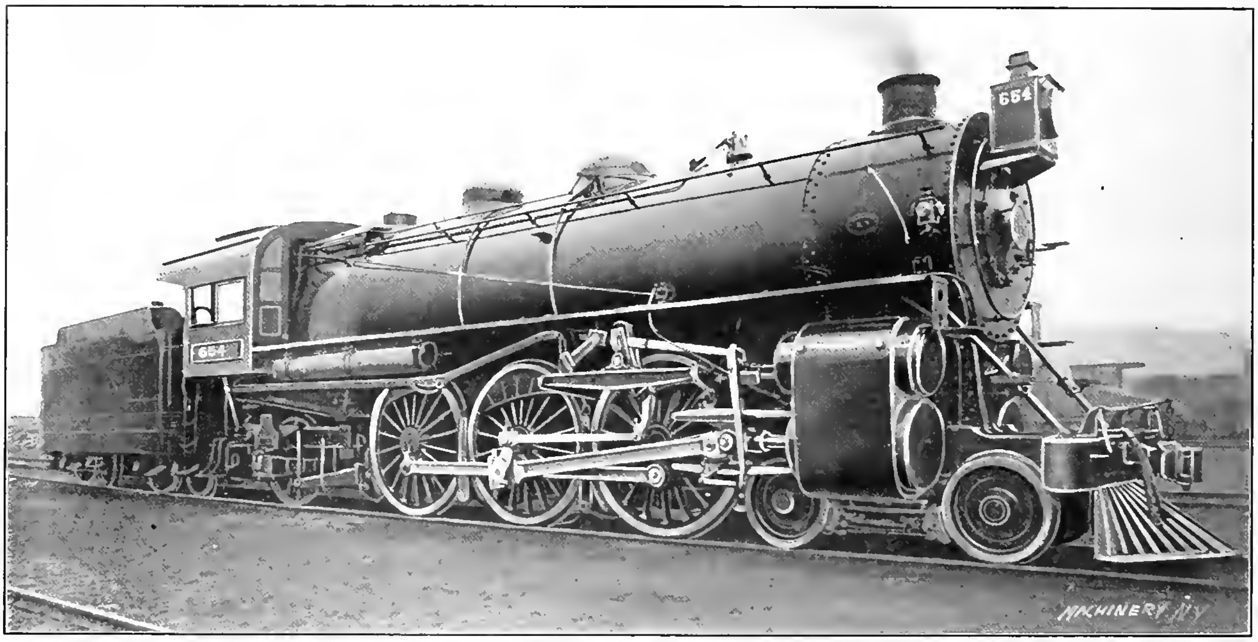


Fig. 1. Pennsylvania R. R. Pacific Type Passenger Locomotive with Form of Walschaerts Valve Gear used for Heavy Service

The Advantages of the Walschaerts Gear

In reality, however, the Walschaerts gear is not as complicated as the Stephenson type. The deciding factor in its adoption, as every railroad man knows, was not the matter of complication, but of dimensions. Of late years engines have grown so tremendously in size and power that it has become next to impossible to find room between the frames, for eccentrics and valve movements of sufficient size and wearing area to give strength and durability for the heavy service required of them. Besides this, the large diameter of the axles of heavy locomotives requires an eccentric of correspondingly large diameter; and with this, the surface speed of the bearing of the eccentric strap on the eccentric is so great as to practically nullify the effect of any increased area which could be given to it by careful designing. These considerations led to the adoption of a form of valve gear which was located entirely outside the wheels, where no serious dimensional limitations were placed on the parts.

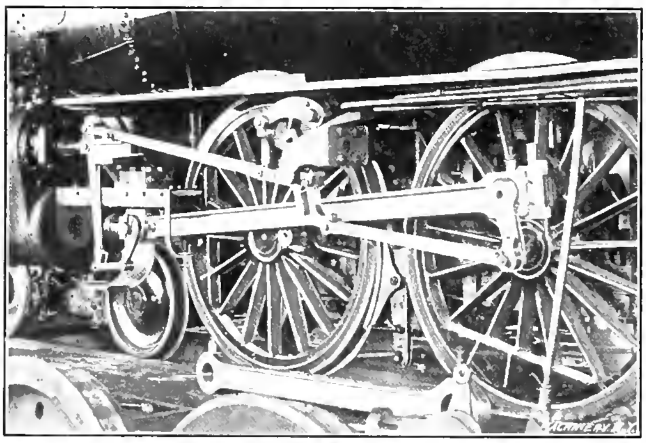

Fig. 2. Design of Walschaerts Valve Gear used on Atlantic Type Engines

When it came to the actual application of the new motion to the locomotive, it was found to have further advantages. One of them lay in the fact that it is always exposed to the view, making it very easy to erect and maintain, leaving it open for the constant inspection of the engineer. Besides this, it may be easily so designed that all its movements are in straight lines, without canting or side strains, thus particularly adapting it to heavy service. In the matter of steam distribution and economy, there is little to choose between the two, though the old gear may have a slight advantage.

We have referred to the Walschaerts gear as a "new" form of gear. This is true, however, only for American service. It has been used to a limited extent in England, but on the Continent it has been employed almost to the exclusion of any other form of valve gear ever since its invention by the Belgian, Egide Walschaerts, about 1844. Although we were so long in applying it in this country, its good qualities were rapidly recognized when once the start was made, as is evidenced by the fact that of 2448 locomotives ordered in this country last year, 1638, or about 67 per cent were of the Walschaerts type; 30 per cent were of the Stephenson type; while the remaining 3 per cent of the total number were furnished with other designs of valve movements, some of which were of a more or less experimental nature.

Two Designs of the Walschaerts Gear

The first two illustrations show the mechanism as applied to the locomotive. Different designs are shown in the two cases, that in Fig. 1 being used for the heavy service, while that in Fig. 2 is adapted to lighter work, being applied in this case to the standard Atlantic type passenger locomotive of the Pennsylvania R. R. The main difference relates to the method of raising and lowering the radius rod in the link, the connection between the radius rod and the link block, and the support of the link.

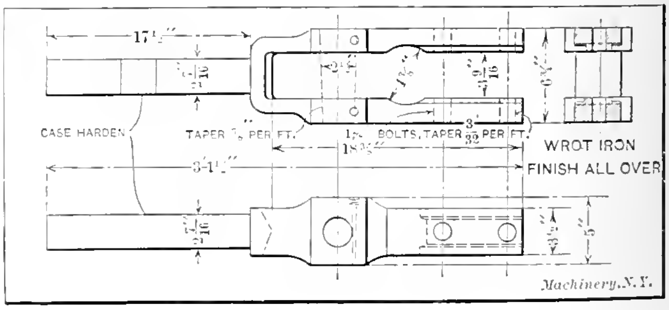

Fig. 3. Radius Rod Extension for Valve Gear shown in Fig. 1

* Associate Editor of MACHINERY.

In Fig. 1 the link is mounted on swinging yokes on each side, pivoted to bearings on a cast steel frame. The radius rod is provided with an extension, which spans the link on each side inside of the yokes and is provided with a finished square shank projecting beyond the link, which bears in the

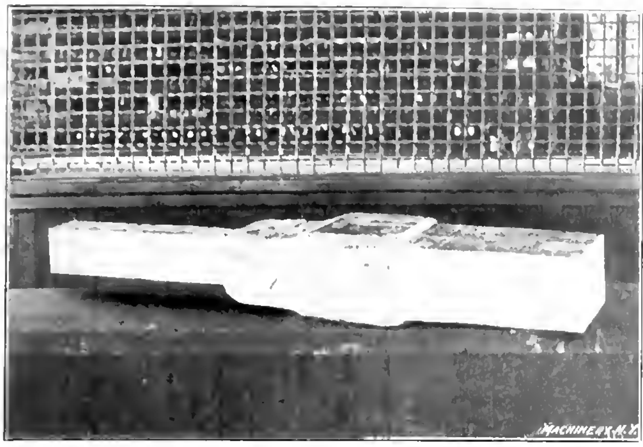

Fig. 4. Rough Forging for Radius Rod Extension

pivoted block on the end of the reversing arm, by which it is raised and lowered for forward and backward running. In Fig. 2 the link is supported in trunnions or saddles at the center, and the radius rod is hung from the reversing arm on a short link.

The operations on the rod work of the valve mechanism in the Juniata shops do not differ materially, except that the work is smaller, from the method of manufacture used in making the main and side rods, described in the February, 1910, number of MACHINERY, railway edition. In describing the shop operations on this valve gear, we will, therefore, confine the description to two particular parts of a special and peculiar design

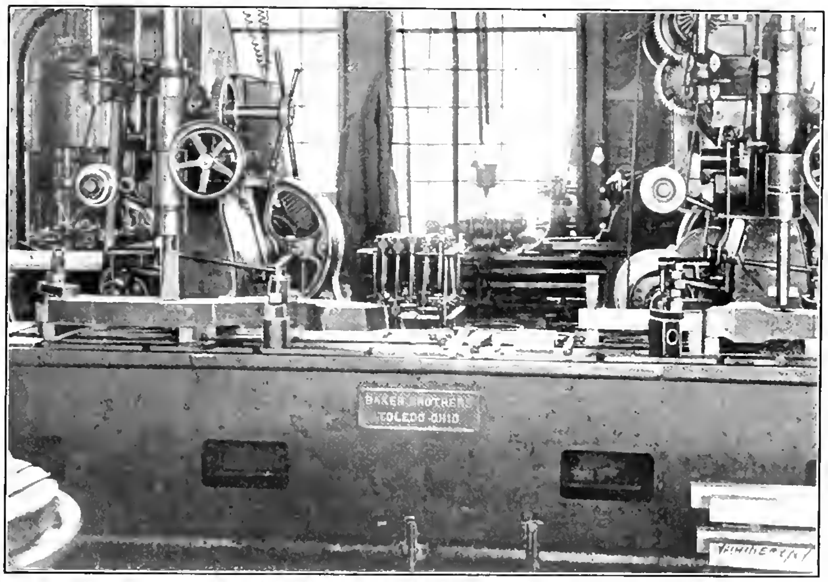

Fig. 6. Drilling Radius Rod Extension and Walschaerts Links

—namely, the links for both types of valve gear, and the radius rod extension for the heavier type of locomotive shown in Fig. 1.

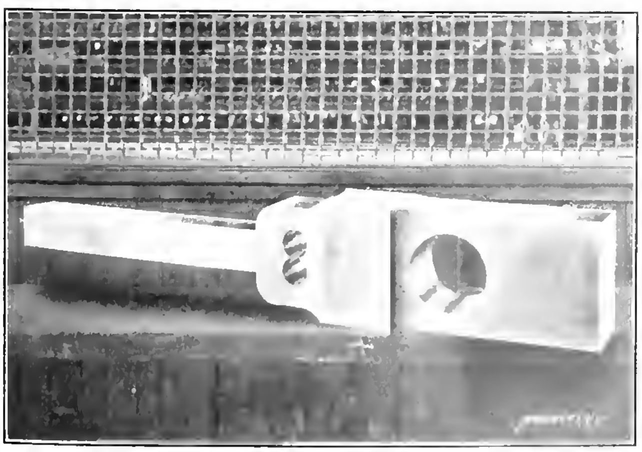

Fig. 7. Radius Rod Extension Drilled for Slotting

Roughing Out the Radius Rod Extension

A drawing of the radius rod extension is shown in Fig. 3. As may be seen, it is made from a wrought iron forging, and is finished all over. The square projecting shank, which bears in the pivoted block of the reversing arm is casehardened to give a durable wearing surface. This casehardening, as will be explained, introduced some difficulties in the course of manufacture. The overcoming of these difficulties gives the part its particular interest from the machinist's standpoint.

The rough forging from which the piece is made is shown

Fig. 5. Forging Roughed all over and Shank Finished

in Fig. 4. The illustration shows that the ends of this forging have been trimmed to size in the cold saw to practically the required length for the finished piece. Fig. 5 shows this forging roughed out all over. The various cuts shown have been taken in the slotting machine and the shaper. On the shank, which is to be casehardened, the finish marks show that the stock was necked out close to the connection with the body of the forging, the cuts being taken crosswise of the work on the four sides on the slotter. The forging was then taken to the shaper and the square was finished down to size. This, of course, is the obvious method of procedure.

The holes have next to be drilled for slotting out the interior of the blank to form the two arms which encircle the link. The machining of these holes is performed on a heavy drill press; or, as in the case shown at the left of Fig. 6, on a regular rod bor-

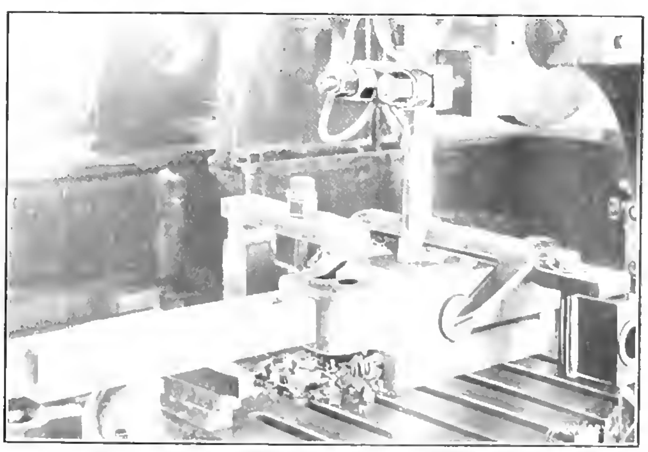

Fig. 8. Working out the Slot in the Slotting Machine

ing machine, using only one of the spindles, leaving the other free for other work. The larger hole is first drilled out, and then it is bored with a bar carrying a double-edged blade, as shown in the engraving. After these boring and drilling operations, the work has arrived at the stage shown in Fig. 7.

The forging is now taken to the slotting machine, where (see Fig. 8) it is mounted on parallels, so as to hold it firmly and accurately to the table of the machine. A square-nosed tool is used for cutting out the block of stock between the holes. The C-clamp, which is shown tightened in place on the forging, prevents the two sides of the newly formed opening from separating under the pressure of the cut. The state of the work at the end of this operation is shown in Fig. 9.

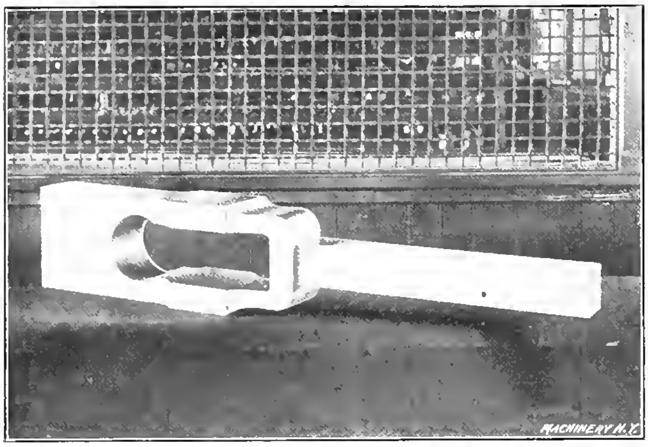

Fig. 9. Work with Center Slotted out ready for Casehardening

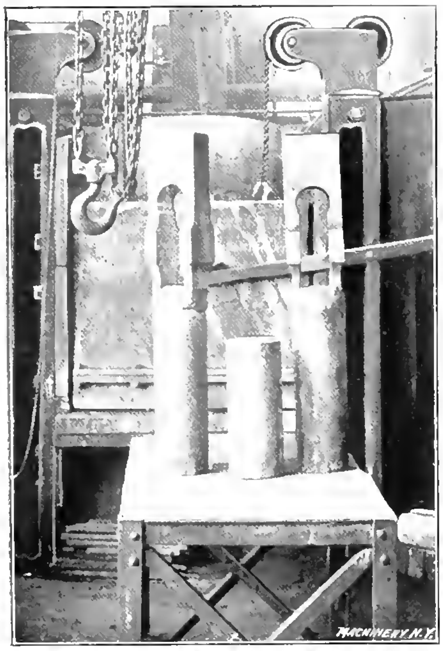

Fig. 10. Work and Test Piece Packed for Hardening

Fig. 11. Work placed in Furnace ready for Casehardening

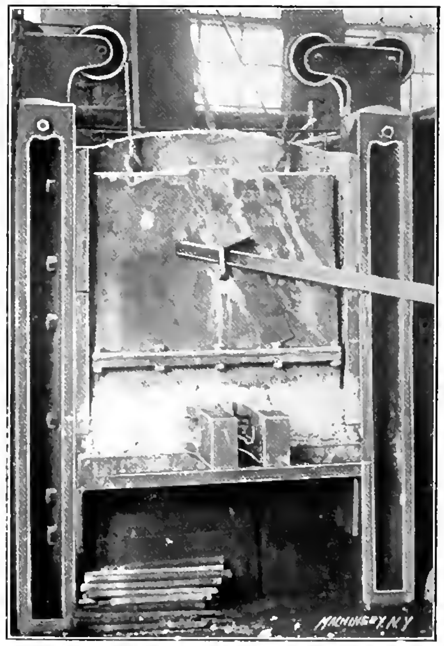

Fig. 12. Casehardening Furnace ready for the Heating

Casehardening the Shanks of the Radius Rod Extension

It has been found advisable to caseharden the shank at this point in the procedure. The advantage of doing it at this time lies in the fact that the remainder of the work is not yet finished to its critical dimensions, and the two sides are still tied together by the mass of material left between them at the outer end. Thus the distortion which is sure to take place in work of this kind in hardening, takes place at a time when it does no harm, as the finishing cuts will be taken with reference to the finished and casehardened surfaces of the shank, with which they will, therefore, be true and accurate. If the opening between the two sides was completely cut out, as shown in Fig. 5, before this hardening operation, they would almost certainly be sprung out of parallel with each other, or out of line with the casehardened portion.

Fig. 10 shows the casehardening furnace and two pieces of work ready for heating. The furnace is fired with oil, and supplied by a blast from the regular blower service of the forge shop. Provision is made, however, for an independent blast for keeping the fire up during the night or at times when the regular forge service is not in operation. This independent service is furnished by a small blower fan, which is itself operated by impingement on its blades of a jet of air from the high-pressure shop service line, used for the pneumatic hammers, riveters, etc. This latter is kept at pressure continually, day and night, so it is available any hour of the twenty-four, making it possible to use the furnace at any time or for any length of time.

As may be seen in Fig. 10, only that portion of the work which is to be hardened is packed. This is inserted in a section of wrought iron pipe, filled with the casehardening material, composed of 11 pounds of prussiate of potash, 30 pounds of sal-soda, 20 pounds of coarse salt and 6 bushels of powdered charcoal (hickory-wood charcoal preferred), thoroughly mixed with 30 quarts of water. The pipe is luted with fire-clay at each end to retain the carbonizing material and exclude the air. The work is placed in the furnace as shown in Figs. 11 and 12. The part that is not to be made hard is left projecting outside the furnace door. A wall of fire-brick and clay is built up to close the space between the lower edge of the door and the bottom of the furnace opening. After soaking for, say, fourteen hours more or less, the work is removed from the furnace and from its packing, and plunged into a tank of water as shown in Fig. 13, being suspended there until cool.

Test Pieces for Casehardening

Fig. 13 also shows a square block of hammered iron marked "Test piece." The use of this test piece gives an idea of the precautions which the Pennsylvania officials have found it wise to adopt, to make sure that all the material and treatment given to the vital parts of their locomotives, are up to the standard required of them. This test piece is forged at the same time and from the same material as the radius rod extensions. It is machined to the same dimensions as the square shank of

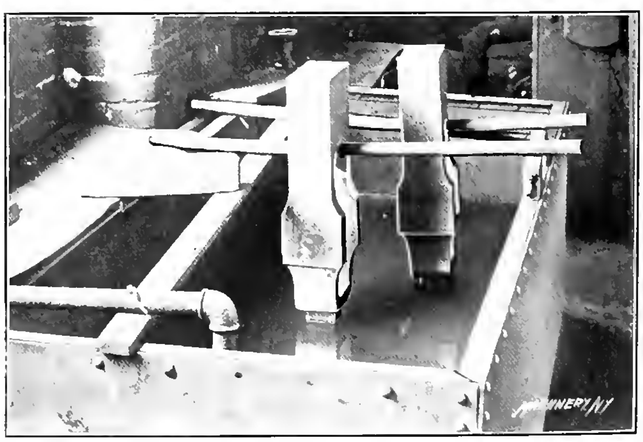

Fig. 13. Cooling the Casehardened Shank of the Work

the extension which is to be casehardened. It is packed in a similar wrought iron casing, as shown between the two pieces of work in Fig. 10, and is placed in the casehardening furnace next to the work itself, remaining there for the same time and subjected to the same degree of heat. It is then cooled and hardened in the same manner. It is evident, then, that the condition of the test piece should give an accurate index of the condition of the work itself, so far as the hardening operation is concerned.

The test piece, thus prepared, is now taken to a press and broken, in order that the condition of the interior may be noted. Figs. 14 and 15 show various examples of these broken test pieces. The examination shows the condition of the metal, the texture of the fiber, and the depth of the casehard-

Fig. 14. Broken Test Pieces for Showing Condition of the Work

ening. One-half of each test piece is thrown away. The other half is retained, marked with the date of hardening and the class and construction number of the engine on which the casehardened parts are to be used. These are kept two years to prove that the work is giving good results in service, and to make sure that no trouble is to be expected from it. It is held by the shop as a sort of guarantee of the good work done in the heat treatment.

Such precautions would be necessary or advisable in hardly any other kind of work, but there are many cases in locomotive practice where the extra expense and trouble is worth while. A defect in a locomotive is a serious matter. It may mean nothing worse than the delay of thousands of tons of valuable freight, or it may mean the loss of human life and serious damage to the prestige of a great railway system. Good steel properly treated is absolutely essential for the vital parts of a locomotive, and

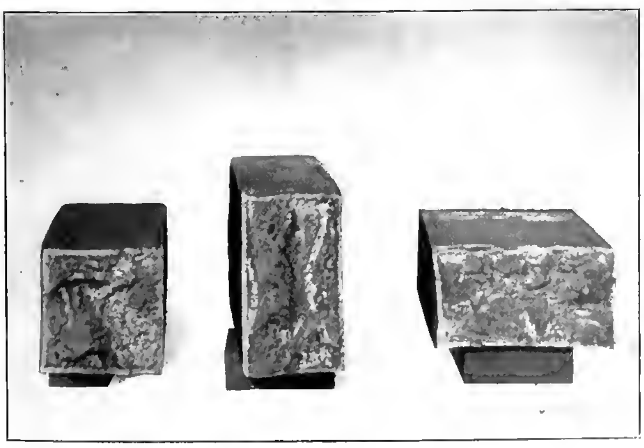

Fig. 15. End View of Test Pieces showing Depth of Hardness and Character of Fracture

every precaution is taken to insure reliability.

It was mentioned that ground coke is one of the ingredients used in casehardening. Fig. 16 shows the mill used here for grinding the coke. The coke had formerly been broken by workmen with hammers, in much the same primitive fashion that ice is pounded for the ice-cream freezer in the ordinary American home. The foreman got sick of this primitive process, however, and bethought himself of a bone grinding mill used on a chicken ranch in his neighborhood, which he pro-

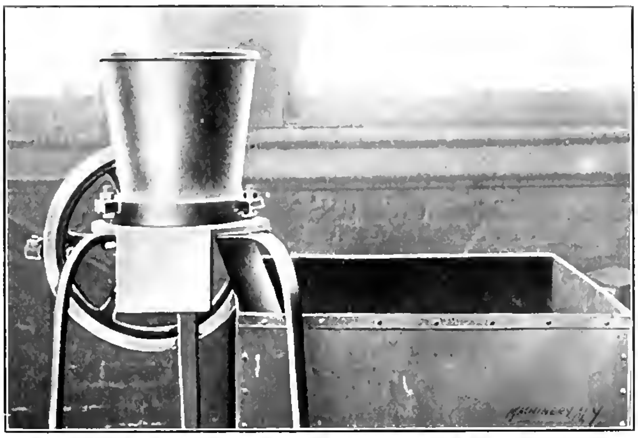

Fig. 16. Coke Crusher Built on the Bone Mill Principle

ceeded to copy. His copy is made of a few simple castings, and consists essentially of a hopper, as shown, having projections on the inside, alternating with similar projections on a revolving cone. The inner surface of the conical hopper and revolving cone taper toward each other, and as the coke passes down through the revolving teeth into this narrowing space, it is crushed finer and finer until it drops through a spout into the box. The fineness can be regulated by raising and lowering the hopper by means of the adjusting nuts on the studs by which it is supported. This crusher is operated by an air motor.

Finishing Operations on the Radius Rod Extension

Fig. 17 shows the completed radius rod and extension as-

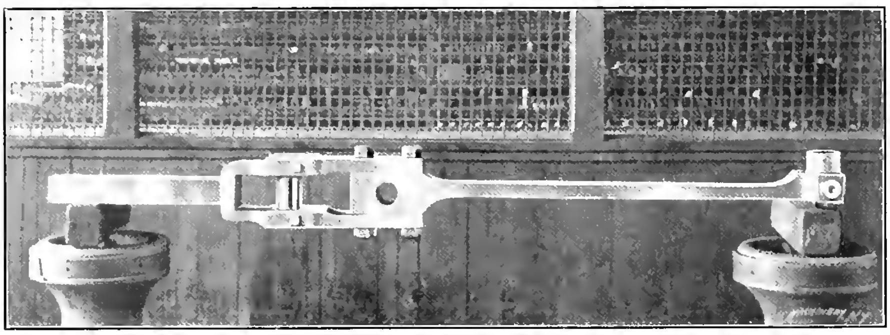

Fig. 17. Radius Rod Extension with Slotting Complete—Assembled with Radius Rod

sembled. The remaining machining operations have been performed, as required by Fig. 3, finishing out the slot between the two sides of the fork, and machining them for the tongue and groove joint of the radius rod head. These tongues are made with a taper, as shown, so that they bear on the sides only. When the bolts are tightened down to form the joint, assurance is given of a firm grip with no possibility of play or backlash.

Another point should be noticed in Fig. 3, which is a regular practice in locomotive construction, but one with which many machine-tool machinists are unfamiliar. This practice is the use of taper bolts. The two bolts shown, which hold the joint, are of 1¼ inch normal diameter, but they are tapered on the body of the bolt 3/32 inch per foot. This is the standard practice for all important bolts used throughout the whole locomotive. After the holes are drilled, the taper reamer is run through them to such a depth that, when the bolts are screwed home, they will draw in to a tight fit in the holes, and come solidly against the head. Each bolt thus serves as a well-fitted dowel, in addition to its duty of drawing the parts together. When the work is properly made, the joint thus formed is of a superior character.

Roughing Out the Link

A general drawing of the link used for the heavy form of Walschaerts gear is shown in Fig. 18. As was explained in connection with Fig. 1, this is of the kind in which the link

is supported by yokes which are attached to it at each end of the slot, and are provided with central pivots mounted in stationary bearings in the side frames. The two jaws of the radius rod span the link inside of the yokes in a way that will be understood by comparing Figs. 1, 17 and 18. The method of manufacture to be described applies in general to the light form of link shown in Fig. 2 as well as to the heavier type.

The first operation is the simple one of machining the sides of the rough forging from which the link is made. This is done in the planer, with the usual holding devices, as shown in Fig. 19. In Fig. 20 these forgings, which have been finished on each side to the required thickness, are laid out on horses, for marking off with a templet. The further one has the

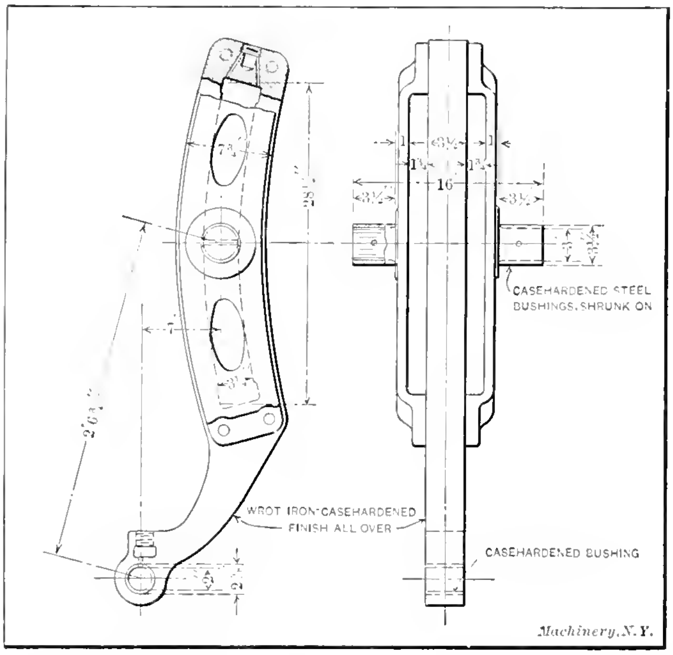

Fig. 18. Link and Mounting used for Heavy Type of Walschaerts Valve Gear

templet clamped to it as shown. From this the outline of the finished piece is scribed, together with the outline of the curved slot for the link block. The location of the pivot for the return crank rod is also indicated, as well as that of the four holes for holding on the yokes. This is an example of standard practice in this shop, where the use of an inexpensive templet saves a great deal of time in laying out work, and gives the assurance of proper location of the various machining cuts.

The slot has next to be worked out. As shown in Fig. 6, the forgings are first drilled through at the ends and in the middle of the slot, one end of the rod boring machine being conveniently employed for the purpose when not otherwise engaged. The links are then taken to the slotting machine, where the stock is roughly worked out by a parting tool as shown in Fig. 21. Two forgings are operated on at a time, with the holes lined up with each other. The parting tool is fed from one hole to the other on each side, removing thin slices of metal from the interior of the slot, and leaving it in condition for finishing to size.

Finishing the Slot of the Link

This finishing operation is performed on a link planing attachment of the usual construction, shown in use in Fig. 22. It would not be necessary to explain this device to railroad men, but for non-railroad readers the accompanying sketch, Fig. 23, will explain the principle. The link, shown at *A*, is mounted on a table *B* with T-slots on the top, which swivels about pin *C* fast in the base *D*. The swiveling of this table is governed by a stud *E* having a roller engaging a swivel guide *F*, clamped to the under side of the ram, or traveling head of the shaper. By setting the guide *F* to the proper angle, it so swivels the work about pivot *C* that the tool *G* will cut to a line closely approximating the true arc of a circle.

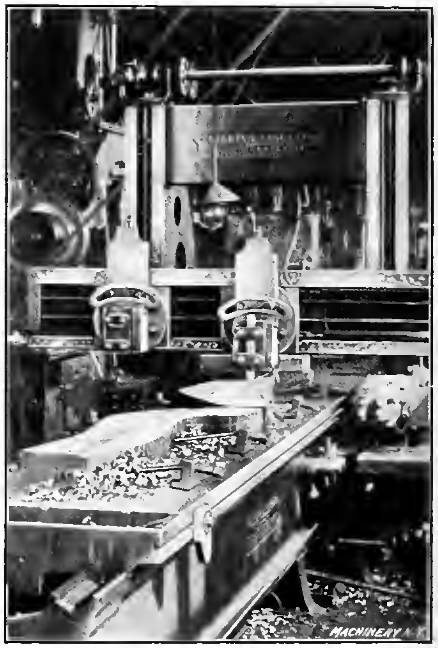

Fig. 19. Planing the Forging for the Links

The diagram Fig. 23 shows the mechanism as applied to the planer rather than to the open-side shaper, inasmuch as it shows guide *F* and tool-point *G* stationary, while the work *A* and work-table *B* are moving backward and forward. The principle is, of course, the same as in the case shown in Fig. 22, where the work-table *B* is stationary and the guide *F* reciprocates with tool *G*, swiveling table *B* and work *A* about stationary pivot *C*. It should be noted that whenever the tool is changed in this attachment for any reason, it must always be set up again with dimension *X* (the distance from the tool-point to the center of the swivel of guide *F*) always the same. If this distance is altered, the radius and position of the arc are changed.

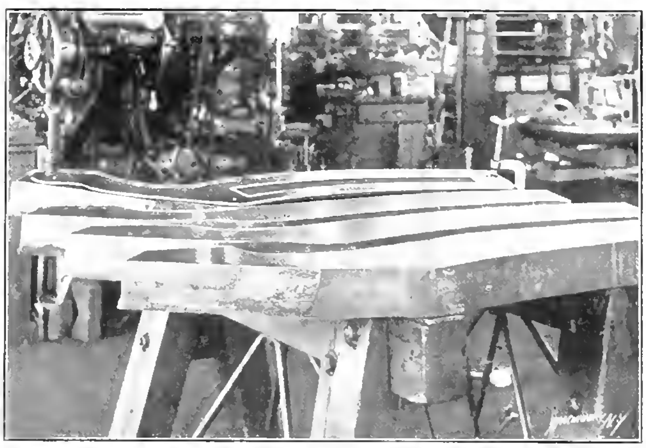

Fig. 20. Laying out the Links with Sheet-iron Templet

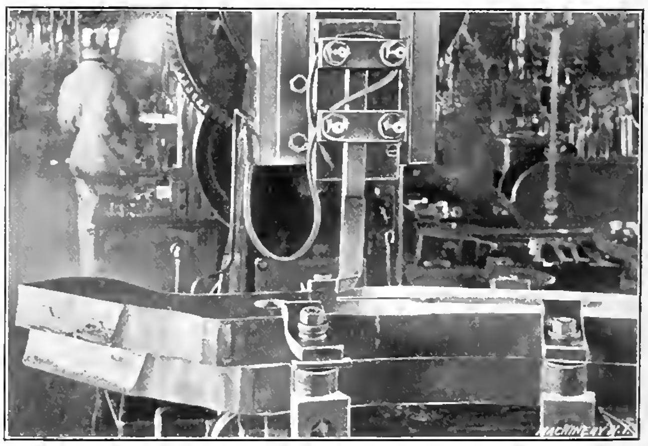

Fig. 21 Slotting the Links Two at a Time after Drilling as in Fig. 6

Inasmuch as the surfaces of the link, thus finished, are approximate and not exactly true, it is customary to finish them more nearly to absolute truth. This is done by grinding on the radius grinder to fit a good bearing with the templet shown in Fig. 24, which is itself accurately machined to the proper radius, and to the proper thickness. It should have been mentioned that the pockets at the ends of the slot have been cut out in a succeeding slotting machine operation to that shown in Fig. 21. These pockets give room for the shaper tool to run out into, as in Fig. 23.

Drilling and Finishing the Link

The slot in the link being the important surface, succeeding operations of importance are located from it. The next thing to be done is the drilling of the holes for the connection with the return crank rod. This operation, which is not shown here, is performed by means of a simple jig, located by a templet fitting the link slot, and carrying a bushing in the proper position for the hole.

The outline of the link has next to be finished. This is

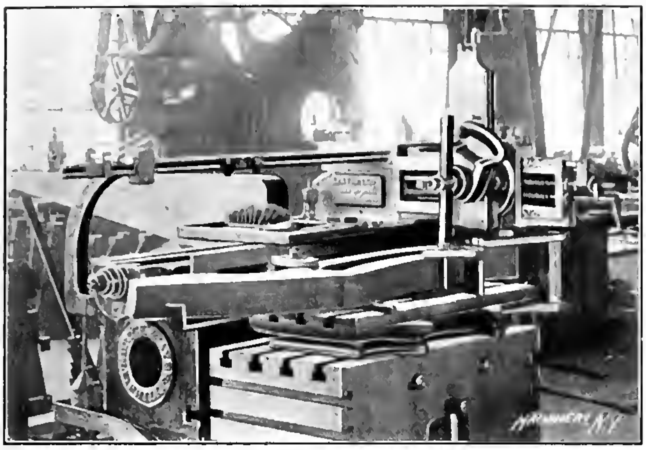

Fig. 22. Planing the Slots in the Links with the Special Planer Attachment

done as shown in Fig. 25 in a vertical milling machine, the table being rotated and fed by hand or power as required, following the outline scribed by the templet. Two links at a time are machined in this way, taking up nearly the full width of the cutter shown in use. They are lined up with each other by a pin through the return crank rod connection hole, and by lining up the sides of the slots.

The oil holes have next to be drilled, and the bolt holes for attaching the yokes. In the case of Fig. 18, the bolt holes are drilled in a way similar to that employed for drilling the return rod connection—namely, by means of a jig carrying a templet which fits the slot, and is provided with a bushing set at the proper relation to the templet. The yokes themselves, shown

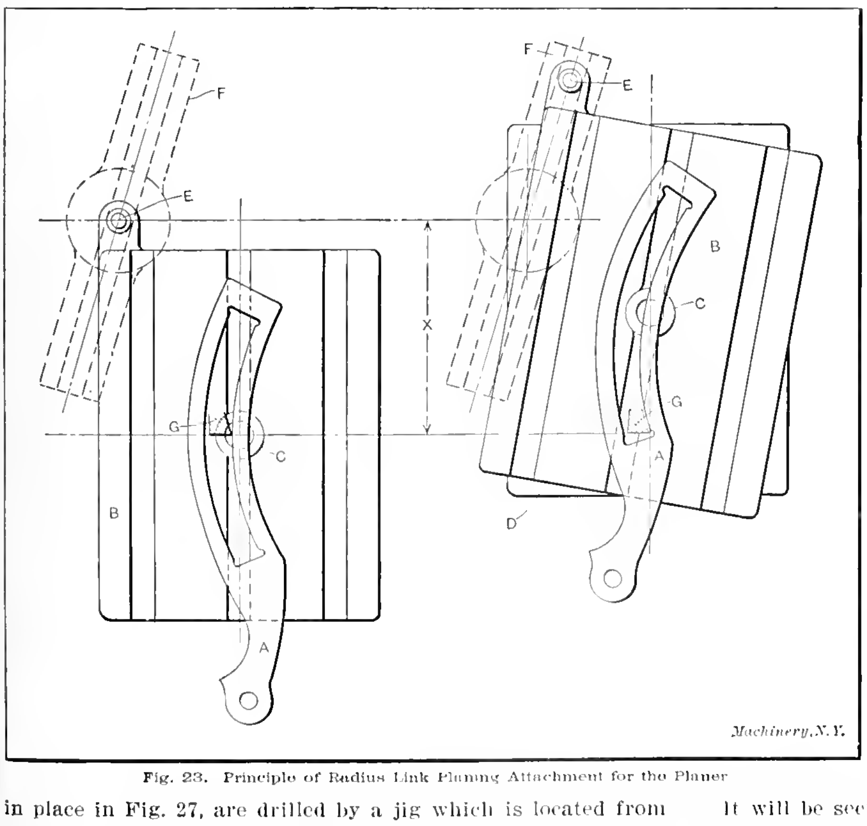

Fig. 23. Principle of Radius Link Planing Attachment for the Planer

in place in Fig. 27, are drilled by a jig which is located from the pivots on which the yokes swing. The holes for holding together the yokes and link are thus so located that the pivots are in the proper position with relation to the slot, and thus are in line with each other as well. These positions and the location of the holes for the return crank rod being the important dimensions, are all located from the slot of each link, and so are in the proper relation to each other.

Fig. 26 shows the method of locating the saddles or pivot supports used for the link on the light type of valve gear shown in Fig. 2. Here a fixture *J* is set into the link slot which fits it snugly, and is provided with pockets for receiving the saddles *H*, which are thus accurately located from the journals of the pivots. When thus located each is held in place by a set-screw as shown. The whole attachment is now slid along through the slot until it makes contact with the distance piece *K*, which is mounted on a stud fitted in the return crank rod hole. By this means, the pivots are located as they should be, with proper reference to the slot, and with proper reference to the return rod connection.

After the yokes in Fig. 27 and the saddles in Fig. 26 have been drilled and bolted into place, the outlines of these members are finished off to match evenly with the outlines of the link, making a good smooth job. Figs. 27 and 28 show a com-

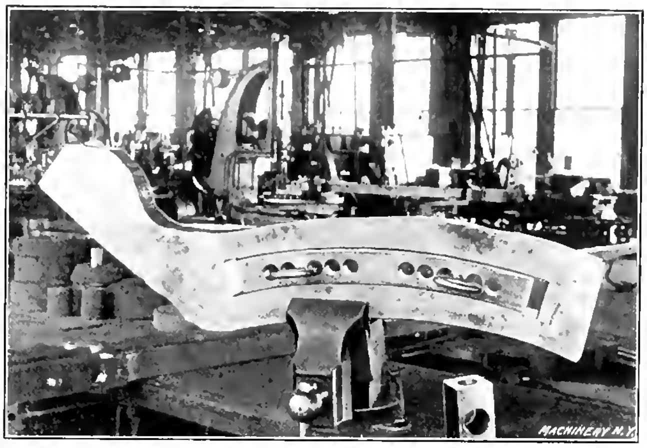

Fig. 24. Templet used for Finishing the Slot in the Link to accommodate the Radius Rod

pleted link of the heavy type, with the block in place ready for assembling in the locomotive.

Manufacturing Methods in Locomotive Building

Locomotives are built at Altoona on a manufacturing basis. When we make this statement, the words "manufacturing basis" mean something different than they do when we say that typewriters or machine tools are so built. In fact the term has a different meaning for all three cases. Manufacturing methods in building locomotives do not involve the use of jigs and fixtures for finishing all the massive parts of which the great machine is built. Jigs and fixtures large enough to do this would be prohibitive in size and cost, and practically no advantage would be gained from their use in any event.

The "manufacturing basis" on which the locomotive is built involves the use of templets for laying off all important outlines, holes, etc. Comparatively few holes are drilled in jigs, those so drilled being mostly the ones on which the accuracy of the valve gear lay-out depends, such as the radius rod and yoke connections in the link we have just described. In locomotive manufacture large use is also made of fixed gages for all the vital measurements of the frame, axles, etc., and for such other parts as are likely to require renewal. These parts are thus practically made on the interchangeable plan, though no such extreme of refinement is needed as that necessary in making typewriter parts interchangeable.

It will be seen that the tools required for this manufacturing work are of the simplest possible nature. The templets are made of sheet iron; the gages are made from bar steel, drawn down and ground at the points to the proper dimensions; and the fixtures are, in general, of a rugged and simple construction. By following this plan, the expense for tools is of comparatively small importance, even when building only

two or three locomotives of a kind. At the same time advantage is taken of about all the benefits of accuracy and interchangeability which can be secured on such large work.

The New K-2 Pacific Type Locomotive

It may be interesting to give a few particulars of the locomotive shown in Fig. 1. This is, as may be seen, of the Pacific type, which has come to be a standard machine for hauling the heavier high-speed passenger trains. The Pennsylvania R. R. has hitherto been able to maintain the schedules on its passenger runs with locomotives of the Atlantic type (see Fig. 2) of considerable lighter weight than other roads had found necessary for the same purpose. It was decided, however, a short time ago, to experiment with heavier machines, and the K-2 locomotive shown herewith is the result. This is probably the heaviest passenger locomotive ever built, outside of the Mallet articulated machines furnished to the Santa Fé, which are in a class by themselves.

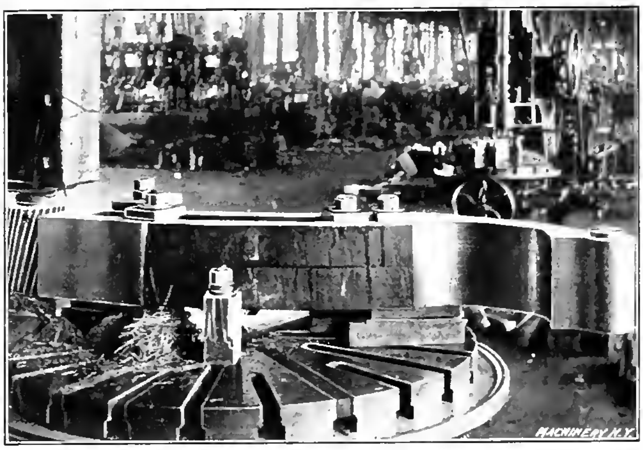

Fig 25. Outlining the Links in the Vertical Milling Machine

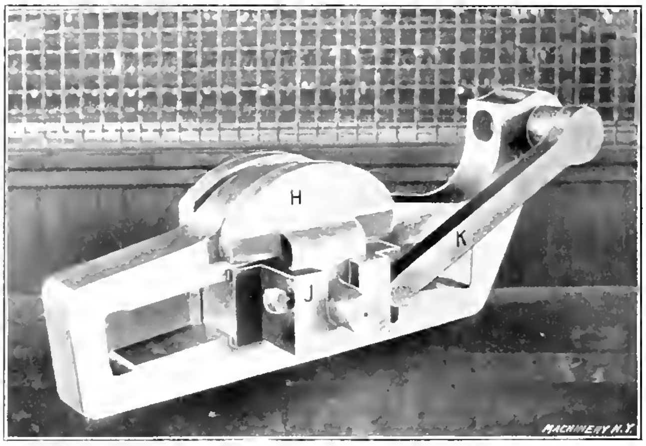

Fig 26. Jig used for Locating Pivot Saddles on Atlantic Type Link

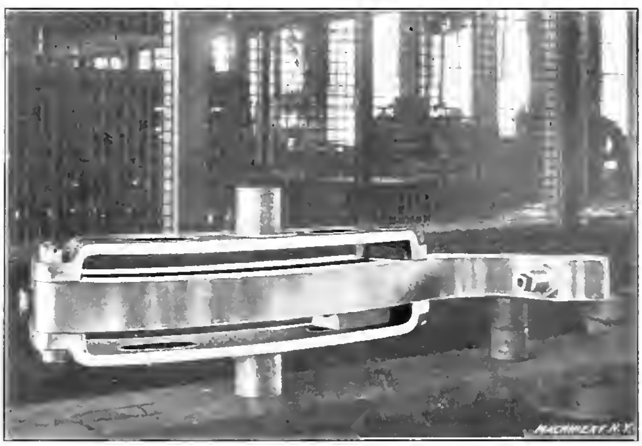

Fig 27. Complete Pacific Type Link with Yokes in Place

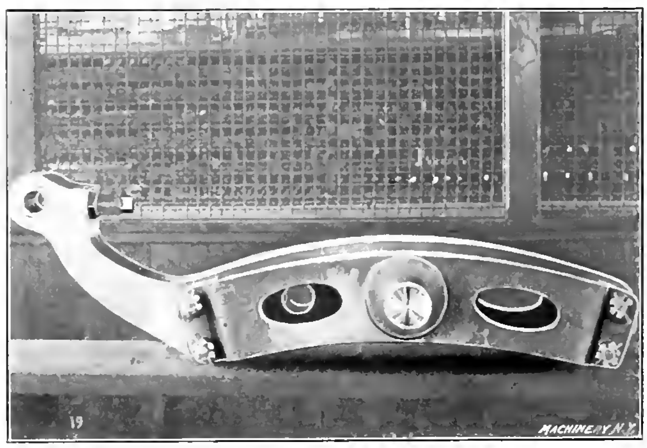

Fig. 28. Another View of the Finished Pacific Type Link

The total weight of the engine alone is 270,000 pounds, of which 176,500 pounds are on the driving wheels. The wheels are 80 inches in diameter. A straight boiler is used 80 inches in diameter at the front end. The grate area is 61.8 square feet. The total heating surface is 4427 square feet. The cylinders are 24 inches in diameter with a 26-inch stroke. The total cylinder horsepower developed is something over 2000, giving about 134 pounds weight per horsepower for engine and boiler. Comparison with any figures which might be taken from stationary practice of similar size would show a tremendously higher ratio than this, giving a good idea of the high degree of specialization which has been reached in locomotive design.

The diameters of the wheels and boiler are so large that even the liberal clearance allowed by the Pennsylvania R. R. have necessitated the shortening of the stack and domes to an unusual degree. On some roads, like the New Haven or the Boston & Albany, everything would be sheared off clean from the top of the boiler the first time the engine ran under a highway bridge. The engine does not show its size in the picture on account of the large diameter of the driving wheels and high clearances allowed. The writer saw it on the testing plant and there it looked imposing indeed. The experiments with the first example of this kind have been so satisfactory that a number are being built for service on various sections of the road, east and west of Pittsburg, with the idea of giving them a more extended trial.

INTERNATIONAL RAILWAY GENERAL FOREMEN'S ASSOCIATION CONVENTION

The sixth annual convention of the International Railway General Foremen's Association was held at the Grand Hotel, Cincinnati, Ohio, May 3-7. C. H. Voges, of the Big Four, Bellefontaine, Ohio, was elected president and L. H. Bryan, Duluth & Iron Range Ry., Two Harbors, Minn., was re-elected secretary-treasurer. A number of interesting papers were read and one of the star events was a talk on the apprenticeship question, by Prof. Herman Schneider, of the University of Cincinnati. Three important committees were appointed to prepare reports, for the next convention, on: Methods of Shop Organization; How Can Shop Foremen Best Promote Shop Efficiency, and Why Should the Press Fit of the Axle be Larger than the Journal; the respective chairmen being D. E. Barton, Santa Fé, Topeka, Kans.; F. C. Pickard, C. H. & D., Indianapolis, and Stephen Motta, Nat. lines of Mexico, Aguascalientes, Mexico.

About sixty supply men had machines and samples on exhibition. The next, or seventh, annual convention will be held in Chicago.

* * *

It is stated in the *Electrical World* that of the 5,000,000 horse-power actually represented by the Niagara Falls, only about 5.5 per cent, or about 270,000 horse-power, has been thus far utilized. Of this, 126,000 horse-power is employed in electro-chemical processes, 56,000 horse-power for railway service, 36,400 horse-power for lighting, and 45,500 horse-power for various industrial services. Nearly 125,000 horse-power is transmitted to points more than ten miles from the falls. Of this amount 12,300 horse-power is transmitted over a distance of more than 100 miles, while 33,500 horse-power is transmitted between 75 and 100 miles.

HARDENING OF CARBON AND LOW-TUNGSTEN STEELS

A research on the hardening of carbon and low-tungsten tool steels has been conducted by Mr. Shipley N. Brayshaw of Manchester, England, and the results of his investigations were presented to the Institution of Mechanical Engineers at the April 15, 1910, meeting. Some of the conclusions arrived at in these investigations are of general interest to all who have to do with the hardening of steel and the effect of this process on its structure, cutting capacity, and strength.

The paper deals exclusively with the results obtained from two kinds of carbon tool steel that, except for minute variations, differed only in the fact that one of them contained about 0.5 per cent of tungsten. The steel contained on an average of 1.16 per cent carbon, 0.15 per cent silicon, 0.36 per cent manganese, 0.018 per cent sulphur, and 0.013 per cent phosphorus. The whole work of investigation was devoted to questions directly connected with machine shop hardening, with the aim in view of throwing light on the many problems met with in daily practice.

Hardening Temperatures

The hardening point of both low-tungsten and carbon steel may be located with great accuracy, and the complete change from soft to hard is accomplished within a range of about 10 degrees F. or less. After the temperature has been raised more than from 35 to 55 degrees F. above the hardening point, the hardness of the steel is lessened by further increases in the temperature, provided the heating is sufficiently prolonged for the steel to acquire thoroughly the condition pertaining to the temperature. There is a "change-point" at about 1615 degrees F. in low-tungsten steel and at a somewhat higher temperature in carbon steel. One of the several indications of this change-point is the shortening of bars hardened in water at temperatures below that point, whereas the bar lengthens if this temperature is exceeded at the time of quenching. Practically the same results are obtained by heating low-tungsten bars to any temperature from 1400 to 1725 degrees F. and quenching in oil, as by quenching in water.

Length of Time of Heating

Regarding the effect of heating to various temperatures for various lengths of time before quenching for hardening, the following conclusions are drawn: Prolonged soaking up to 120 minutes at temperatures at which the hardening change is half accomplished in 30 minutes, does not suffice to complete the change. Prolonged soaking for hardening at a temperature of 1400 degrees F. has a slightly injurious effect on the steel, but does not materially influence the hardness. At a temperature of about 1490 degrees F. a great degree of hardness is attained by quick heating, but the hardness is impaired with 30 minutes soaking. Prolonged soaking for hardening at a temperature of about 1615 degrees F. has a seriously injurious effect upon the steel. A specially great degree of hardness may be obtained by means of soaking at a high temperature, such as 1615 for a very short time, but even as long a time as 7½ minutes is long enough to seriously impair the hardness.

The temperature of brine for quenching is of considerable importance. Both low-tungsten and carbon steel bars quenched at 41 degrees F. were decidedly harder than bars quenched at 75 degrees, and quenching at 124 degrees F. rendered the bars much softer.

Effects of Previous Annealing

The method of previous annealing affects the hardness of steel considerably. The elastic limit of low-tungsten bars hardened at either 1400 or 1580 degrees F. varies according to the annealing they have undergone. The elastic limit is high after annealing at about 1470 degrees F. for 30 minutes, or 1290 degrees F. for 120 minutes, but it is seriously impaired by annealing at 1470 degrees F. for 120 minutes. If low-tungsten steel is annealed at 1725 degrees F. and hardened at 1400 degrees F., the elastic limit is inferior, and the adverse effect of the previous annealing is much more pronounced if the hardness is done at 1580 degrees F. The elastic limit of carbon steel annealed at any temperature between 1290 and 1725 degrees F. and hardened at either 1400 or 1580 degrees F. does not vary by nearly such great amounts as the elastic limit of the low-tungsten bars, and the highest annealing temperature given above is not injurious so far as the elastic limit is concerned.

The hardness of low-tungsten bars hardened at 1400 degrees F. decreases from a high scleroscope figure to a low one as the temperature of annealing increases from 1290 to 1725 degrees F. The hardness is increased by prolonging the annealing at the lower temperature. The hardness of low-tungsten steel hardened at 1580 degrees F. is fairly constant at a moderately high scleroscope figure, whatever the temperature of annealing.

Effect of Heating in Two Furnaces

An interesting part of the experiments relates to the use of two furnace heats for hardening, heating the steel first in one furnace to a certain temperature for a given time, and then immediately, without cooling, soaking in a second furnace at a known temperature and for a definite time. These experiments show that low-tungsten and carbon steel bars heated for half an hour to temperatures between 1545 and 1650 degrees F. are not much affected so far as their elastic limit and maximum strength are concerned by a further immediate soaking for half an hour at 1400 degrees F. If, however, the temperature in the first furnace is 1725 degrees F., the low-tungsten steel is much improved by a further soaking at 1400 degrees F., but the carbon steel is much injured by the same treatment. Bars of low-tungsten steel heated for 30 minutes at 1616 degrees F. and then soaked at 1332 degrees F. for a further 30 minutes, give a high elastic limit and maximum strength, and are harder than if the second soaking were at a temperature of 1400 degrees F. The carbon steel, again, is but little affected by these variations in the second furnace.

The change of length in hardening, however, of both low-tungsten and carbon steel is much affected by the above variations in the temperature of the second furnace. Good results as regards elastic limit and maximum strength, and also as regards hardness, are obtained by very short soaking, first at a high temperature, say 1615 degrees F., and then at a low one, the results being best when the second temperature is near to or a little below the hardening point. If the furnace be at a sufficiently high temperature it is easy either by variations of the temperatures of the two furnaces, or by variations in the time of soaking, to arrive at a treatment of the steel, both low-tungsten and carbon, whereby they neither lengthen nor shorten. Under the same treatment carbon steel has a greater tendency to shorten than low-tungsten steel.

Miscellaneous Results

Other experiments showed that low-tungsten steel heated to 1580 degrees F. for 15 minutes and quenched in oil has a higher elastic limit and is harder than carbon steel similarly treated. As regards annealing, it was found that bars annealed at a temperature of 1470 degrees F. or below became slightly shorter by the annealing process, and its action was more pronounced in the case of carbon steel than tungsten steel. Annealing at a temperature of 1650 degrees F. causes both low-tungsten and carbon steel to lengthen.

It was found that recalescence of low-tungsten steel takes place gradually at a temperature of 1348 degrees F., and more readily at 1337 degrees F., and further that the recalescence at either of the above temperatures is very much retarded if the steel is cooled from a maximum heat of 1634 degrees F.

Regarding hardening cracks, it is shown that both for low-tungsten and carbon steel, such treatment as produced the highest elastic limit accompanied by the greatest hardness is frequently the most risky. The risk of hardening cracks is reduced if the steel is heated for a sufficient length of time to a temperature of 1650 degrees F. or a little above. Low-tungsten steel is more liable to crack in hardening than is carbon steel.

Effect of Tempering

Tempering experiments showed that little effect was produced by the tempering of carbon steel to 300 degrees F. for 30 minutes. Tempering the same steel to 480 degrees F. for 15 min-

utes, however, caused it to soften considerably and to shorten in length. For low-tungsten steel the elastic limit was increased considerably by tempering up to a temperature of 480 degrees F. The maximum strength of the same steel coincides with the elastic limit for bars either untempered or tempered at 300 degrees F. for 15 minutes, but it then rises rapidly with further tempering. The hardness, as measured by the scleroscope, was considerably reduced by tempering at 300 degrees F. and still more at 390 degrees F., but was not so much affected by further tempering at 480 degrees F. The length of the low-tungsten bars was reduced by tempering up to a temperature of 480 degrees F.; the higher the temperature, the greater was the reduction in length.

Effect of Tensile Strength

The following conclusions refer to low-tungsten steel, but there is no reason to doubt that they are also applicable to carbon steel. A variation in the hardening temperature of only 9 degrees F., the extremes being respectively above and below the proper hardening temperature or decalescence point, has a tremendous influence on the extension under load, but the maximum strength of the bars so treated did not differ much. A very good bar was produced by quenching from a temperature fully 108 degrees above the hardening temperature. A heat of only 5 minutes' duration produced a harder bar than a heat of 25 minutes, the maximum temperature in both cases being 1470 degrees F., or a little above; but the bar heated for a shorter time gave a much lower elastic limit. The maximum strength alone is not necessarily any indication of the condition of the steel in question, or of the treatment to which it has been subjected; nor is the hardness alone necessarily an indication of the condition of the steel or the treatment.

The following conclusions refer both to tungsten and carbon steels. Tempering up to a temperature of 570 degrees F. gradually increases the maximum strength and the elastic limit, although some irregularities enter which have not been fully accounted for. Tempering to this temperature reduces for a given stress the extension under load and the permanent extension.

Conclusion

In conclusion it may be stated, that these experiments show that steel of the quality treated in these experiments may be hardened within a temperature range of about 215 degrees F. The lower end of this range is very sharply defined, but the highest temperature allowable is difficult to determine, and as far as the appearance of the fracture is concerned there is little evidence of improper hardening until the temperature of the proper hardening point has been exceeded by 270 degrees F. So wide in effect is the margin of allowable variation for hardening that when the hardness is decided by the appearance of the fracture alone, any workman of average skill can easily keep within the limits and judge the temperature by sight alone, and as a matter of fact this is being done all the time in the manufacture of such articles as pocket knives, small files, etc., which are hardened by the thousands with practically no waste. But, of course, it must not be understood that articles so hardened reach anything like their maximum efficiency, because even small variations in the heat treatment previous to the quenching have a pronounced effect upon the condition of the steel, and even the previous treatment, such as the annealing to which the steel has been subjected, may influence the final result.

While it is thus easy to harden so as to obtain reasonably *good* results, the production of the *best* results given necessitates a degree of accuracy which can never be obtained by sight alone, and it is also important to notice that the difference between good hardening and the best hardening is very great.

As an example may be mentioned the hardening of razors. It is sometimes said that whatever price one pays for a razor, the buying is a game of chance. Occasionally one hears of a remarkable razor that holds its edge as if by magic, while others of the same make and type may not be anywhere near as good. All of them, however, would show to the eye practically the same fracture, and apparently seem to have been treated in the same way. The experiments referred to above, however, indicate that there may have been a slight difference in the hardening temperature and consequently in the subsequent condition of the steel, and also that it would be possible to harden every razor in a gross so that each one would be truly a duplicate of the best. The same, of course, holds true of a great number of other tools.

The author concludes by saying that there have, for some years past, been efforts of steel makers to discover new alloy steels, and splendid success has been obtained in this direction, but there is still a wide field for the steel users for discovering the best use of the material already known. It is of little avail that occasionally tools show marvelous results, unless the hardener can at any time produce the same results with the same steel. The time is likely to come when all the factors in the hardening of tool steel will be controlled with accuracy within predetermined limits, and any failure may be investigated and the cause located with as much certainty as if a mistake had been made in the machine shop.

* * *

FROGS, SWITCHES AND CROSS-OVERS*

As a rule, men who are primarily interested in machine construction are, for obvious reasons, not very well informed on track work. It often happens, however, that draftsmen, superintendents and others who have no training in this class of work are required to lay out, approve, or order industrial track systems to be used inside of a machine shop or in the yards outside. It is then necessary to decide upon the various details in connection with the frogs and switches, and some elementary information relating to this work will undoubtedly be of value to any man who is, or expects some day to be placed, in a responsible position where he may be occasionally called upon to carry out work of this character.

Switches are used for leading the wheels of cars from the main track onto a turn-out track. It is evident that when the outer switch rail reaches the opposite main rail, the wheel flange must pass through the main rail. The device by means of which the rail of the turn-out curve crosses the rail of the main track is called a frog, the general appearance of which is as shown in Table I of the accompanying Data Sheet Supplement. Frogs are made of various dimensions, determined by the angle of the frog, that is, the angle which the main rail gage line makes with the turn-out rail gage line at the point where these lines cross each other. Frogs of different angles are known by numbers, and a table is given in the accompanying Supplement of frog numbers with their corresponding angles, the numbers being given from $1\frac{1}{2}$ up to 20. Formulas are also given by means of which the frog number can be found when the angle is known, and the angle found when the frog number is known. As shown in the Data Sheet, dimension L is the length along the center line. This is, theoretically, the correct dimension to be measured for determining the frog angle. In practice, however, the length is usually measured along the gage line, because of convenience in taking the measurement in this way. As the angles are small, approximately correct results are obtained by inserting the dimension thus obtained in place of L in the formulas.

A circular turn-out is shown in Table II of the Data Sheet. In the illustration the various dimensions, such as theoretical lead, actual lead, radius, etc., are defined, and formulas for finding each are given. When a turn-out of this kind is being laid out, the angle can be determined when the radius and the gage are known, and when the angle has been found the corresponding frog to be used, as defined by its number, is determined from the table already referred to. The lower part of Table II gives formulas for a turn-out using straight frog and switch. In this case the formulas are somewhat more complicated than in the simple circular turn-out.

In Table III is shown a diagram of a three-throw turn-out, and formulas are given for determining the angle between the outer rails of the two turn-out curves. In the lower part of the same table is a diagram of a double cross-over with straight crossing and curved switches, and also for a double cross-over with reverse curve, formulas for the required angles and dimensions being given for both. In Table IV some of the dimensions which can be found by

* With Data Sheet Supplement.

the formulas given in the previous tables have been tabulated and collected for six different gages. These tables give the radius in feet, the angle in degrees and minutes and the theoretical lead in feet and inches. A special table for 4-foot $8\frac{1}{2}$-inch, or standard gage, is also included, which gives the number of frog, the corresponding angle, the theoretical lead, the radius of the turn-out curve and the degree of the curve.

The expression "degree of curve" may require some explanation to persons not familiar with railroad track work. The degree of a curve is the center angle that would be subtended by a chord 100 feet long. For curves from 1 to 10 degrees the radius may be found by dividing 5,730 feet, which is the radius of a one-degree curve, by the degree of the curve. The results are sufficiently accurate for all practical purposes, but for sharp curves, that is, for those exceeding 10 degrees, the following formula should be used:

$$R = \frac{50}{\sin D}$$

in which R = the radius of the curve, and

D = the angle of the curve in degrees.

It is evident that the degree of a curve has nothing to do with the length of the arc of the curve, but merely with the length of the radius. The shorter the radius, the greater the degree of the curve. The last-mentioned table may be used for finding the corresponding dimensions required for the use of a frog of a certain number, or it may be used for finding the required frog when any of the other dimensions are given. As the tabulated data in Table IV give the dimensions for the most commonly occurring conditions, it will save considerable calculation in laying out frogs and switches.

* * *

The gold production in 1909 exceeded that of 1905 by \$15,000,000. The total amount of gold mined is valued at over \$450,000,000, of which the United States furnished about \$100,000,000, Africa \$170,000,000, and Australasia \$72,000,000.

DRAFTING-ROOM OF THE TAFT-PEIRCE MANUFACTURING CO.

The Taft-Peirce Mfg. Co., located at Woonsocket, R. I., has recently refitted its drafting department, and now has a model drafting-room and equipment. This company is unique in New England in the respect that a very important feature of its business is the development of new inventions from ideas furnished by inventors and their promoters. Work of this character renders essential a highly organized engineering force, and to provide this force with adequate and suitable quarters the company established the conveniences described.

Two things are of prime importance in a drafting room, the lighting and the drafting tables. If the best work is expected, the draftsman must have a good table for his work, as well as adequate light, properly distributed. In the case of the Taft-Peirce Mfg. Co., the lighting has been provided for by placing the room in a second-story wing, thus affording natural lighting on three sides through large windows located at even intervals which make the wall space about equal in width to the window. The artificial lighting is provided for by Cooper-Hewitt mercury vapor lamps hung from the ceiling and by tungsten drop lights, two for each table. The drop lights are all at a fixed height, and remain in that position at all times. It is expected, however, from what has already been learned by use that the drop lights will probably be dispensed with and that the vapor lamps will be sufficient for all artificial lighting. The walls and ceiling are painted with white enamel waterpoof paint, which can be wiped clean, and which does not absorb light.

The tables, which are the most striking feature of the equipment, were built by the Washburn Shops of the Worcester Polytechnic Institute. An illustration and description of this table was published in MACHINERY, November, 1909. Each table is provided with an automatic releasing and locking rise and fall device which permits tilting to any angle.

Drafting-room of the Taft-Peirce Manufacturing Co.

between the horizontal and the vertical planes. The table top is provided with a parallel ruler, as will be seen in the installation shown; if desired, a drafting machine can be readily attached. In the installation shown the table tripods are screwed to the floor, a light shelf is attached to the rear of the tripod posts, and is used to lay handbooks, extra drawings and tools upon. With the automatic rise and fall device, it has been found more convenient to raise or lower the table top to or from the drop light than to adjust the cord, and the absence of loops or adjusting devices in the cords greatly improves the appearance of the room.

Toilets, wash- and coat-rooms are provided. It will be noted that each draftsman wears a white laundered coat. The blueprinting equipment consists of a continuous blueprinting machine using Cooper-Hewitt lamps. As the printing room is above the level of any nearby roofs, sun printing can be readily accomplished if desired. In taking the photograph for the illustration the camera was set up near the chief draftsman's office which occupies a corner of the main room. This office is provided with the necessary equipment for a complete system of indexing, comparing and cost-keeping so essential in engineering drafting.

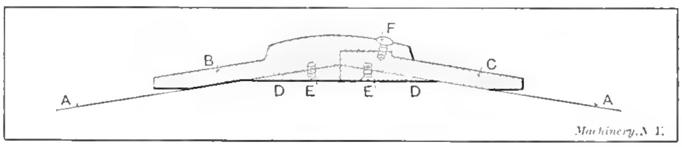
THE TRANSMISSION OF POWER BY STEEL BELTS

In a paper on the transmission of power by belts, recently read by Mr. R. Krall before the British Institution of Engineers, a number of interesting details regarding the transmission of power by steel belts were given. The use of steel belts for power transmission is a recent development, being thus far mostly applied in Germany and Belgium, and has previously been referred to in MACHINERY in the February, 1908, issue, engineering edition.

The thickness of the steel belts varies from 0.2 to 0.9 millimeter (0.008 to 0.035 inch) and the width of the belt varies from 22 millimeters to 200 millimeters (⅞ inch to 8 inches). For a 200-H. P. drive at a given speed, for example, one belt 6 inches wide by 0.024 inch thick is used. For a 440-H. P. drive at the same rate of speed, again, two belts are used, each being 6 inches wide by 0.027 inch thick. One of the first difficulties met with in the production of steel belts was that of producing a perfectly homogeneous metal. The material for the belts now is made of specially manufactured steel of high tensile strength. Another difficulty met with has been the proper construction of the joint between the ends of the belt. An ideal drive would, of course, be obtained by the employment of a continuous steel band, but there are many difficulties in the way of the production of such a belt and its cost would be prohibitive. It would be more difficult to handle and transport, and would often present great difficulties in mounting on the pulleys. A joint as shown in the accompanying illustration is, therefore, adopted. The belt is soldered to the joints at the factory, and the user, when putting the belt in place, has only to insert a few screws. In the illustration, *A* indicates the steel driving belt, *B* and *C* are the two halves of the joint, and at *D* are shown two small triangular filling pieces. Two rows of small screws *E* secure these triangular pieces to the belt and to locking pieces *B* and *C*. At *F* is indicated a row of larger screws uniting the locking pieces. All that has to be done when putting the belt in position is to insert the screws *F*.



Construction of Joint for Steel Belts

It will be noticed that the locking pieces are prolonged for a considerable distance beyond the joint proper. This construction is the result of experience, as it was discovered that when this additional length of the locking pieces was not provided the belt broke near the small triangular pieces *D*. A small curve is provided on the under surface of the joint, but it is very slight, the joint being nearly flat. In order to determine the length of the belt a special apparatus is used by means of which a light tape of steel is placed over the pulleys and subjected to a predetermined tension, the two ends being drawn together and permitted to overlap. Both ends are then cut through at the same point and a band the exact length of the required belt is obtained. The manufacturers make the length of the belt to this gage.

The steel belts run fairly well on smooth cast iron pulleys, but after a time there is a tendency to polish the surface of the pulleys and it has been found desirable to cover them with a thin cork covering which is glued to a piece of canvas which, in turn, is cemented to the pulleys. There is practically no slip whatever on pulleys treated in this way, and the cork covering does not wear away.

Tests undertaken at the Charlottenburg University with these belts indicate that it is the best practice to use an initial tension of 10,000 pounds per square inch of section of belt. The belts were run in these tests at velocities ranging from 3000 feet per minute to 7000 feet per minute, and the percentage of slip varied from 0.036 per cent to 2.2 per cent, the average being about 0.55 per cent.

Although this method of driving by steel belts is too new to have fully established its claims, some thousands of steel belts are already in use, and no doubt the system must be regarded as having an important future. According to figures published by the manufacturers of the steel belts, a steel belt 4 inches in width will transmit the same power as an ordinary leather belt 19 inches wide, or as 6 ropes with 1¾ inch diameter each. The weight of the driving pulleys as compared with those for leather belting is but one-half, and as compared with those for rope drive is hardly more than one-quarter. The total cost of steel belting installed is stated to be 60 per cent less than that for leather belting, and 33 per cent less than that for rope driving, while the loss of power through slippage is almost negligible with steel belting. Steel belts, therefore, appear to have some considerable advantages over those of other materials. They do not stretch, and therefore never have to be taken up. Very high speeds, up to 10,000 feet per minute, may be employed. The belts apparently do not wear, due to the fact that they do not slip. Short drives may be used, and the pull on the bearings and the consequent wear is reduced on account of the decreased weight of pulleys.

On the other hand, the material in the steel belts may not prove as reliable, although this point is speedily being remedied, and it can be added that steel belts have been in continual successful use for over two years. Another consideration is that unless properly guarded these belts would be extremely dangerous if failing when running at a high speed, and the necessity of having to be extremely careful about the exact length may sometimes prove troublesome. The belt must be extremely well applied to insure that the power is evenly distributed over the full width of the steel band, as otherwise excessive stresses would be set up at one edge, and the belt would then be stressed at this point beyond its breaking strength with the result that the whole belt would fail.

* * *

Attention is called in the *Zeitschrift des Vereines deutscher Ingenieure* to the development in the building of motors for airships and aeroplanes. It is stated that the Daimler-Motoren-Gesellschaft, Untertürkheim, Germany, in 1890 built a 5-horse-power motor for an airship, the weight of which was seventy pounds per horse-power. This year the same company has built a 115-horse-power motor for a flying machine in which the weight per horse-power is only 4.8 pounds. It will be remembered in this connection that the weight per horse-power of the Adams-Farwell aeronautic gasoline motor, described in the engineering edition of MACHINERY, July, 1908, is only 2.7 pounds per horse-power.

* * *

The Santos-Dumont new monoplane flying machine, which is fitted with wheels driven by the engine, so that it can run on the road as well as fly, and which weighs complete only 242 pounds, is being built by the French Clement Co., and sells at $1,250 each. This price apparently brings the flying machine into direct competition with the automobile.

WOODEN DRAWINGS

By W. H. SARGENT

The boss patternmaker had put a bit into an upright drill and was boring furiously into a block of wood. "What are you making, chips?" I asked. "No, I'm making a wooden drawing," he replied. "You see, here is the blueprint of a pattern. It needs four views to show the thing up. The back side view is projected n an angle to show a diagonal brace and it is all covered over with dimensions, until no man in the shop can read it. Now I am trying to rough out something which will show the shape so that a man will know just what he is trying to do. It isn't a model, nor a pattern. It is something to work by the same as a paper drawing, so I call it a wooden drawing."

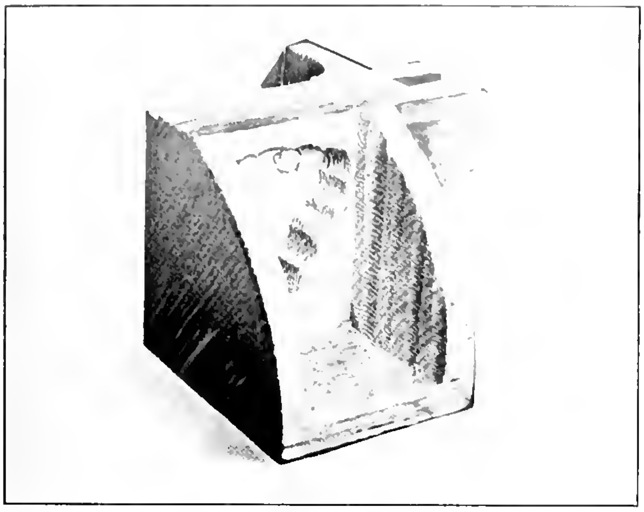


Fig 1. Example of a Wooden Drawing

He handed me the article shown in Fig. 1 which he had grubbed out. The drawing was quarter size and he had made this the same. It was roughly done, being made entirely with a saw and a bit, but it showed what was wanted, and left nothing to the imagination.

Fig. 2 shows a "wooden drawing" of a portion of a 200-ton scale of new design. Rough as this was, it helped astonishingly to give one the sense of proportion. Instead of a number of confusing drawings, more or less incomplete and all on a flat surface, here was in effect the full-sized machine, showing not only the strength and symmetry of the various parts but their weaknesses as well. Careful examinations were made by different men to determine the handiness and accessibility of the various parts and a full discussion was held to consider the general appearance of the design.

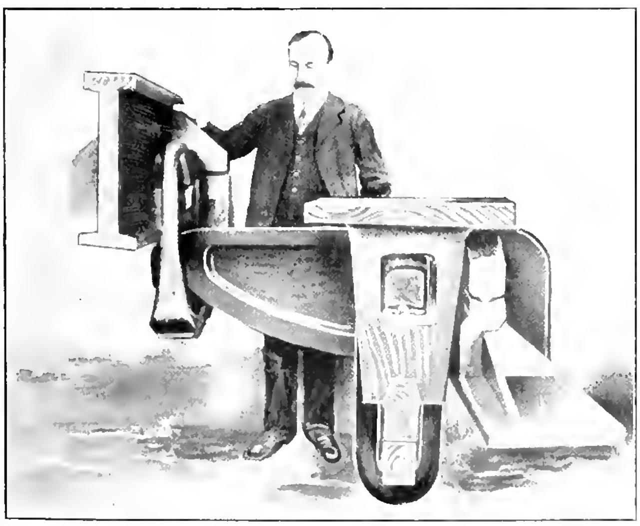

Fig 2. Wooden Drawing of Part of the Mechanism of a 200-ton Scale

No paneling was done. The model was painted a dull lead color and the effect of sunken parts was done with darker paint on a flat surface similar to Fig. 3. Perhaps none of the men concerned in getting up this scale were able to comprehend from the drawings exactly how it was going to look; whether there would be freedom enough between certain parts or whether certain other parts would interfere with each other, yet all these points were satisfactorily decided from the model without the expense of an elaborate set of patterns

Fig. 3 The Wooden Drawings are not panelled, Sunken Effects being obtained by Shading

and core-boxes or the aid of heavy castings with pivots set to a gage. The design was accepted with but very few changes. Fig. 4 shows this part of the scale somewhat modified and as finally completed and erected.

A certain bridge company spent $600 to construct a full sized model of a panel point for the purpose of familiarizing their own men with the details of the work and of impressing

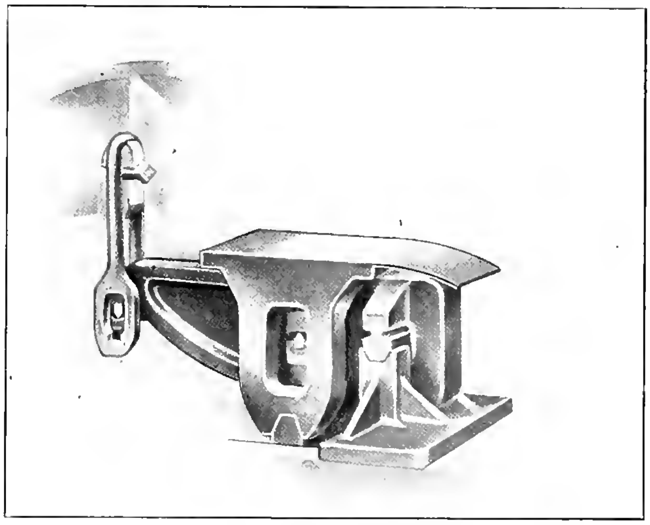

Fig. 4 Completed Design of Part for which Preliminary Wooden Drawing, Fig. 2, was made

others with its importance and magnitude—a large price for something which has no commercial value. The question arises—does it pay to put so much money into something which can neither be sold nor used? Of course it pays; in these days of commercial rivalry anything pays which enables one to find the answer before the other fellow gets his pencil

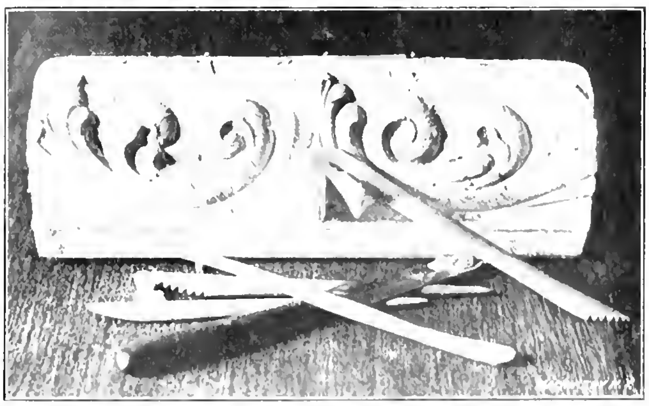

Fig. 5. Clay Model of Scroll Work and Modeling Tools

sharpened. There is no question about the commercial value of good appearances. A "good front" is a distinct financial asset, whether on the salesman or on the goods. No matter

* Address: St. Johnsbury, Vt.

how good the old machines were, the new ones are better if only "just as good," and this isn't as Irish as it may seem, because while some of the old machines may still do good work, yet their misproportions were so disguised with moldings and covered with curling curves and required so much "manicuring" that their total product was materially less than the plain and simple machines of to-day. Ornament has its place but it should not be used to disguise poor construction. "The beautiful is often as useful as the useful" and designers of the beautiful make more frequent use of preliminary models than designers of the useful. In most cases they use modeling clay, building up the design with their fingers and working out the details with the small wooden tools shown in Fig. 5.

While paper drawings are necessary, "wooden drawings" are also helpful in showing which points to emphasize and what to disguise. The Lord didn't make man with the ribs in sight but added flesh to make "the human form divine," so it is up to the draftsman to assemble the mechanical elements—the dried bones, so to speak, and clothe them with a suitable and proper dress.

BILLINGS & SPENCER CO.'S EMERGENCY HOSPITAL

The Billings & Spencer Co., of Hartford, Conn., has recently added to its plant an emergency hospital for administering "first aid to the injured." Located in a corner of the machine department, it is easily accessible from all other departments of the factory, and all injuries, minor or serious, are ordered to report there for treatment.

For a number of years the company has been doing this work in a crude and rather unsatisfactory manner, using a corner of one of the lavatories for the purpose, and keeping the outfit in a wall cabinet. The results attained have been

Billings and Spencer Co.'s "First Aid to the Injured" Hospital

such that they believed better accommodations would insure even better results; hence the recent establishment of the emergency room. The room, erected for the purpose is 12 feet by 20 feet, and is finished throughout in white enamel, which can be easily cleansed. The outfit consists of an iron enameled bed; sterilizer for both instruments and dressings; cabinet for instruments, solutions and dressings; hot and cold water equipment; stretcher for transportation of serious cases from various departments; and other minor necessities.

An injury sustained by an employe is immediately reported to the foreman of his department, who orders the case to the hospital for treatment, where it is taken care of. If the injury proves too serious, the injured is either ordered home for care by his own physician or to one of the city hospitals. A custom has been established, whereby all secondary dressings are ordered to report at 9 A. M. every day for inspection and advice.

The room is under the immediate supervision of Mr. E. J. Beams, chief clerk of the factory office, whose previous experience in hospital work fits him to have charge.

* * *

According to the *Brass World*, an addition of 2 per cent of metallic sodium to lead hardens it so that it may be used for bearing surfaces. The alloy is so hard that it rings when struck.

THE EXPERIENCES OF A YOUNG TOOLMAKER*

By T. COVEY

"Mr. Anderson," said Jim, "may I eat my lunch beside you this noon, and ask you a few questions?"

"Well, Jim, I've no objection to your company," said Mr. Anderson, "and you may ask as many questions as you like, but whether I answer them or not will depend upon my ability. I would as soon talk as not, though what I say may not amount to much. If that is satisfactory, go ahead."

"I'll take chances on that," said Jim. "I've heard several of the men make remarks about multiplying errors, and I am a little curious on the subject. I should like to know how and why it is done."

"Well, it is usually done to acquire greater accuracy, and

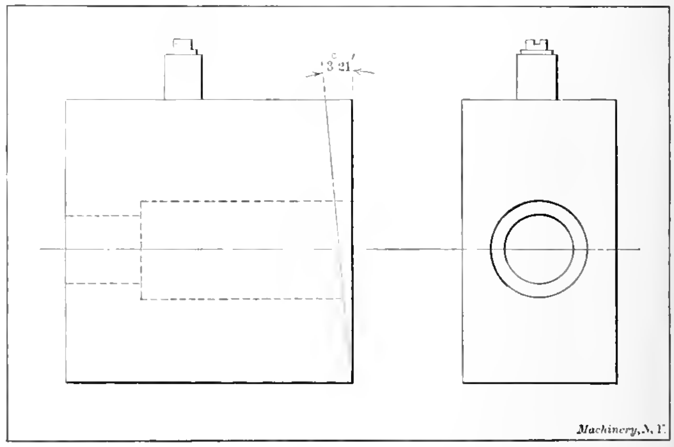

Fig. 1. Small Jig with Button Attached by which Work is set for Boring

there are innumerable ways of doing it; in fact, we have many machines and instruments for that very purpose, such as our micrometers, indicators, graduated dials, etc. However, I do not think that an explanation of them is what you want. What you have in mind is the numerous little methods and kinks obtained by practice and observation whereby we obtain greater accuracy in our work, probably the most common of which is the doubling of an error with the dividers. Suppose that I wished to lay out a radius of say 3 inches as accurate as possible, and the nearest I could be sure of getting, by setting the dividers off a scale, is within 0.0025 inch. To obtain greater accuracy than that I would scribe a straight line on a layout plate, set my dividers as near as I could to 3 inches, place one leg of the dividers on the line and with the other scribe a circle. Then taking a larger pair of dividers, or a set of trams would be better as the legs stand straighter, set one leg on the circle where it crossed the line and the point of the other where the circle crosses the line on the opposite side, using a magnifying glass to see that both points are in the proper position; then try the tram points on a scale and see what the distance between them measures. If the dividers were set right, the distance will be just 6 inches, but suppose that I am able to see that the tram points measure more than 6 inches apart, then I know that the dividers were not set right, and I proceed to readjust them; then selecting a new point on the straight line I repeat the operation. Suppose that this time I am unable to discern an error, or that the diameter of a circle scribed with the dividers is within 0.0025 of 6 inches; then, since any error that exists in the dividers would occur twice in scribing the circle, or be doubled, I know that the dividers are right within half of the least

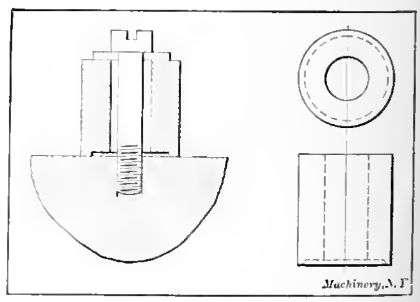

Fig. 2. Steel Bushing or Button used in Precision Work

* Previous installments of this series of articles appeared in the numbers for August and December, 1909, February and April, 1910.

error that I am able to detect, or half of 0.0025 which is 0.00125 inch. This method is practiced extensively by templet makers in laying out their work and can frequently be made use of in other ways as well.

"Here is another instance in this little jig that is lying here. (See Fig. 1.) The man that is making it has got it all squared up and a button set where he wishes to bore a hole. The next thing that he will do is to set it up on the faceplate of a lathe and chuck it true, or approximately so; then, applying an indicator to the button and revolving the lathe, note the amount that the instrument indicates that the button is out of true. This amount is just twice what the actual error is. Suppose that he is able, with the assistance of the indicator, to get the button true within ¼ of one-thousandth; he then removes the button and bores the hole; the center of the hole will not be out more than half of the amount that appeared in the periphery of the button. This can probably be best illustrated by likening it to the pin on a crankshaft which, should the distance from the center of the pin to the center of the shaft be 4 inches, would make the throw of the pin 8 inches. This would, of course, hold good down to the minutest measurements, and in the case of the button we measure the 'throw,' which is just twice the amount that the button is off center."

"I don't just understand why the button is used, Mr. Anderson," said Jim.

"Well, if you had a hole bored in that jig, for convenience say, just one inch in diameter, then if you were to put a one-inch plug in the hole and allow it to project a little it would be an easy matter to measure from the edge of the plug to the edge of the jig and add half the diameter of the plug to the measurement and thus get the distance from the edge of the jig to the center of the hole. Now suppose that instead of inserting a plug in a hole, which we can only do after the hole is bored out and its location fixed, we first lay out the hole approximately, and drill a small hole and tap it out for one of these screws that are used to fasten these buttons on with; then on fastening one of the buttons in place we have the same conditions that exist with a plug sticking out of a hole, with the exception that we can change the location of the button within certain limits, on account of the hole in the button being larger than the screw (see Fig. 2). Now assuming that we want the location of a hole very accurate, we should have the jig squared up accurately so that we can make all of our measurements from the edges of the jig; then length-rods would be made equal in length to the distance from the two edges of the jig to the center of the hole, less half the diameter of the button. Considerable care should be exercised in making these length-rods. Preferably they should be made of round cold-rolled steel, or drill rod, and they should be made like Fig. 4, with the ends faced off square between the centers of a lathe to insure their being parallel to each other. After making the length-rods and measuring them with a micrometer to make sure that they are right, one of the faces of the jig from which we wish to measure is set down on the surface-plate. The button is then adjusted until the proper length-rod can just pass between it and the faceplate. The jig is then turned onto the other surface that is to be measured from and the button is set so that the other length-rod just passes between it and the plate. These operations are repeated until the button is set so that both length-rods touch it alike from their respective sides. This is easier to do if we place a washer of paper under the button and use a fiber washer between the button and its screw head. After the button is set the jig is chucked in a lathe and the button is set to run true; it is then removed and the hole bored.

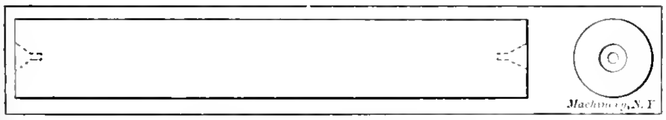

Fig. 4 Length Geges used in Toolmaking

"To return to the subject of multiplying errors, let us suppose that one side of this jig had to be machined to an angle of 3 degrees 21 minutes (see dotted line in Fig. 1). This is an angle that would be difficult to secure accurately with any bevel protractor, but with the assistance of a little trigonometry and a little ingenuity, it is an easy matter. We first take a piece of paper and lay out a triangle as shown in Fig. 3. Then figure out the height of this triangle for a certain length, say 15 inches, which represents the side adjacent to the angle. The side adjacent times the tangent equals the side opposite, or in this case the height of the angle. Looking in a table of natural tangents, we find that the tangent for 3 degrees 21 minutes is 0.05854, which, multiplied by 15, equals 0.8781, which would be the height of the angle.

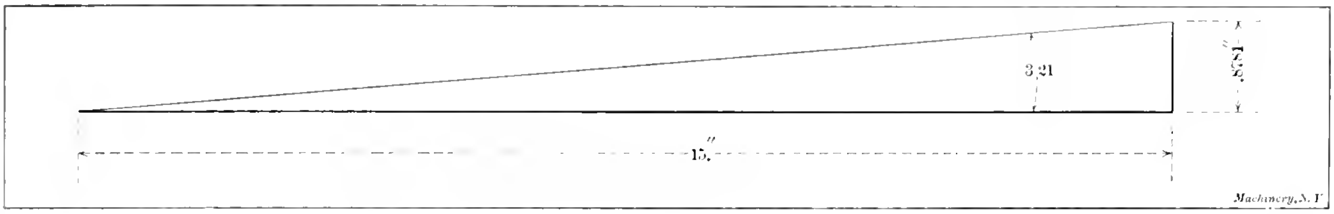

Fig. 3. Preliminary Calculation for Setting Straightedge on Machine Table as shown in Fig. 5.

"Suppose, for convenience, that we do this operation on a milling machine using an end mill. We will select a spot on the table where it will be convenient to clamp the jig securely and set it there temporarily, then get a straightedge about 18 inches long and clamp it at one end to the table so that the squared edge of the jig can be brought against it without changing its position materially (see Fig. 5); then measure from the edge of the table to the straightedge at the clamped end and note the measurement (as at a); lay off a distance of 15 inches from this point toward the opposite end of the straightedge and set the latter so that at this point it measures about 0.8781 inch more from the edge of the table than it does at the first point. (Dimension b would then be 0.8781 inch greater than a.) Now if you have an indicator, fix it securely in the spindle of the machine by means of a suitable fixture (if there is no indicator a stiff rod pointed at the end will do, by using a piece of tissue paper to get the touch with) so that the point can be brought in contact with the straightedge, and after the table is adjusted so that the end of the straightedge nearest the machine is about opposite the spindle, move the saddle in so that the indicator registers some certain amount; then set the dial on the table feed-screw to zero; next move the table toward the opposite end of the straightedge just 15 inches, counting off the proper number of revolutions, and bring the dial to zero; then set the dial on the saddle feed-screw to zero and move the saddle in just

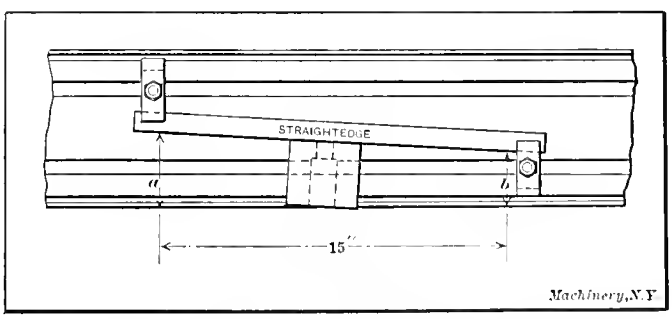

Fig. 5. Method of Accurately Setting Straightedge to a Given Angle by using Test Indicator and Graduated Feed-Screw Dials

0.8781 inch. If the straightedge is properly set, the indicator should register the same as it did at the other end; if it does not, then the position of the straightedge must be altered until it does. Thus you see the lengthwise movement of the table represents the side adjacent to the angle, and the movement of the saddle, the side opposite, or height.

"Now, since we have the straightedge clamped on the table at the proper angle, it is an easy matter to set the jig up

against it and clamp it there, and if a piece of tissue paper is placed between the straightedge and each corner of the jig, and if, when the jig is clamped fast, each piece of paper has about the same tension or 'feel' when pulled, we may be reasonably sure that the jig is properly set. The straightedge can then be removed and the piece machined with the assurance that the angle will be as correct as the straightedge was set. Now suppose that there was an error in setting the straightedge of, say 0.0025 inch, which is a liberal amount on a machine in reasonably good condition, and assuming that we are careful in having the backlash all out of the screws when we take the measurements, then the error existing in the angle on the jig will be in the same proportion to the error in the straightedge as the length of the straightedge is to the length of the jig bearing against it. In this case the length of the jig is three inches, then $15 \div 3 = 5$, and $0.0025 \div 5 = 0.0005$, or an error in the angle on the jig of 0.0005 inch, which is much more accurate than we could ever hope to set a bevel protractor

"As I said before, there are numerous ways of multiplying errors, and a little study of the subject will show many ways to take advantage of them; although there are instances where they act to a disadvantage. I remember once that I had a job of making a jig for drilling twenty-four 1/8-inch holes in a straight line and each a half inch apart. As a half-thousandth of an inch was tolerable for accuracy it was thought to be an easy matter, and that a short jig having three holes in it would do the work. I made up a jig of this kind which was to be used by drilling the first hole and inserting a plug, lining the jig up and drilling a second hole and inserting a plug and drilling the third, after which it was intended to move the jig along and set it by using a plug through the center hole and one in the end hole, the plugs being inserted in the last two holes drilled. On trying the jig out, however, it was found that the two end holes were about six thousandths too far apart, and that the holes were not in a straight line but on a slight curve. This was due to a slight and almost indiscernible error in the jig, but this error was repeated on each hole drilled, and therefore multiplied by the number of holes. Well, that illustrated the impracticability of the method, and the jig was thrown away and one made having thirteen holes in it, the first two and the last two a half inch apart, with the intervening holes one inch apart. In using this jig the two end holes were drilled first and plugs inserted in them; then the intervening holes were drilled, after which the plugs were removed and the jig moved along until the first hole at one end of the jig matched the second hole drilled from that end. A plug was inserted in this hole and also in the second hole from the other end of the jig; the rest of the holes were then drilled. This made a very satisfactory job, and though it was more work to make the jig, much faster drilling could be done."

"Were you blamed for making the jig wrong in the first place?" asked Jim.

"Well, no; in the first place I had made the jig according to instructions, and then it was what might be called a profitable mistake. That is, it showed the fallacy of a design that might be applied to other work of a similar character. It has been well said that we learn more from our mistakes than we do from our successes. When we make a mistake we have a precept, which is more indelibly fixed in our minds than any other training or instruction could be, that instinctively halts us when similar circumstances arise.

"A man that does not make a mistake, generally consumes so much time avoiding them that he rarely accomplishes anything else. There is a difference between mistakes and carelessness, and we should not get the two confused."

"While you were talking about machining that angle on the milling machine," said Jim, "I was reminded of an argument that I overheard between Mr. Corbin and Joe Pitts a few days ago. It seemed Joe had bored a hole in a jig on a milling machine and it did not come out right. Mr. Corbin claimed that the table of the machine was not properly set, while Joe maintained that that made no difference."

"I remember that," said Anderson. "Joe was wrong. He set his job up using an indicator along the side of the jig that was at right angles with the hole that he was to bore, with the result that while he proved that the jig was set in the proper alignment with the table, he did not prove that the table was set at right angles to the spindle, or to the saddle guides, relying on the graduations of the table base for this. Of course, when the hole was bored, it was no more accurate than the machine. You can readily see that if a piece were placed between the centers of a milling machine table, the table swiveled to one or two degrees, and a hole bored through the piece, the hole would be at an angle the same as that to which the table was set. I have frequently made use of this scheme to give draft to keyways, etc. It is evident that if one desires to bore a hole in a piece set parallel to the table guides, and have that hole at right angles to the side of the piece that was set parallel, one must be sure that the table guides are set at right angles to the saddle guides, or the spindle of the machine. This can be done by setting an indicator in the spindle of the machine so that the registering point will describe a circle of at least six or eight inches when the spindle is revolved; the indicator should then be set at one extreme of its horizontal movement and that portion of the table that has been machined parallel to the table guides brought up against the indicator until it registers some certain amount. Next revolve the spindle half over and note the amount registered; if it registers the same in both places the table is set square to the spindle, and if it does not then the table should be adjusted until it does. The machine will then be set accurate enough for all practical purposes. However, if it is desired to bore a hole of any considerable length, say five inches or more, and there is a surface on the piece that is to be bored that lies parallel to the hole other than the top and bottom, it is much more desirable to disregard the position of the table and set the work parallel to the saddle guides using an indicator along the side of the work that is parallel to the hole, thus dong away with any error in squaring the table of the machine; in fact if the table were set 10 or 15 degrees off square, it would not affect the accuracy of the work. There is a good opportunity for a man to lose sight of the fundamental principles of the thing and get confused as Joe did, but once you thoroughly understand it, it is plain to see that if work is set in line with the table guides, then to bore a hole at right angles, the table must be properly set, but if work is set in line with the saddle guides, the hole will be bored parallel to the guides regardless of whether the table is set properly or not, assuming, of course, that the piece is square and the previous work correctly done. Ah! there is the whistle, and we must get to work."

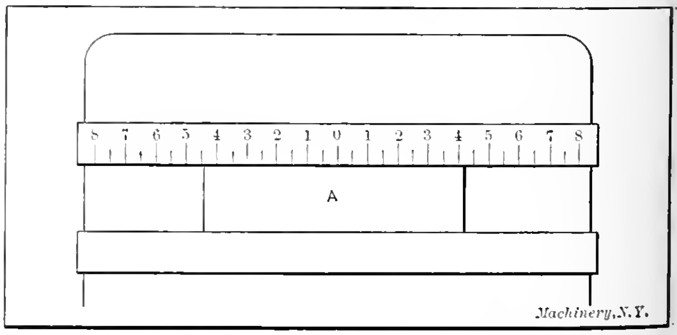
SUGGESTION FOR THE MACHINE VISE

By C. F. EMERSON

The sketch submitted herewith very clearly shows a suggestion which I have often thought would be most practical if carried out. By having the steel jaw of a shaper or planer vise graduated somewhat after the manner shown, it would



Plan View of Graduated Machine Vise Jaw

not be necessary to change the position of the stroke of the shaper ram or planer, as is so often the case after the work *A* has been placed in the vise a second time, owing to the fact that the graduations would enable the operator to place the piece in its exact former position. These graduations would also be useful on milling machine vises, as they would do away with the necessity of changing the position of the dogs of the feed-tripping mechanism.

MACHINE SHOP PRACTICE*

LAYING OUT AND MACHINING A PISTON-ROD KEY SLOT

As the laying out and machining of a slot for the keyed connection between an engine piston-rod and its crosshead, is a typical example of the kind of work the all-round machinist is often called upon to do, we shall consider this operation somewhat in detail. A very common method of attaching a piston-rod to a crosshead is shown in Fig. 1. The end of the rod is tapered and it is held in place by a cotter or key *C*, which is inserted in a slot passing through the crosshead and rod. As this key is driven in, the taper side, which bears against the inner end of the rod slot, tends to wedge or draw the rod tightly into place. In order that the key will have this drawing action, the slot in the rod must be off-set as shown, and as keys are usually made to a standard size, evidently this slot must be laid out and machined so that the tapering side of the key, when driven tightly in place, will bear evenly across the slot. It is also desirable that the key

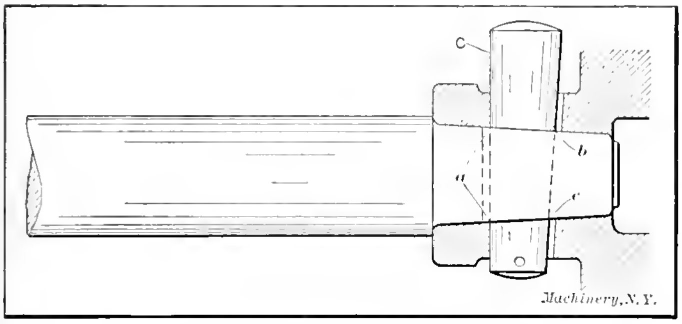


Fig 1. View showing Method of Securing a Piston-rod to its Crosshead by a Key or Cotter

be tight soon after the small end has passed through the crosshead as in Fig. 1.

It will be seen that the most important thing in connection with the laying-out operation, is to locate points corresponding to *b* and *c* on the rod, as this is the side of the slot against which the key bears. To quickly and accurately locate these points, first insert the key in the crosshead, as in Fig. 2, in the position which it will occupy when it is driven through the slotted rod; then with a hook scriber, draw lines l and l_1 across one side of the key to coincide with the inner sides of the crosshead bore. After the key is removed, the rod should be driven in and the outline of the crosshead slot on each side transferred to it by using a sharp pointed scriber. The rod before being removed should be marked in some way so that the scribed line, representing, say, the outer half of the crosshead slot, can be identified. (By outer half is meant the side from which the key is driven.) To locate a line representing the point *b* (Fig. 1) on the rod, the latter is clamped in a vise with the marked or outer side up. The exact width of the key at l (Fig. 2) is then measured and a pair of dividers is used in transferring this measurement to the rod, as illustrated in Fig. 3. The line corresponding to

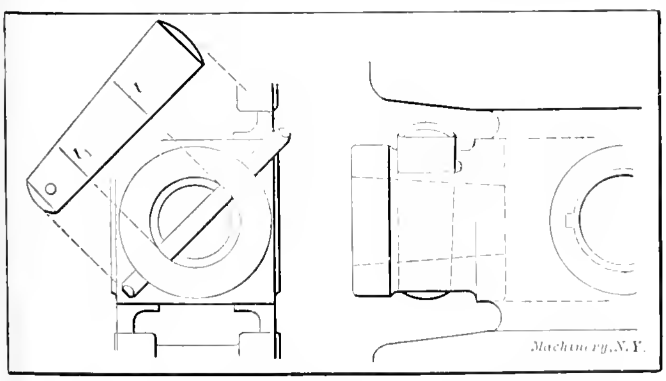

Fig 2. Using Key in Connection with Laying-out Operation

* With Shop Operation Sheet Supplement

point *c* (Fig. 1) is also scribed on the opposite side of the rod with the dividers set to the width of the key at l_1. Circles are now laid out on each side of the rod, as shown by the heavy lines, for drilling. The last circle on the end next to the shoulder should extend 1/8 or 3/16 inch beyond the end line *a* so that the slot will clear the key on this side. The diameter of these circles is, of course, equal to the width of the key, as many are laid out as will come within the length of the slot so that as much metal as possible will be removed by drilling.

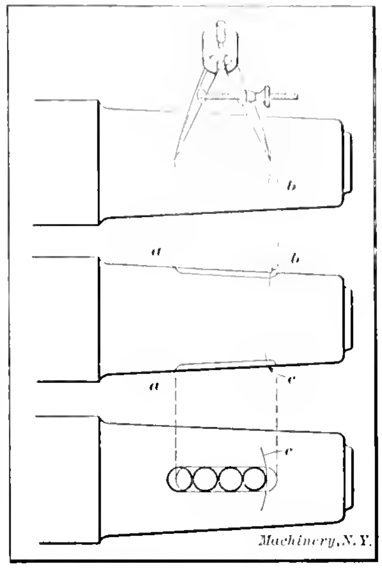

Fig. 3 Laying out the Slot

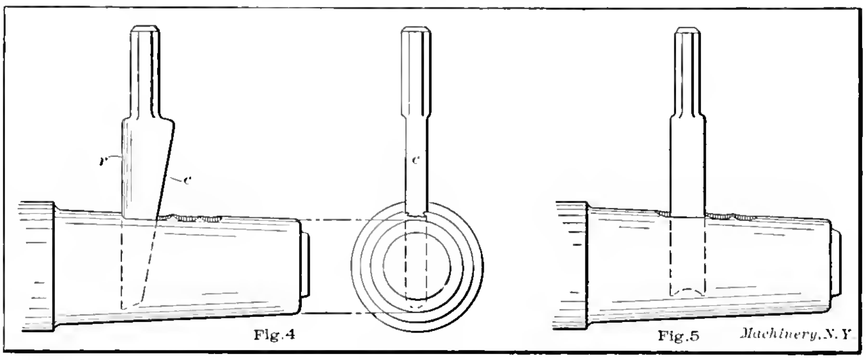
After all the holes have been drilled half way through from each side, as described in the Shop Operation Sheet accompanying this number, the slot is finished by chipping or broaching, and filing. The ridges on the sides may be removed by the use of an ordinary side chisel, but where slots are frequently cut, the work can be done more quickly by the use of a special chisel such as is shown in Fig. 4, or by a broaching chisel as illustrated in Fig. 5. The first tool is shaped somewhat like a gouge. The side *r* is rounded to fit easily in the drilled holes, and the cutting is done by the corners *c*, which are given a little clearance on the sides. As the tool is driven down through the slot, the tapering cutting edges advance and shear off the ridges on both sides, which have been left between the holes. The width of this tool is slightly less than the required width of the slot so that



Figs. 4 and 5. Tools used for Trimming Slot after Drilling

practically all superfluous metal is removed, and little filing needs to be done. The broaching chisel shown in Fig. 5 can also be employed for this work. The end is ground concave so that it will cut with a shearing action and the tool is given a slight amount of clearance on all sides. The manner of using these tools should be apparent from an inspection of the illustration.

After the chipping or broaching operation is completed, the slot should be finished by filing, a flat file being used for the sides, and a round or "rat-tail" file for the ends. The taper end against which the key is to bear, should be finished to coincide with the lines *b* and *c*, Fig. 3. The accuracy of the work may be tested by inserting the rod into the crosshead (after all the burrs around the slot edges have been removed) and then driving the key in tightly. If, when the latter is removed, there is not a good bearing across the end of the slot, the "high spots" should be filed down until the bearing is uniform.

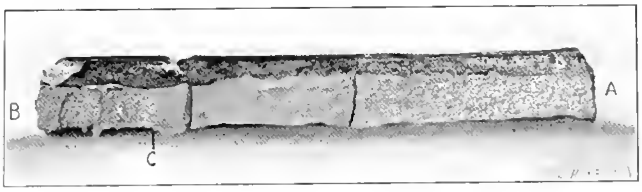
To prevent a key from dropping out of its slot in case it becomes loose, a small split cotter is inserted in the end. In order to have this cotter close up to the crosshead where it will be the most effective, the hole for it should be laid out after the slot is finished and the key is driven to its final position.

HEAT TREATMENT OF CARBON STEEL

By J. H. GILL*

High-speed steel is in fashion nowadays. This fact together with the high degree of skill required to get the best results from carbon has caused carbon steel to be neglected. For some kinds of work, however, carbon steel is superior to any high-speed steel on the market, if it is dressed properly and receives the proper heat treatment.

The carbon in steel may be in one of two forms: Annealed steel has the carbon in the non-hardening or cementite form. Hardened steel has the carbon in the hardening or martensite form. That these are two distinct forms may be seen by taking a small piece of annealed steel and a small piece of hardened steel and dissolving each in hydrochloric acid. The annealed steel will dissolve, leaving a black residne, while the hardened piece dissolves, leaving no residue. This shows that in one case some of the carbon is in the free or graphitic form and does not dissolve in acid while in the other case, the carbon is in the combined form and all dissolves.



Sample of Carbon Steel broken to show Difference in Grain at Different Hardening Heats

Another point that is more important to the steel worker is that the carbon changes form suddenly at the critical temperature. This is shown in the sample reproduced in the accompanying half-tone. This sample was made in the following way: A piece of steel ½ inch x 1 inch was heated and nicked parallel with the axis as seen in the engraving; then this piece was heated till it began to fuse on the end *A* the heat gradually decreasing toward *B*. The end *B* was not hot enough to harden. In this condition the piece was cooled as quickly as possible and then broken along the nick. The characteristic burned grain is seen at *A*. This gets finer as the part that is not so badly burned is reached. Just before the point *C* is reached we find the maximum fineness and the maximum hardness; as soon as the line *C* is crossed, we find the grain of the annealed steel. The sample is soft from *B* to *C*. This shows that there is a sudden change, on the rising heat, at *C*. The best condition for hardening is just after crossing this line.

The determining of the point *C* is a very important matter. The temperature at which this change takes place varies with the different steels. There are several ways of determining this point. One is by heating the steel to a dark red, plunging it into the hardening bath and trying with a file. If not hard, reheat to a little higher temperature and try in the same way. In this way go up step by step till a point is reached at which the steel hardens. This reheating and hardening is a severe treatment and is likely to cause cracks, but if carefully done it will give the lowest heat at which the steel will harden.

There are two other methods which depend on the fact that steel loses its magnetic properties when the hardening point is reached. A piece of steel heated to a dull red and brought into the plane of a magnetic needle will attract the needle. [See MACHINERY, April, 1908.] If heated until the temperature is above the hardening point, there will be no attraction and the needle will not be affected by the presence of the steel. In using this test, care must be taken that the presence of the tongs does not mislead the workman. The comparatively cool tongs may attract the needle even when the steel is above the critical point. An ordinary horse-shoe magnet may be used instead of the magnetic needle. It is less likely to mislead because of the tongs or cooler parts of the steel but is less sensitive. A bar magnet hung on a pivot at the center and provided with a handle can be used very satisfactorily. It can be introdnced into the furnace to test the steel during the process of heating and is more convenient than either of the other methods. It is not necessary to test every piece of steel, but a test should be made whenever the person takes another grade of steel or whenever the light changes. The intensity of the light makes a great difference in the color of a piece of iron or steel at a given temperature.

If steel workers would observe the following in all cases when hardening steel, they would have better results: *Harden carbon steel at the lowest possible heat and always on the rising heat.* The last part of this rule is the one more often overlooked. Steel may be forged at a higher heat than the hardening heat but should in all cases be annealed before being heated for hardening. The grain of the steel corresponds to the highest heat it has received since it was black. If a piece of steel is forged at 1600 degrees F. and allowed to cool down to 1400 degrees F. to harden, it will have a grain corresponding to 1600 degrees. If the piece is forged at 1600 degrees F. then cooled down to the black heat and reheated to 1400 degrees F. and hardened, it will have a grain very much finer and the tool will be very much better.

In making tools that are machined to shape it is always best to rough out the tool, and then anneal it to relieve all internal strains. After annealing, finish to size and it will be much more likely to come from the hardening bath straight and free from cracks. If, in heating for hardening, any part of the tool gets too hot, lay it one side and let it cool slowly to the black heat and then reheat more carefully.

In working steel always have even, thorough heat, all the way through. More steel is injured by uneven heat than by too high a heat.

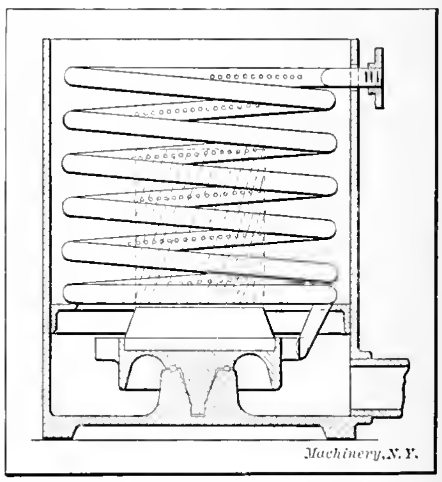
APPARATUS FOR HARDENING MILLING CUTTERS

The accompanying illustration from the *Practical Engineer* (London) shows an apparatus for hardening milling cutters, patented by Mr. J. M. Gledhill of Armstrong, Whitworth & Co., Ltd., Manchester, England. As is well known the best results in hardening milling cutters are obtained when only the teeth are hardened and the interior of the cutter left comparatively soft. Instead of plunging the cutter directly into water or other cooling liquid, the exterior of the cutter only is subjected to the action of the cooling liquid in the form of a spray through a series of fine jets at high pressure. The interior is kept soft by previously plugging the hole to protect it from the sudden chilling action. The cutter is made to revolve during the hardening or sprinkling process in order to expose thoroughly every part of the teeth to the spray. The chilling action may be stopped at any desired point by turning off the water, and the cutter is then gradually cooled by immersion in oil or other suitable cooling medium. This method also almost entirely eliminates the cracking of cutters in hardening. The illustration clearly indicates the construction of the apparatus with a coiled pipe surrounding the cutter which is shown in dotted lines. The cutter rests on a carrier mounted on a ball bearing. The carrier is provided with vanes so that it may be caused to revolve by the action of a jet of water from the end of the coil. The water is drained off through an outlet at the bottom of the tank.



Hardening Milling Cutter Teeth by a Spray of Cooling Liquid, leaving the Central Portion Comparatively Soft

The best mixture for bronze letters used for signs is, according to the *Brass World*, 88 per cent. by weight, of copper, 8 per cent of tin, 2 per cent of lead, and 2 per cent of zinc.

AREAMETER FOR MEASURING HIDES

By FRANK C. PERKINS*

The general construction and method of operation of a novel form of areameter may be seen in the accompanying engravings, Figs. 1 and 2. This instrument is of great value for the accurate measurements of patterns and hides, as well as other areas having irregular outlines. In Fig. 1 the areameter is shown suspended over a table large enough to accommodate a hide of the size usually handled, and as the measurement is obtained by tracing the outer edges of the hide, a table accessible on all sides is preferable.

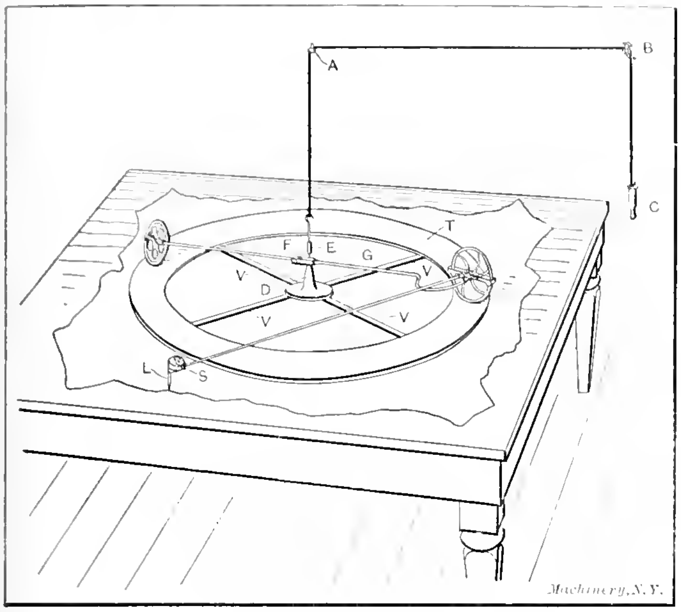

Fig. 1 Areameter used for Measuring Hides

The ordinary pulley *A* is screwed into the ceiling above the center of the table, and the self-locking pulley *B* is placed to one side of pulley *A*, approximately over the edge of the table, where the operator can reach the weight *C* conveniently.

A large wooden disk *T* with center weight *D* and cross-braces *V* is placed on the table, and a center pin screwed firmly into the center weight. The areameter is placed on the disk, being held in position by the center pin *F*, which is inserted through the hole at the middle of the jointed arm. The balanced wheels are fastened to the ends of the arm *G* as shown in Fig. 1. The swivel *E* is then securely fastened to the center pin and the cord which is attached to the lifting weight is passed over the two pulleys. The areameter is then ready to be used.

Fig. 2. Pointer and Dial of Areameter

In measuring hides, the areameter is placed on the leather in such a position that every portion can be reached by the pointer *L*. Small pieces of leather and patterns must be placed outside the wooden disk, unless, of course, they are larger than the disk, in which case the latter should be placed on them in the same manner as on a hide. The pointer is then placed at some designated mark on the outer edge of the hide, both hands on the dial *S* pointing to zero. By lifting the pointer slightly and guiding it with the aid of the thumb or forefinger along the outer edge of the leather, it is made to follow the outline of the hide back to the starting mark. The dial will then show the total of the area measured. The large circle of figures shows the number of square feet from zero to ten, and the small circle of figures shows every five feet, as shown in the engraving of the indicator in Fig. 2.

The operator traces the outer edge of the hide to the right. In case of holes, the complete hide should be measured first, and the pointer then passed around the holes to the *left*; then the exact area with the holes deducted will be indicated directly on the dial. The speed at which leather can be measured varies with the size of the hide, a 50- to 60-foot hide being measured in less than a half minute's time.

FORMULAS FOR THE VOLUME OF A PART OF A SPHERICAL SEGMENT

In the March, 1910, issue of MACHINERY a formula by Mr. R. A. Jewett, for finding the volume of a part of a spherical segment, was published. Mr. John B. Sperry, of 583 Benton St., Aurora, Ill., offered a different solution and formula previous to that submitted by Mr. Jewett, but, owing to an oversight, this formula was not published at the time it was submitted, and is, therefore, given below.

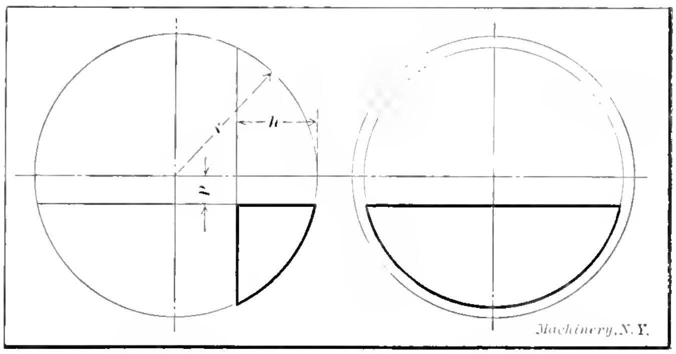
If V equals the volume of a part of a spherical segment, and h, p, and r equal the dimensions indicated in the accompanying engraving, then:

$$V=0.5236\left(3rh^2-h^3-3pr^2+6pr^2\,\frac{\sin^{-1}\dfrac{r-h}{r}}{180}\right)+p(r-h)$$

$$\sqrt{2rh-h^2}$$

This formula is derived by calculus, and owing to the length of the derivation, it is not possible to reproduce it in MACHINERY.

A simplified form of the formula by Mr. Jewett is offered by Mr. W. L. Tryon, 8 Hamburg Ave., Schenectady, N. Y. The symbols in this formula are the same as those used in the



Notation used in Formula for Part of a Spherical Segment

Jewett formula published in the March, 1910, issue, and the simplified formula is as follows:

$$V=\frac{2SP\sqrt{r^2-S^2-P^2}}{3}-\frac{3r^2P-P^3}{3}\tan^{-1}\frac{\sqrt{r^2-S^2-P^2}}{S}-\frac{3r^2S-S^3}{3}\tan^{-1}\frac{\sqrt{r^2-S^2-P^2}}{P}+\frac{2r^3}{3}\tan^{-1}\frac{r\sqrt{r^2-S^2-P^2}}{PS}$$

It will be seen that in the formula above there is but one radical ($\sqrt{r^2-S^2-P^2}$) the square root of which must be extracted, and this makes the formula very much simpler than that in the March issue from which it was derived. The derivation is too lengthy for publication.

* * *

It is stated in the *Iron Age* that, according to computations by the British Commercial Commissioner to Canada, the capital employed by American manufacturers in Canadian branch works amounts to about $125,000,000. The number of firms having branches in Canada amounts to nearly 150. The tendency of American capitalists to manufacture in Canada is, of course, largely caused by the Canadian tariff, which, in turn, is largely due to our own tariff against Canadian products. Here is then a case where the tariff indirectly has caused an exodus of capital from, and a diminished demand for labor in, the United States.

The English Admiralty specification for phosphor-bronze of great strength is, according to the *Brass World*, as follows: copper, 90 per cent; tin, 9.7 per cent, and phosphorus, 0.3 per cent.

LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY

A POINT IN ROUGH TURNING

In manufacturing the ordinary sizes of machine tools there are many places that have to be machined, belonging to the class indicated in Fig. 1, which have to be reduced an inch or more in diameter and a few inches in length. The particular piece illustrated, which will be taken as an example of this class of work, is a rough-turned pinion for a lathe apron. The stock comes to the lathe cut off and centered, to be rough turned from 2 1/8 inches in diameter to 15/16 inch diameter—a reduction of 1 3/16. As this is merely a question of rapidly removing the stock, no attention need be paid to the smoothness of the cut. Now if one single tool should be used, either

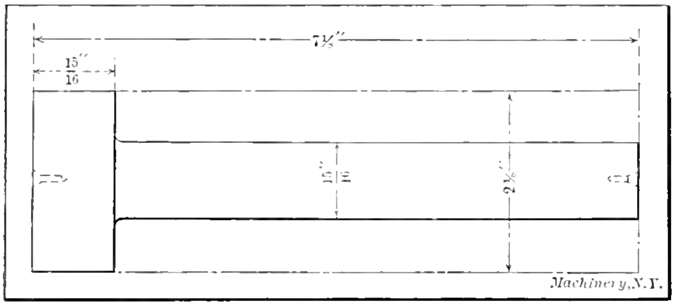

Fig 1. Class of Work on which Two Tools can be advantageously used for Roughing

two separate roughing cuts would have to be taken, or a fine feed used, because of the cutting pressure on the work. Neither the tool nor the machine, however, would be loaded anywhere near its full capacity, as the size of the cut is limited in this case by the strength of the work, and not by the capacity of the machine or tool.

The tool pressure produces, as the cut starts, a large compression of the metal surrounding the rear center, and, if the center is small, it is liable to break out or destroy the tailstock center. Furthermore, the tool pressure causes the work to spring, and when the turned diameter is only 15/16 inch, this bending is very likely to cause trouble. In order to counteract these drawbacks and to insure the possibility of loading the machine to the full capacity, lathes are equipped with two tool-posts and two turning tools, one being used in the front

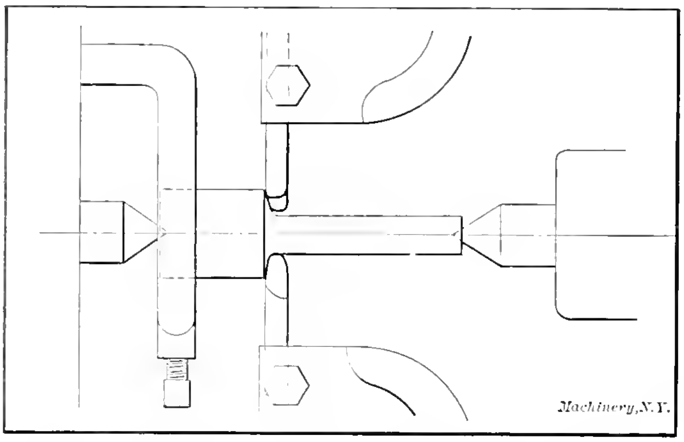

Fig 2. Arrangement of Tools for Taking Heavy Cuts on Small Work

and one in the rear in an inverted position. The arrangement is illustrated in Fig. 2.

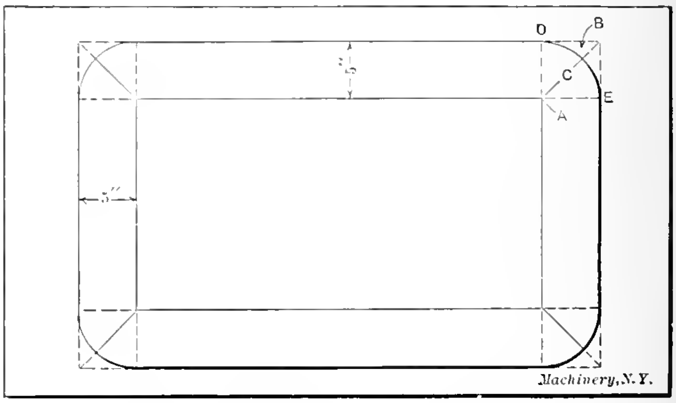
Considering the pressure on the work, the tool pressure on one side is downward and on the other upward, these tending to balance each other as far as bending is concerned. The rear center and the turned part of the work are thus relieved from nearly all the strain. There is a slight strain, however, as the front tool is usually set to take a slightly deeper cut than the back one. By this method the time of rough turning the class of work referred to in the foregoing, can be reduced to less than one-half, because each of the two tools can be made to remove more stock than would a single tool.

Cleveland, Ohio. OSKAR KYLIN

[The principle of two opposed tools to balance heavy lathe cuts is well known and much used in certain classes of manufacture, of course, but it is doubtless not used as generally as it could be with profit.—EDITOR.]

TINNING STEEL PANS

Before steel pans can be tinned all scale must be removed; this can be done in a pickling solution, composed of equal parts of hydrochloric acid (or muriatic acid, as it is often called) and water. Lead tanks are sometimes used for holding the acid, but it is better to obtain an enameled fire-clay bath (such as used for lavatory sinks) or any earthenware vessel that is large enough to cover a quantity of the steel pans at the same time. During the time the pans are in the pickle they should be moved about, so that all parts may be equally exposed to the action of the acid. The length of time for pickling will depend upon the temperature and strength of the acid and on the condition of the pan surfaces. If the acid is fresh, then the pickling may be done in about ten minutes, but if the acid is partly spent thirty or forty-five minutes will be required. The acid must not be heated to increase the speed of working, as the pan surface produced will not be so good as when pickled by cool acid. Any increase of temperature over and above that of the atmosphere required for the effective working of the pickle, is soon obtained by the



Method of Making Tank for Steel Tinning

heat generated through the chemical action. If the pickling solution is too hot, the action upon the pans will not be uniform, and the surfaces will be somewhat rough. To obtain a good-looking surface after tinning, the operator should be careful not to over pickle, as this will cause the pans to look "dead" and "dry." When properly cleaned, the pans should instantly be plunged into a water tank for washing; they are then ready for the flux.

The tank used for tinning can easily be made from 1/16-inch sheet steel. To form the sides, lay out a line 5 inches in from the edge all around, as shown in the accompanying engraving, and then with the intersecting points *A* as centers, scribe arcs for rounding the corners; the portion *B* is then cut away. In working up the corners care should be taken to get them true; the way this is done is as follows: Press the corners over the tip of a sharp stake and bend on the line *C*; this will start the corners and slightly turn up the sides, which can then be bent on a sharp stake assisted by a large wood mallet. When the sides are bent up sufficiently, the corners should be knocked together to make the points *D* and *E* meet, and then bent around on the ends of the pan against which they should be closely flattened. This completes the tank.

When preparing the bath of molten tin, sufficient metal should be obtained to cover the steel pans. The tin can readily be melted over an ordinary forge fire, but care must be taken not to overheat it; the temperature should be about 400 or 450 degrees F.

The flux into which the pans are dipped previous to tinning them is composed of a solution of chloride of zinc, that is

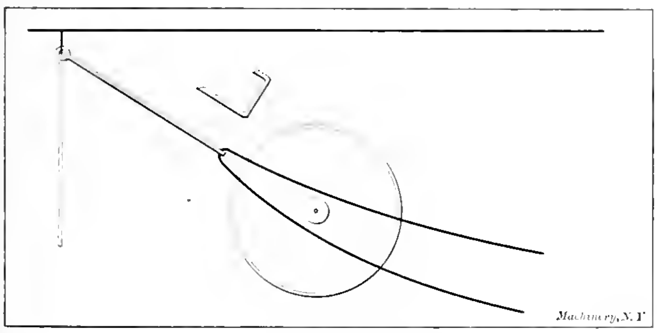
made by dissolving zinc in hydrochloric acid to the saturation point. The steel pans should be heated slightly before putting them into the molten metal. Care should also be taken when immersing the pans to place them in gently, as the molten tin coming in contact with the damp surface of the work boils and "spits." The pan should be moved briskly in the molten metal by means of a pair of smith's tongs, and then removed quickly and shaken over the bath. When the tin has drained to the lower edge, it should be wiped off with a pad of tow or wadding. If the coating of tin is not satisfactory after the first attempt, the work should again be dipped in a solution of zinc chloride and then in the tin, as previously described. A second dip generally improves the appearance of the surface. The work should finally be washed with plenty of water and then dried with clean sawdust. This completes the tinning operation and if the proper method has been followed and care exercised, the pan should have a smooth coating, uniform in depth and color.

FOREMAN TINNER

BELT KINKS

In a small shop where I worked they take very good care of their belts, and here are some points as to how they do it.

Near each pulley on the line-shaft where a belt drives a machine that is liable to stand idle for some time, a staple is driven into the ceiling and a hook of 5/16 or 3/8 inch round iron is hung from the staple. The hook is long enough to reach almost to the rim of the pulley but a little to one side of it. When a belt is run off its pulley, it is hooked up by the belt stick on this hook, the slack of the belt allowing it to be caught on the hook, and when the belt sags, the hook swings so as to make the belt clear the side of the



Method of Suspending an Idle Belt

pulley and also the shaft, as shown in the illustration. This avoids the trouble of tieing belts to beams, hangers, etc: and it is so little trouble to hook the belt up, that it is done when it might not be tied up. Care must be used, of course, in placing each hook, so that the belt, when off the pulley, will reach the hook.

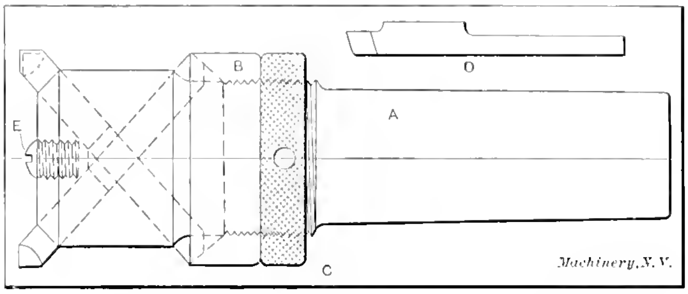
Here is another important point in the treatment of belts: At inventory time or other "shut-down," the belts are examined and the greasy or dirty ones are first scraped to remove the surface dirt, and are then washed with warm soap and water, care being taken that the water is not hot enough to be uncomfortable to the hands. After drying, they are given a light, even coating of castor oil on the working side, and if very dry, on both sides. In fact, those belts running in hot or dusty places are oiled rather frequently. This improves the driving power greatly and can be done without taking the belts down, but simply running them off their pulleys.

For belt joints, they have given up all hooks and lacings for permanent joints. When a new belt is put on, it is laced as tight as it will run, and after the stretch is pretty well out, the ends are beveled, the belt is drawn up with clamps, and a lap-joint is made, the slack due to the stretch of the new belt furnishing all the lap that is needed. This is usually not over three inches and frequently not more than one and a half or two inches for short belts, but long experience shows that it is enough. This treatment has been applied to high-speed and low-speed belts of the widths usual for the average machines and tools—or say up to four inches—and for several years it has been a success. It also enables all the short pieces of belting to be used without the usual trouble due to several laced joints in one belt, and it is surprising to see how much good belting will be found in a lot of old belts that have been well cleaned and oiled.

TAD

EXPANDING BORING TOOL

An expanding boring tool, intended for use in a turret lathe, is shown in the accompanying illustration. This tool can also be employed in a common lathe or drill press, but it is especially adapted for boring cored holes, brass bushings, etc. The shank *A*, which is made from mild steel, is turned to fit the turret and is threaded 14 threads per inch for the knurled nut *C*. The collar *B* is a sliding fit over the threads and is casehardened. The holes for the cutters are 3/8



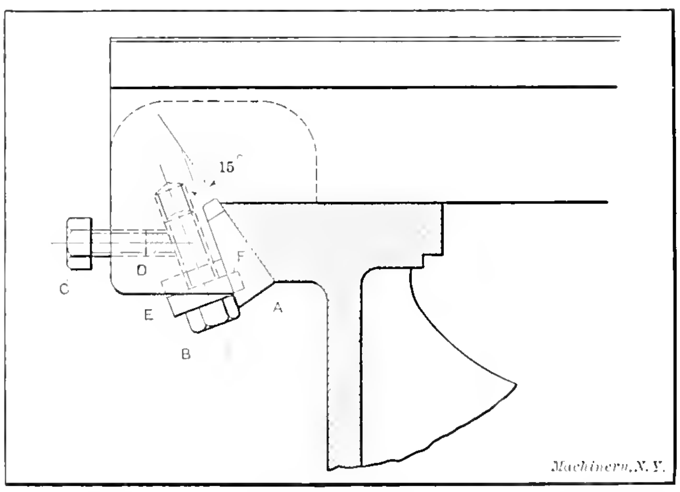
Expanding Boring Tool for Cored Holes, Brass Bushings, etc.

inch in diameter and cross each other. The cutters are made from 3/8-inch round steel and are cut down for part of their length to the center line as shown at *D* so that they will cross each other when in position. After the cutters are made and hardened, they are put in place and adjusted to a trifle over the desired size, and locked with screw *E*. They are then ground to size in a grinding machine and backed off.

Harrison, N. J. A. L. MORE

IMPROVED ADJUSTING STRIP FOR SLIDES

It seems to be a universally accepted fact that the taper strip for taking up the wear in the slides of machines is a big improvement over the older types in which all the pressure was taken by the adjusting screws. The metal-to-metal contact of the former is practically equal to a solid slide; but at the same time it is rather an awkward job to plane, as the taper necessitates an extra setting of the slide; in addition to which the planing and fitting of the strip are much more difficult than with the older designs. To overcome this constructional difficulty, I designed the adjusting strip shown in the



Adjusting Strip for Slides which is moved Crosswise for taking up Wear

accompanying sketch, and I think it will be admitted that where it can be used, and especially where the pressure tending to lift the slide is small compared with the side pressure, it is just as effective as the other kind and much easier to machine and fit.

The illustration shows the application of this strip to a lathe saddle, it being at the rear for convenience of adjustment. The strip *A* instead of tapering lengthwise, tapers 15 degrees in cross section. It is adjusted by screw *B* (of which there are two or more) which has a collar sunk into the strip

at F; E is a counterbored hole to receive the collar of the screw when the latter is screwed up.

At D there is a brass block which is tapped in position to fit the threads of screw B; C is a lock-screw which clamps the brass block onto screw B, thus effectively locking it.

Of course there are, no doubt, many places where the usual end adjustment is the only one that is possible, but the strip described in the foregoing, where it can be used, has a few advantages from a manufacturing point of view. RACQUET

DIE-MAKERS' CLAMP

There are many forms of die-makers' clamps in use, and many have been described and illustrated in the mechanical publications, but the one illustrated herewith has the good points of several combined in one. First, the range of adjustment in the ordinary clamp is too limited, especially where there are punches with round shanks to mark off, as they add at least two inches to the height; and those with three arms are only useful for round jobs. This clamp is adjustable for

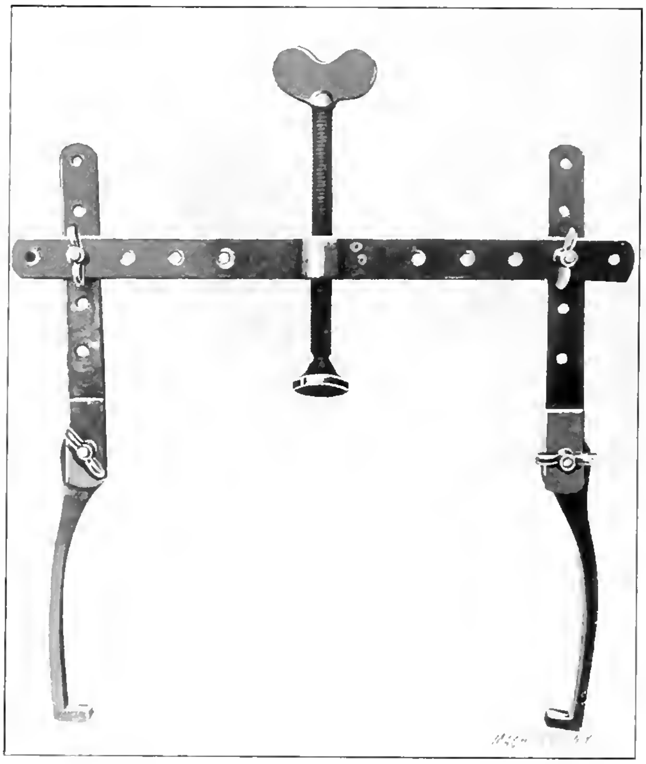


Fig 1. Die-makers' Clamp with Wide Range of Adjustment

width and height, by spaces of one inch. It will take in, extreme adjustment, 11 by 11 inches, and it can be contracted to 1 inch in width and to zero in height. The adjustment is quickly changed by four ¼-inch thumb-screws. The clamp-screw, which is ½ inch diameter, has a 5-inch length of thread, with a ball tip and button shoe, that adjusts itself to any angle. Fig. 2 shows the arms or tongs uncoupled from the extension arms and coupled direct to the cross beam, thus giving the clamp a quick adjustment for small work.

The clamp can be easily made as it is built up of riveted strips of standard stock, the only forged parts being the tongs.

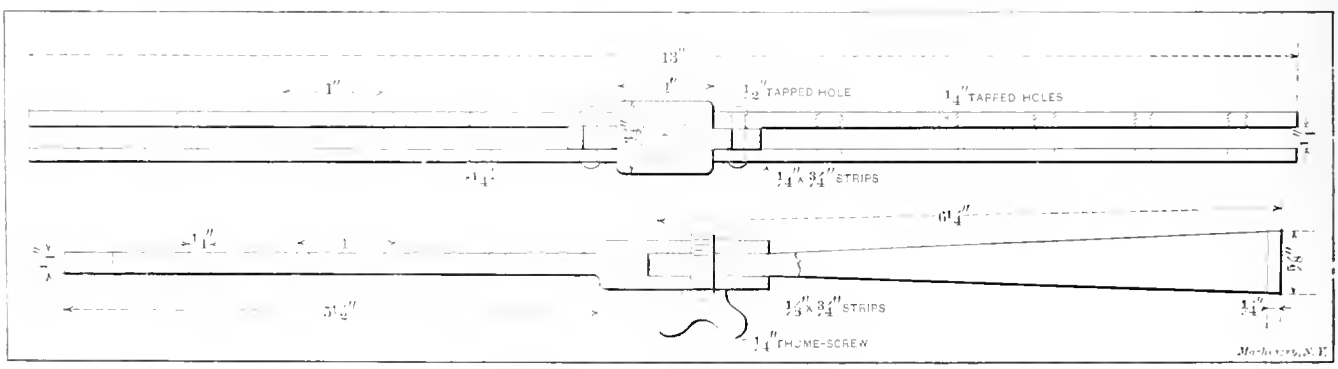

Fig. 3. Details of Die-makers' Clamp

SUGGESTION BOX IN THE FACTORY

A system for rewarding meritorious suggestions on economical methods in the shop was first introduced in our factory about two years ago, the plan being similar to that adopted by the National Cash Register Co. of Dayton, Ohio.

The adoption of this idea in our shop can be traced directly to an incident in which I was directly concerned, and which had to do with a dispute that arose as to whether I or the

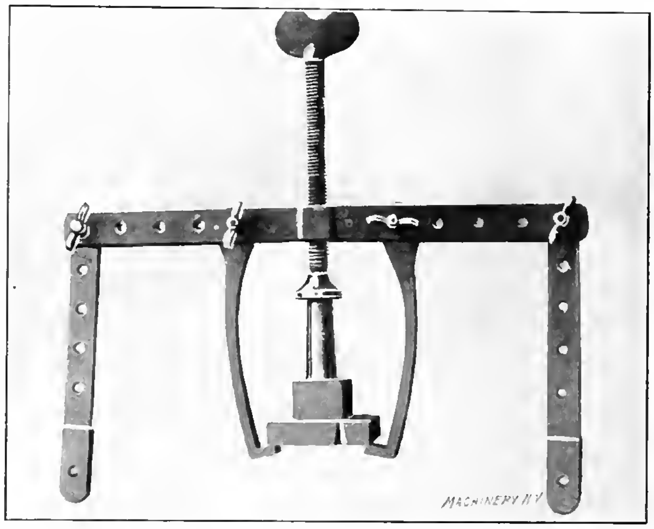

Fig. 2. Tongs of the Clamp attached direct to the Cross Beam for Small Work

superintendent of the factory was the original discoverer of a means whereby, with the adoption of follow dies, the separate operations on a blank could be reduced from three to two, with a consequent saving in time and cost of tools.

While endeavoring to improve the manufacturing methods on a certain part of the typewriter which we manufacture, I called the superintendent to my board to consider the advisability of making certain changes in the construction of the press tools used on this piece, with the idea of reducing the number of operations necessary to finish it. He, after having carefully gone over my suggestion, pronounced it impractical, and let the matter drop. A few days after he came to me, and reminding me of the job on which I had been working, proceeded calmly to unfold to me as a good idea of his own conception the very suggestion which I had made to him a few days previous. As the general manager of the company was present at the time, and as the superintendent was taking the credit to himself for my idea, I produced my sketch book, showing in black and white that he was either mistaken in his claims or had deliberately stolen my thunder.

So impressed was the general manager with this incident that a system of reward for suggestions on improvements in the shop and office systems, followed in a few weeks time. The plan provides that all suggestions shall be written out fully and clearly, accompanied by necessary sketches, and be considered by a committee from the factory composed of the foremen of the most important departments, together with the superintendent. If the suggestion offered is adopted, a nominal reward of two dollars is paid the man who offered it, and his name is included in a list made up at the end of every month, containing the names of those who have had their suggestions adopted.

This plan has been of undoubted value in securing suggestions from some who would otherwise be reticent about offering their ideas for the good of the service, owing to the fact that the foreman is so often given the credit, or because the plan is often rejected without proper consideration if coming from some one not in authority, as it is thought unworthy of serious thought and attention. Nothing is so galling to a man in the shop, perhaps, as to see someone else praised for something which was his own idea.

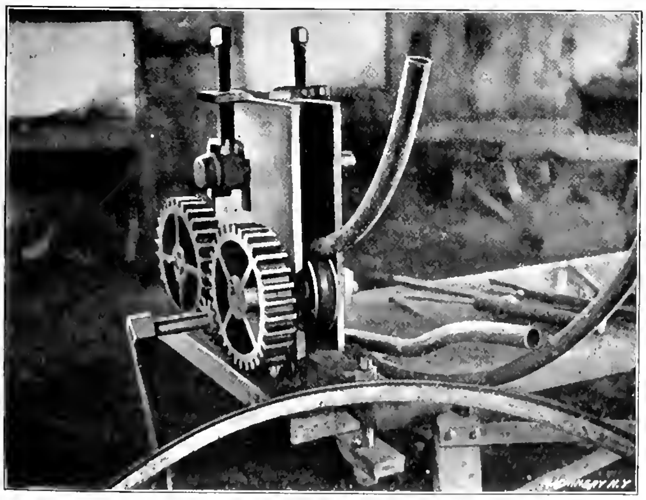
The main benefit to the man rewarded, is not so much in the two dollars which is given him to cover the time spent in preparing his suggestion, which work must usually be done at home or at the noon hour, as in the knowledge that his efforts are appreciated, and that his name is before those in authority. He also realizes that the next time promotions are made he stands a better chance of consideration through what he has accomplished.

The management of our company is highly pleased with the results accomplished after having this system in operation for a year and a half. The money spent in this way is many times repaid by the economies made possible, and besides that consideration, the men in the shop are imbued with a more loyal and liberal spirit toward those in authority.

DESIGNER

MACHINE FOR BENDING PIPE AND ANGLE IRON

A machine which is adapted for bending either pipe or angle iron, is illustrated herewith. The machine as shown in the illustration, is set up for bending pipes. It has three concave rolls (when used for bending pipe) which are located so that the centers of the rolls form a triangle. The pipe is given the desired curvature by screwing down the upper central roller by the two screws shown. The particular pipes bent in this machine are 3/32 inch thick, and this tubing after being bent is about 1/32 inch out of round. When the machine is used for bending angle iron, the concave rolls are replaced by three rolls which are grooved to receive one leg of the angle; in addition there are four side-bearing rolls which are to prevent the angle iron from bending to one side. This machine is cheaply constructed, but very substantial. The side-plates or frame are made from ⅞-inch boiler plate. The shafting is of cold-rolled steel. The pipe rolls are of cast iron, while those for bending the angle iron are of steel. Elongated holes through which the shaft of the upper roller passes, permit the necessary



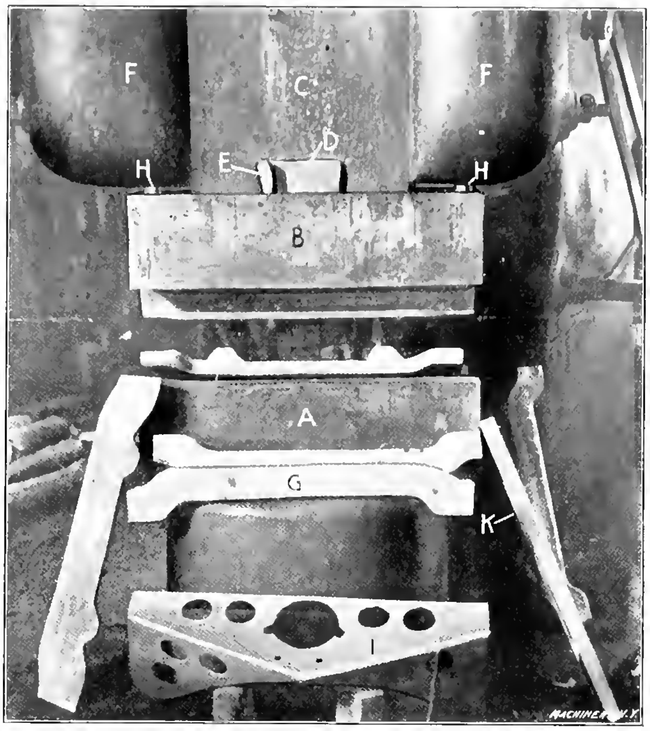
Machine for Bending Pipe and Angle Iron

vertical adjustment. This machine rolled fifty-six angle irons to a circular shape 71¾ inches in diameter in four hours, the work being done by three laborers. None of these angle iron hoops which were subsequently used in connection with a well-casing, were out of round more than one-half inch.

Jackson, Tenn. T. O. MARTIN

MAKING PRESSED STEEL PARTS UNDER THE STEAM-HAMMER

A steam-hammer that is equipped with dies and used as a press for forming pressed steel parts, is illustrated herewith. This hammer does the work very accurately, and much more rapidly than is possible with the hydraulic press. There are three sets of dies used for forming the three differently-shaped cross-members, *G*, *I*, and *K* for automobile frames. Either of these sets of dies, which are made from a good quality of cast iron, may be quickly attached to the hammer. The dies used for pressing the parts *G* and *K*, were cast in chills, it being an easy matter to forge the chills so that very little was left to machine. The dies for pressing the member *I*, were cast from a pattern, and have given excellent service. Each set of dies is equipped with positive knock-outs for removing the pressed part on the upward stroke of the ram. These knock-outs, which are indicated at *H*, consist of round-headed bolts which are set into counterbored holes in the upper die *B*. Beneath the head of each knock-out pin, and



Steam-hammer equipped with Dies for Forming Steel Parts

in the counterbored part of the hole, there are small springs which support the knock-out pins. When the die *B* approaches the end of its upward stroke, the knock-outs are forced down by the frame *F*, thus removing the pressed part. The two knock-out pins are then returned to their original position by the spring as the ram descends.

The dovetailed piece *D* by which the die *B* is keyed to the ram, is detachable, being attached to the die by means of cap-screws which fit in counterbored holes and pass through the dovetailed piece into the die. This same dovetail is used on all the dies; this is done in order to lessen the cost and complication in the die making. When a new set of dies is to be attached to the hammer, the holes in the piece *D* are transferred to the punch as follows: After putting the bottom die in place and keying it securely in the anvil block, the upper die or punch is placed in position. Two center punches which have been machined to fit the holes in the dovetailed piece *D*, and which are about 1/16 inch longer than *D*, are placed in the holes, after which *D* is fastened in place by driving in the key *E*. The ram is then let down with the result that the projecting centers of the punches mark the top of the die *B* at points concentric with the holes. These centers are then used to lay off holes in the upper die, which are drilled and tapped for the bolts.

The efficiency of the steam-hammer for doing pressed steel work, is shown by the following figures: The three frame members *G*, *I*, and *K* were pressed at a cost of 9 cents per set. Three laborers can press five hundred of the pieces *I* in ten hours, one man running the hammer, one keeping the pressed parts out of the way, and one placing the work in position. This same hammer is also used for doing some heavy and difficult pressed steel work for boilers. T. O. MARTIN

Jackson, Tenn.

EFFECTIVE METHOD FOR HOLDING RACK ON PLANER

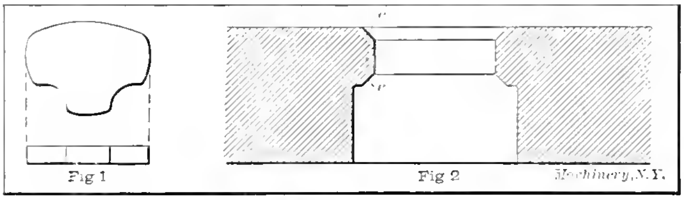
Some readers of MACHINERY may recognize in the following an experience similar to one of their own. I was running a planer which had a rack built in two pieces, and as usual, it was held by screws counterbored in the middle slot of the table. The normal condition of these screws was about half a turn loose and although securely tightened, they persisted in working back to normal, in which state they had worn elliptical holes so that a comfortable little "chug chug" was emitted at the end of each stroke. This continued until one day when the screw sheared off, the table stopped and the rack slid off on the floor. Now at last the machine had to be repaired, but instead of drilling out the holes and setting new screws, I decided to put in new ones of the same size and let the driving thrust be taken by keys. This was accomplished by cutting two half-inch keyways in each section of the rack and corresponding ones in the table. After putting in the new screws, the keys were carefully fitted and the planer was again ready for business.

On the face of it this planer construction, which is so common, seems to be in defiance of theory—relying on bolts under tension to resist the lateral stress which would be caused by the thrust of the cut. Yet in the majority of cases this manner of holding the rack has been effective. Possibly it has no parallel in machine tool design.

Middletown, N. Y. DONALD A. HAMPSON

LAPPING A SIZING AND SWAGING DIE

A die was required for swaging and burnishing pieces of mild steel which had been punched to the shape shown in Fig. 1. These pieces measured about one inch long, across the wide part, ¾ inch the other way and they were about 5/32 inch thick. As they were rough after being blanked out in the press, a die was needed for sizing and burnishing the irregularly-shaped edges. A sectional view of this die is shown in Fig. 2. The hole through it was made perfectly straight for about ⅝ inch from the top, the remainder of the hole being relieved or enlarged as shown. The two edges *e* were then beveled sufficiently to leave about 5/16 inch of the hole straight and smooth. This die was made as hard as possible around the hole, after which it was heated just enough to ease any internal strains which may have existed. As the hole shrank quite a little it was necessary to lap it to size.



Figs. 1 and 2. Punching to be swaged and Section of Die

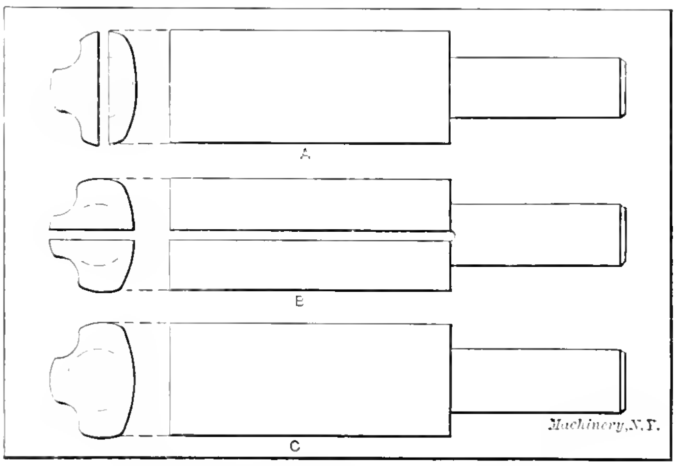


Fig. 3. The Three Laps used for the Die shown in Fig. 2

Three cast-iron laps of the shape and size the hole was to be, were made for this operation. These laps, which are shown in Fig. 3, were two inches long and were provided with a ¾-inch round shank about one inch in length. Two of the laps, *A* and *B*, were slotted, one across the wide part and one across the narrow way as shown. The third lap *C* for finishing, was left solid.

A small Dwight-Slate drill press which was in the shop was used for the lapping operation. One of the split laps was first caught in the drill chuck and the lapping done by working the spindle lever by hand. This method, however, proved too slow so it was decided to rig up the drill press so that the reciprocating movement necessary could be obtained by power from the machine. The way the required motion was transmitted from the driving pulley shaft to the spindle of the machine is shown in Fig. 4. A crank *A* was attached to the shaft and this was connected to the arm *C* by rod *B*. As the pulley shaft only projected ½ inch beyond its bearing, it was necessary to drill and tap it, for a ⅝-inch stud on which to mount the crank. Lever *C* was attached to the screw or stud in the spring-case *D*.

After the parts were connected, the die was placed on two parallel strips on the drill press table. The lap was held in the drill chuck as before, and the lapping done by using carborundum flour and oil as an abrasive. It will be seen that with the driving pulley connected to the drill spindle as shown, the latter is given a vertical movement up and down. The slotted laps *A* and *B*, Fig. 3, which were expanded by the use of wooden wedges, were used first. By changing the split laps and using first one and then the other, the hole was soon lapped practically to size. The solid lap was then used to finish the hole, which completed the die.

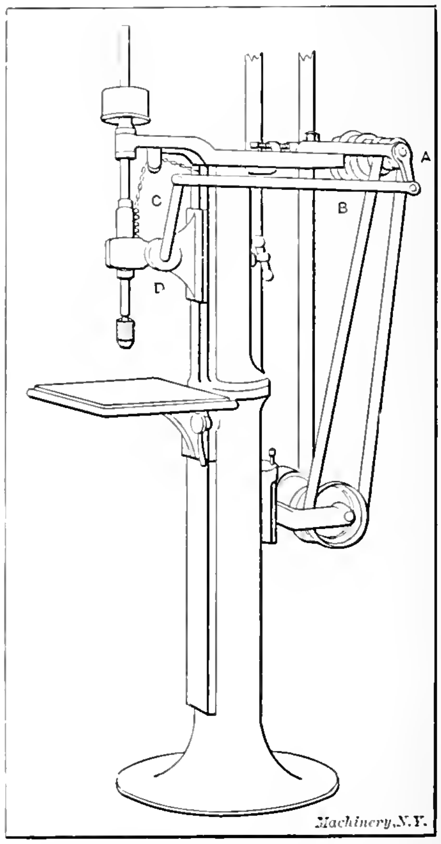

Fig. 4. Drill Press arranged to give Reciprocating Movement to Spindle for Lapping

Those who have not had experience in die work might be interested in knowing how these laps were made. First the approximate center of a sample punching was found, and a ⅜-inch hole drilled through it. Then an end was turned on the rough cast-iron laps to fit the hole and long enough to go through the punching. A smaller hole ⅛ inch in diameter was then drilled and into this a pin was inserted to hold the punching in place. The lap was then inserted between the centers of the milling machine and milled approximately to the required shape, the sample being used as a guide. In this way the laps were roughed out so close to the required shape that little filing was needed. A. S. GUN

GRAPHITE CUTTING COMPOUND

Although there are so many new things on the market, all said to do some particular work better than anything else has ever done it, and though there are so many of those so-called panaceas that one has not time to even read about them, much less try them, we think it will be interesting to readers of MACHINERY to know of some remarkable performances which have been obtained from the use of a new and unique product. We refer to the graphite lubricant, "Aquadag," used as a cutting compound.

Some weeks ago we were cutting off in the lathe a large

number of cold rolled steel rods averaging about 1 inch diameter. Records showed that the average number of cuts made by the cutting-off tool with one sharpening was 60 when using an ordinary soap cutting compound. Having had a sample of deflocculated graphite [see MACHINERY, July, 1907] presented to us we mixed a small amount of it with our cutting compound, and were as much astonished as gratified to find that the tool did not blunt anything like as rapidly as before. In fact the cutting-off tool actually made 980 cuts with only one sharpening. Fig. 1 shows 60 cuts made, representing the maximum that could be done with the plain compound, and Fig. 3 shows the 980 cuts made by the same tool in the same machine, the only difference in conditions being the addition of the graphite to the cutting compound. One also notes that not only did the tool in the second case do about 16 times as much work as in the first, but also that the ends were very much smoother, that is, the work was done much better.

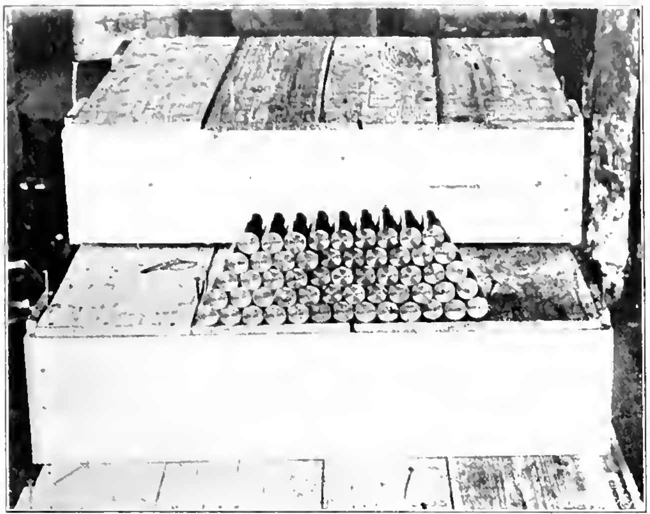

Fig. 1. Sixty 1-inch Cuts made with Plain Compound

We have also used "Aquadag" for many other machine tool operations with the same good results. For instance, in boring and reaming a large number of holes in bronze bushings we find that with our ordinary cutting compound the hole is always about 0.0002 inch smaller than the reamer used, but, through the addition of Aquadag to the compound, we find that we can cut a hole practically the full size of the reamer, this again being a conclusive argument that graphite greatly increases the cutting possibilities of the tool. We have also been enabled to effect considerable reduction in power consumed. We have in our factory a machine for a certain operation in which it was necessary to run with the back gears when using an ordinary cooling compound. However, by the above mentioned addition of graphite to the compound we ran with open belt. One sees here not only a reduction of power consumed by the cutting tool but also that an increase of speed is made possible.

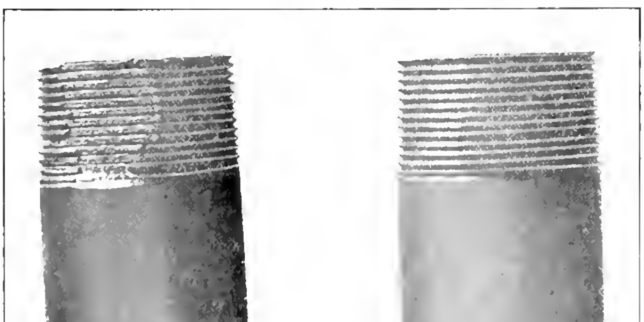

Fig. 2. Left-hand Pipe Thread cut with Lard Oil and Right-hand Thread with "Aquadag" using same Die

As yet, our experience with this product has been somewhat limited; in fact, it was only a few weeks ago that we commenced to use it, but so far, the results show a very much better operation, whether it be in the lathe, for turning or cutting off, or whether it be for milling or thread cutting, than could be obtained without it. Personally we are quite interested in this idea of using deflocculated graphite for a machine-tool lubricant and we shall be glad to hear of the experiences of other readers who may experiment with the same. We should mention that "Aquadag" is a mixture of pure graphite and water, made by the International Acheson Graphite Co., Niagara Falls, N. Y., the graphite contained being so extremely fine that it will feed through a fountain pen and will remain permanently suspended in water.

Niagara Falls, N. Y. NIAGARA MACHINE CO.

A SPLINE MILLING FIXTURE

The description and illustrations of the jig for slot milling long, slender work, published in the March number of MACHINERY by Mr. O. R. Barrett, reminds me of a somewhat similar device designed some time ago for spline milling steel shafts. This fixture contains several improvements over that described by Mr. Barrett, which is open to the following criticism:

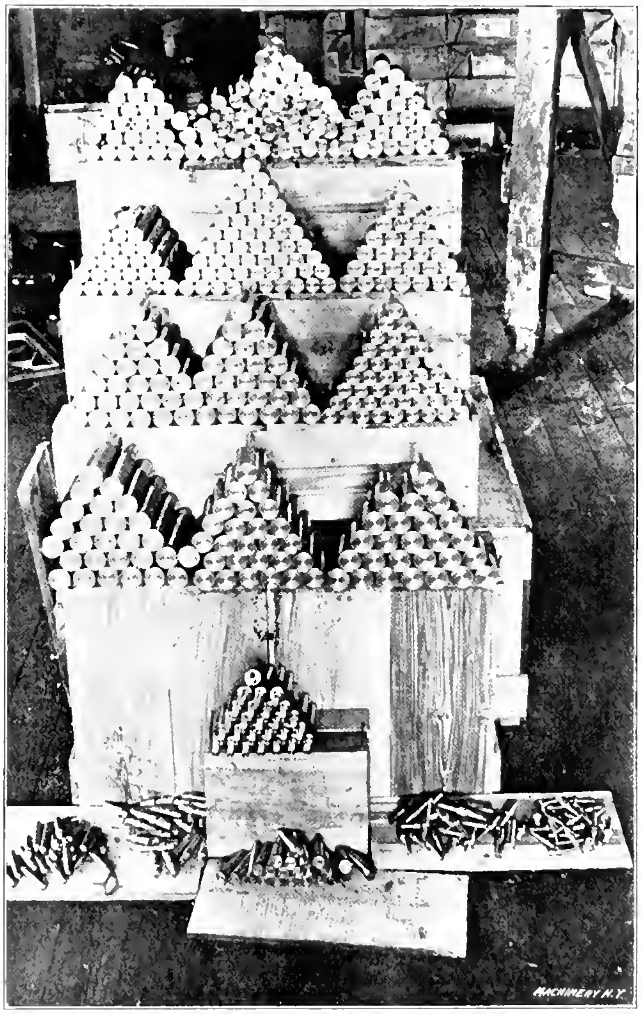

Fig. 3. Nine-hundred eighty Cuts made with "Aquadag" as the Lubricant

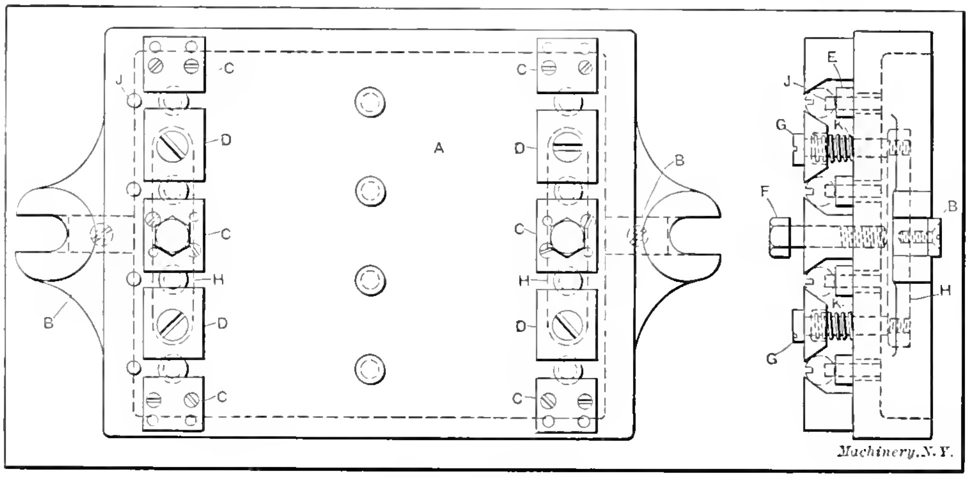
In the first place, the pins upon which the work rests between the clamps, are "blind driven" into the base casting, rendering it extremely difficult to remove them when it becomes necessary to renew them on account of wear. Besides, pins of this character taking the thrust from a clamp, should be made with a substantial shoulder, as it is much easier to get them all to the same height above the base surface.

Another weak point in this device is that four nuts must be turned, in order to clamp the four castings, while a little additional thought on the subject would have shown that this could have been accomplished by means of two bolts and a pair of equalizer bars, as will be described later when considering the spline milling fixture.

I also notice that the various blocks, against which the clamping action takes place, are not doweled in position, and while this may be an oversight in the drawing, and was undoubtedly taken care of by the toolmaker, it should not be forgotten that dowel pins are what really hold a block in accurate location and that the screws merely serve to clamp the block against the base and to resist any upward or tilting thrust which may exist; consequently, the two screws which hold the outer blocks should be placed side by side, close to the inner or clamping edge of the block, and the dowel pins should be placed behind the screws, as shown in the accompanying illustration.



Fixture for Spline Milling Shafts

The fixture referred to for spline milling steel shafts consists of a cast iron fixture base, which is provided with steel tongues B, to engage the groove of the milling machine platen. Hardened tool-steel blocks C, mounted on the base casting by means of fillister-head screws, and dowel pins, serve as blocks against which the work is clamped, and it should be noticed that the surfaces of these blocks, as well as the surfaces of the clamps D are straight, in order that the work being clamped will not be mutilated by the pressure being concentrated at one point of contact. [The advantage of having clamps with a single point contact for holding long, slender and rough work, is that there is less danger of springing it. This point was carefully explained by Mr. Barrett.—EDITOR.]

The clamps D are of machine steel, carbonized and hardened, and are counterbored from the under side to receive the helical springs K, which serve to release the clamp by their upward pressure. These clamps are actuated by the casehardened steel screws F, which are threaded through the base casting and bear against the middle portion of the equalizer bars H. These bars are of machine steel, carbonized and hardened, and carry at their extremities screws G, which pass through the clamp blocks D and serve to pull them against the work when the operating bolt F is turned.

The work rests upon hardened tool-steel pins E, which are driven into the base against a shoulder, and the end thrust of the cutter is absorbed by the steel stop-pins J. A socket wrench is used to operate the clamp bolts F.

It will be noticed that this fixture is much more rapid in its operation than Mr. Barrett's yet it accommodates the same quantity of work, and costs practically the same to build.

C. NOSRAC

SETTING A BENCH LATHE SLIDE-REST FOR STRAIGHT GRINDING

To set the slide-rest of a bench lathe to grind parallel, a cylindrical test piece having centers in each end and a collar on one end, may be used and accurate results obtained. The collar is first ground true, after which the position of the test piece is reversed. When the emery wheel is moved up to the other end, its position with relation to the collar as indicated by the sparks, will make it possible to set the slide-rest very accurately, though it may be necessary to repeat this cut-and-try method once or twice.

For inside setting when finishing holes by grinding, particularly when the work is hardened and is to be lapped, it is especially desirable to get the hole as nearly parallel as possible. This may be done by feeding the emery wheel through the hole and making it cut first on one side and then on the other. By noting the sparking of the wheel, the slide can be set so that the hole can be ground parallel, to an extreme degree of accuracy. If the hole is very deep or small in diameter so that the sparks cannot be seen, a "listener" is used which consists of a piece of a small drill rod with a handle on one end. The end of the rod is applied to some part of the grinder and the handle is held close to the left ear. By the sound emitted when the wheel is in contact with the work, it is easy to tell if the cut is the same throughout the length of the hole on both sides. If this "listener" is not sensitive enough, the bottom of a tin can (having one end open) may be applied to some part of the grinder or to the top of the tool-post screw. The contact of the emery wheel with the work can then be easily heard by listening at the open end of the can, even though the wheel is not taking a cut deep enough to make a visible mark in the hole.

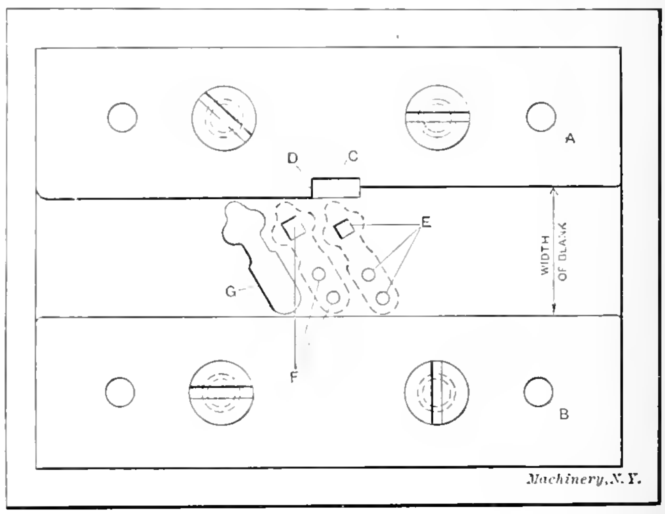
These methods are not only better, but far quicker than the old way of calipering for parallelism.

A. L. MONRAD

East Hartford, Conn.

FEEDING DEVICE FOR PUNCH PRESSES

Seeing an article on feeding devices for punch presses in the April issue of MACHINERY brought to my mind a feeding device which I have used to good advantage when the feeding space was not more than one inch long. The accompanying sketch shows clearly the method used. A and B are the two guide strips which are fastened to the die blank as shown. The stock is cut the required width to slide in between the guide strips. The punch which is inserted in hole C in the die shaves off one side of the strip, allowing it to be located at the point D. Holes E are used for piercing the piece and holes F are made large enough to clear the pierced holes which are embossed and not clean cut. The blank is then punched at G. After feeding the stock in to the die, from right to left, until the end projects past the opposite end of the die, the stock can be grasped by the hand and drawn through the die, the point D acting as a stop. One advantage of this feeding device is that no pilots are required on the punches for spacing accurately. It should be mentioned that it is not advisable to use this device for blanks requiring a feed of more than 1 inch.



Feeding Device for Small Blanks

CHARLES PABESHUTZ

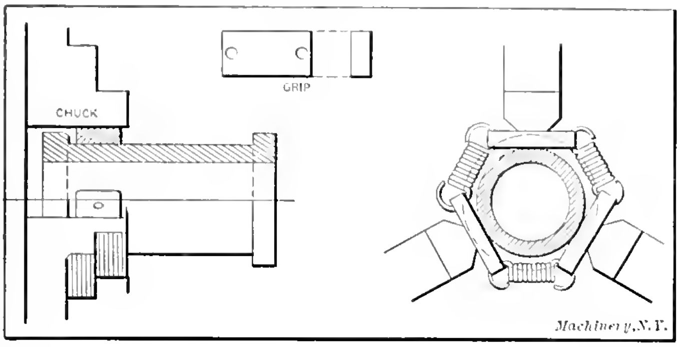
SHOP KINKS

PRACTICAL IDEAS FOR THE SHOP AND DRAFTING-ROOM

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary

CHUCK GRIPS FOR FLANGED WORK

Three or four strips of bar stock, drilled at each end, and hooked together with coil springs, as illustrated in the accompanying engraving, make handy grips for holding

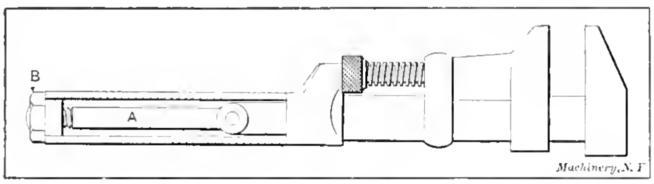


flanged bushings, etc., in a chuck. The number of grips required will, of course, depend upon the type of chuck used. Grips 5-16-inch thick, 5/8-inch wide, and 1 1/4-inch long are a handy size. Charles E. Burns

Beverly, Mass.

HANDLE FOR MONKEY-WRENCH

The way the broken handle of a 12-inch monkey-wrench was replaced with a strong iron one, is shown in the accompanying illustration. The only material required was one



piece of pipe 1 inch by 4 1/2 inches long, and one 3/8-inch steel bolt *A* with a slot cut in the end to fit the tongue-piece of the wrench. This bolt was fastened by a pin as shown, and the nut *B* served to hold the handle in place. W. F. Oliver

Plainfield, N. J.

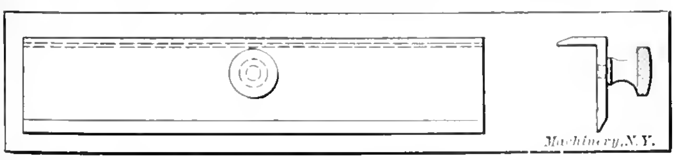
STARTING A DRILL

In the "Experiences of a Young Toolmaker" in the December number of Machinery "George" tells "Jim" that he does not need a centering tool. George is right about the centering or spotting tool, but if he and Jim will use the drill with the lips vertical instead of horizontal, they will find it will not have so much tendency to travel up and down and will take its central position more readily. J. R. Rand

Springfield, Mass.

BOX-SQUARE WITH HOLDER

Probably every machinist has had trouble, at times, in holding a box-square securely on the piece of work to be marked. I have found it so troublesome to hold while using, that I decided to have some sort of a handle attached to it, so I drilled a hole in the center of the broad side and tapped it out for an ordinary thumb-screw which happened to be at hand. After filing the end of the screw even with the inside, the holder was finished. The illustration indicates so plainly the advantage of this little screw that further explanation is unnecessary.



New York City. Arthur Blofield

HOW TO PUT A TAP IN STRAIGHT

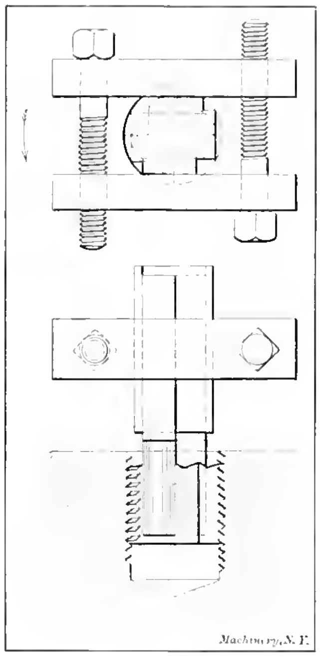
Recently the apprentices at our shop were asked at an examination, how they could tell whether a tap is going in straight or not, if the hole being tapped passed through the center of a sphere. The answer was, by securing a faced nut over the tap and down against the work. If it touched evenly all around this would indicate that the tap was going in straight. Canadian Pacific Railway Apprentice.

MAKING SMALL EMERY WHEELS FROM BROKEN PARTS

If an emery wheel breaks, small wheels may be made from the pieces by drilling a hole in the center of each piece for the arbor and trimming the part to a true circular shape. The center of the broken part should first be found and then a circle drawn equal in diameter to the size of the wheel. The hole should then be drilled for the arbor and the piece ground to shape on an emery wheel. When it is nearly round, it can be finished by mounting it on the arbor of a small wheel-stand, and dressing the periphery with a diamond tool. When drilling the hole, the drill press can easily be driven by hand; it should run slowly, say from 10 to 20 revolutions per minute, and water should be used on the drill. In this way a perfect hole is drilled and the drill itself is uninjured. John C. Monrad

Buffalo, N. Y.

A TAP EXTRACTOR

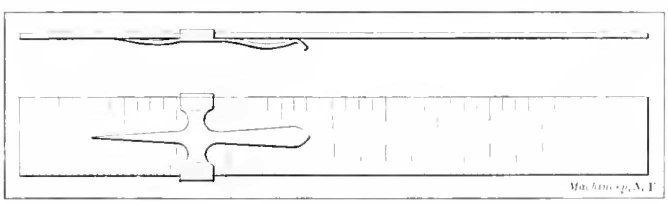


The illustration shows a device for extracting a broken piece of tap from its hole. Take a couple of steel strips, either square or rectangular, and file them part of the way, up to a curved shape, as seen dotted in the plan. Prepare a piece of steel with slight ledges on opposite sides, and bind the strips to this by means of a lathe dog or clamp, as shown. The thin, wedge-shaped ends will pass down the opposite flutes of the tap, and catch against the lands when the rig is turned to the left, thus unscrewing the bit of tap. Fred Horner

Bath, England.

COMBINATION SCALE AND SCRIBER

The accompanying illustration shows a 6-inch scale to which is attached a scriber that is made of tool steel. This scriber



also acts as a pocket clip; in fact, that is the purpose for which it was originally designed. As a scriber is mostly used with the scale, the upper part of the clip was extended so as to form a scriber point, thus combining two tools in one.

Cleveland, Ohio. A. Nielsen

PUMPING HOT WATER

Hot water, even up to 180 degrees F., may be lifted about ten feet if the following piping is run: At the point where the vertical riser from the well meets the horizontal suction pipe to the pump, instead of an elbow use a tee, and on the run of the tee extend the vertical pipe for about four feet and cap it over. If the lift is not too great, this will operate satisfactorily. R. E. Bradley

Winchester, Mass.

HOW AND WHY

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details and name and address. The latter are for our own convenience and will not be published

INFLUENCE OF BELT THICKNESS ON PULLEY SPEED

R. D.—Should the thickness of the belt be taken into consideration when calculating pulley speeds?

A.—When the diameters of the pulleys are small and the belt is relatively thick the thickness of the belt should be taken into consideration in pulley speed calculations, more particularly so when the difference of the two pulley diameters is great. In ordinary pulley calculations, however, where the pulleys are, say, twelve inches in diameter or more, it is not customary to consider the thickness of the belt. In the case of a feed belt of an engine lathe, the thickness of the belt makes an appreciable difference in the ratio of the pulley speeds. If the driving pulley is, say, 6 inches in diameter and the driven pulley is 2 inches in diameter, then the ratio of the driving and driven diameters, not considering the belt, would be as 6 to 2, or as 3 to 1. Considering the thickness of the belt, however, to be $\frac{1}{4}$ inch and taking this thickness into consideration, the ratio would be as $6\frac{1}{4}$ to $2\frac{1}{4}$ or as 2.77 to 1. It will therefore be seen that the thickness of the belt makes a difference of about 8 per cent in the speed of the driven pulley.

CRUCIBLE FURNACE CONSTRUCTION FOR GAS FUEL

W. R.—I enclose a sketch of a crucible furnace, see Fig. 1, with which we are having no end of trouble on account of the rapid burning out of the cast-iron gas burners. The furnace is used for casehardening small steel parts. Gas is burned under moderate air blast from the shop line. We would appreciate some solution of the difficulty.

Answered by E. W. Beardsley, Waterbury, Conn

A.—In Fig. 2 at *A* I have reproduced your sketch of the furnace and crucible, adding a cover, a vent at the top, and a

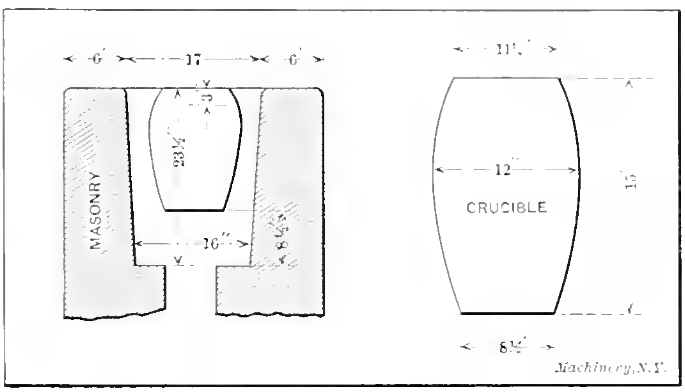


Fig. 1. Furnace Construction which gives Trouble with Burners

burner at the bottom, as illustrative of the probable present construction. The burning out of the cast-iron burner is probably due either to the large surface exposed to radiation from the furnace chamber, or to combustion taking place inside of the burner, on account of faulty design or operation.

At *B* is shown a much better application of burners, which, in a furnace of this size, should probably be not less than two in number. At *C* is a sectional plan of furnace *B*, showing more clearly the tangent relation of the burners to the circular chamber. With this arrangement the flame will probably travel several times around the crucible instead of taking as nearly as possible a straight line from the burner to the vent, as at present.

At *D* is shown a section of a burner which can be made up from standard pipe fittings. If the tip burns out, as it probably will in time, the flange joint enables easy removal and the burned parts can be cheaply and easily replaced. Use a gasket of asbestos paper or similar material between the flanges. Fittings for $1\frac{1}{2}$-inch wrought-iron pipe will probably be large enough for your furnace with two burners, and a 2-inch pipe will be sufficient to bring the gas and air from the mixer to the tee supplying the burners.

If the "shop line" from which the air is taken carries compressed air at a pressure of 40 pounds per square inch or more, the air should be used in a jet blower, for economy. The one shown in Fig. 3 is a combined jet blower and mixer which can be easily constructed from pipe and fittings. These fittings should be not smaller than 2-inch pipe size for the cross, $1\frac{1}{2}$-inch pipe for the gas, and $\frac{1}{8}$-inch or possibly $\frac{1}{4}$-inch for the compressed air. The pressure beyond the mixer need not be more than 2 pounds per square inch, and probably 1 pound will be sufficient.

The changes recommended would probably result in a saving of not less than 10 per cent and very likely 25 per cent of the

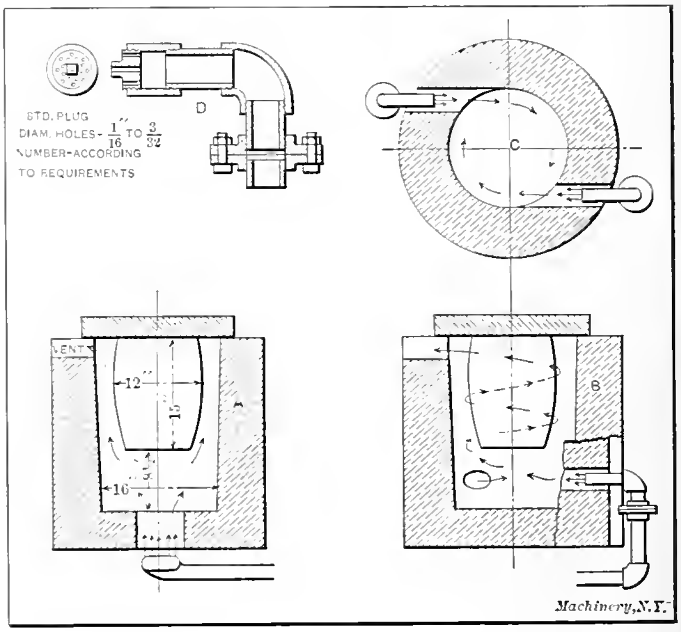

Fig. 2. Suggested Improvements over Furnace A are shown at B, C and D

gas you are now using. With a suitable furnace using fuel oil or coal instead of illuminating gas, you could probably save not less than 60 per cent of the present fuel cost. If in a coal or oil furnace you would use a cast-iron box in place of the crucible which is the usual practice, the saving would probably be 80 per cent or even 90 per cent.

Suitable furnaces for casehardening with any of these fuels can be bought from various manufacturers whose advertise-

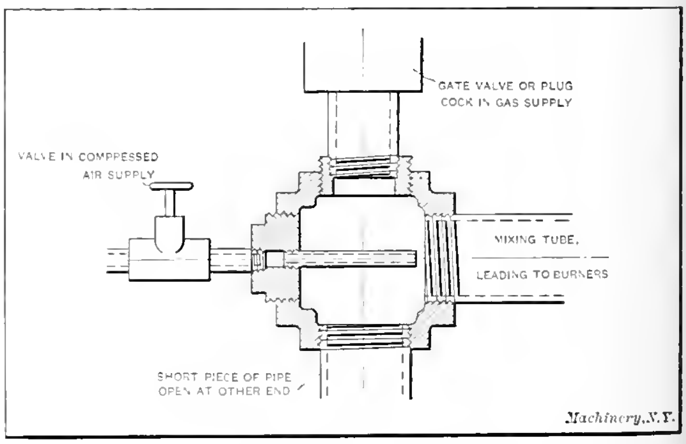

Fig. 3. Combined Jet Blower and Mixer Operated from Shop Compressed-air Service

ments you will find in this paper, at a lower cost than you can make one yourself. You can probably also buy suitable gas burners alone, from the gas furnace manufacturers.

* * *

Some concerns in certain lines of manufacture requiring many comparatively simple and cheap special machines, make a practice of purchasing second-hand machine tools. The headstocks and slides are worked over at small cost so as to adapt them to the desired purpose. Many special machines are in use in a certain factory, built up from regular machine tools at very low cost, the functions of which are quite different from those for which the machines were originally designed.

NEW MACHINERY AND TOOLS

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP

Comprising the description and illustration of new designs and improvements in American metal-working machinery and tools, published without expense to the manufacturer, and forming the most complete record of new tool developments for the previous month.

MORTON TRAVELING-HEAD CYLINDER PLANER

The traveling-head cylinder planer illustrated herewith, which is built by the Morton Mfg. Co., Muskegon Heights, Mich., is a machine that is particularly adapted to that class of work which, when finished with standard tools, requires, in some instances, more time for adjustment than in the actual machining operations. As this machine, besides being an efficient planer, is also capable of performing boring and milling operations, parts can often be finished at one setting, thus effecting a considerable saving in time.

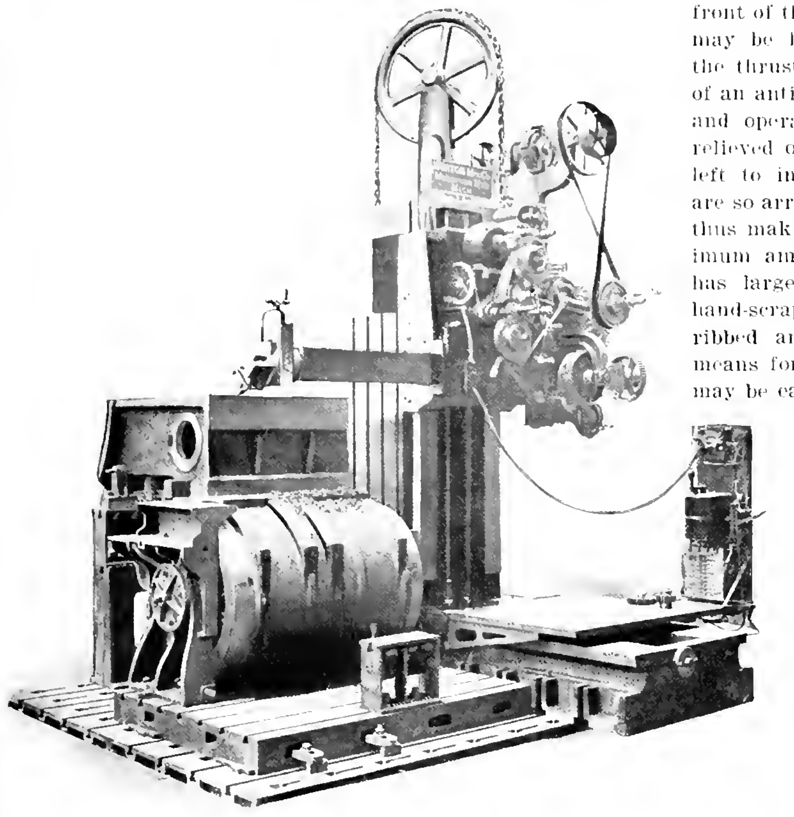

Fig. 1 Morton Traveling-head Planer with Locomotive Cylinder in Position for Planing

This planer is electrically driven by a 10-horsepower variable speed motor, which is attached directly to the base of the column. The power is transmitted through gears to a vertical shaft which is connected with the directly-attached countershaft. From this shaft connection is made by open and cross belts to friction clutch pulleys, which control the reciprocating motion of the ram, and are so arranged that reversals are made without shock or jar. By means of a clutch, the countershaft may be stopped and started independently of the motor and it can be reversed for back-facing, boring, etc., when necessary.

The vertically moving apron which is closely fitted to the column and provided with means for compensating for wear, carries the feeding and other working mechanism of the machine. This slide is provided with taper gibs and is so constructed that it is unnecessary to employ binder clamps back of the bearing rails. The saddle casting is extended in such a manner that in connecting with the taper gibs, it forms a bearing which insures rigidity. The counterbalance for the apron and its mechanism consists of an air cylinder placed on the rear side of the column, in which a given pressure is automatically maintained. A compressor, which is driven direct from the motor, makes the machine independent of any outside connection.

The column and its saddle are made in one piece and are heavily constructed throughout. The T-slotted plate on the front of the column presents a surface against which a bearing may be bolted for supporting high work, thereby bringing the thrust of the cut directly against the column. By means of an anti-friction carriage which is placed beneath the column and operates on a steel track, the bearings on the bed are relieved of a certain portion of the weight, just enough being left to insure the machines working steadily. Coil springs are so arranged that the tension can be increased or diminished, thus making it possible to adjust to the point where the minimum amount of power is required for operation. The bed has large bearing surfaces and square bearings which are hand-scraped and fitted. It is very rigidly constructed, being ribbed and cross-ribbed. Open slots on each side provide means for screwing the bed to the floor-plate by bolts; these may be easily removed, making the machine portable.

The cast-steel ram is made hollow and square and it has a bearing on all four sides which extends through the entire length of the apron. Provision is made for taking up wear by wedge gibs above and by the adjustment of a ram cap on the side. Power is applied to the ram by a rack and pinion movement. The main driving pinion and bevel gears are made of steel and are so arranged that they are entirely enclosed and run in oil, thus insuring practically noiseless operation and great durability. The gearing is all cut from the solid. The stroke of the ram may be quickly adjusted by tappets on a circular disk. The minimum stroke is 3 inches and the

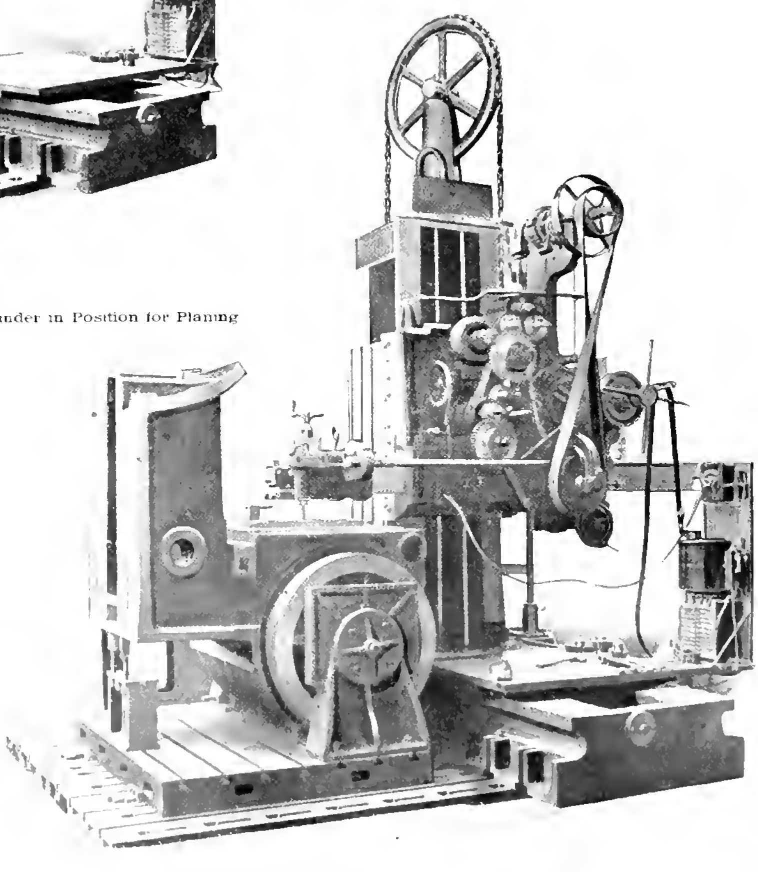

Fig. 2 Morton Cylinder Planer equipped with Port Milling Attachment

maximum 48 inches. The head of the ram is made entirely of steel, and is provided with special steel clamps. It is graduated for planing to angles, and the clapper-box is arranged to relieve the tool on the return stroke.

The feed is a new design of the compound disk friction type, the disks of which are lined on each side with vulcanized fiber. It is of the automatic relieving type and is provided with an instantaneous quick change by adjusting tappets on a circular disk containing holes so that the tappets may be securely locked in position. The feed is reversible so that it may be made to occur at either end of the stroke. When the full feed is required, the tappets may be so arranged as to cause it to operate at both reversals. The feeding mechanism for milling and boring consists of a special feed box secured to the vertically moving saddle, which gives ten changes, covering a range suitable for either boring or milling. Provision is made for reversing so that the saddle may be fed vertically in either direction and the column horizontally in either direction. The ram may also be fed in and out and the arrangement is such that all boring and milling feeds are stopped and started with one lever. The feed screws are of large diameter and the feed nuts are all of bronze and of the revolving type. They have long bearings on the screws and are provided with ball bearing thrust collars with hardened steel plates.

This machine is provided with an auxiliary table 30 inches high, 36 inches wide and 8 feet long, which may be bolted to the floor-plate. By means of parallel strips which may be placed between the bed and the lower edge of the table, the latter can be set in perfect alignment with the bed. It can be used for holding parts being planed or, as illustrated in Fig. 3, in connection with rotary planing.

The milling and boring attachment is provided with a hollow steel arbor which passes through the ram and is journalled in bronze bearings. The front bearing is tapered and adjustable for wear. A special steel yoke which is attached to the back end of the ram, carries a powerful train

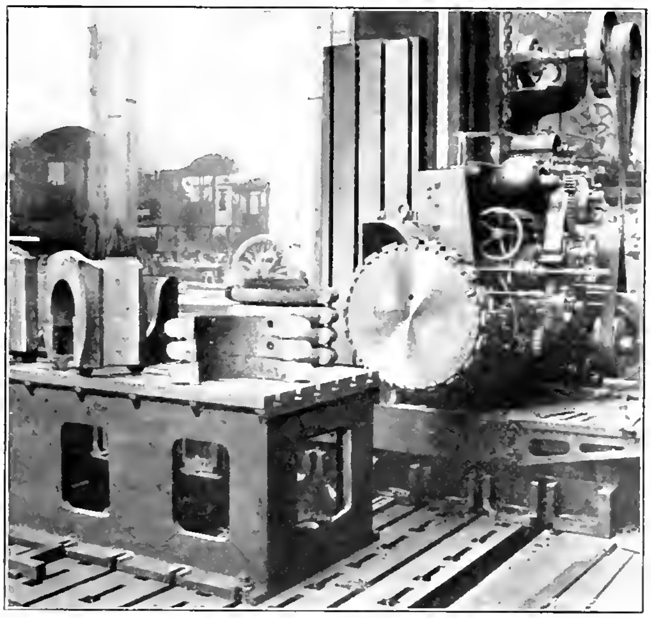

Fig. 3. Cylinder Planer Arranged for Rotary Planing

of gearing for driving. This yoke is so designed that it may be quickly removed with the gearing when necessary. The arbor is bored for receiving taper shank milling cutters, boring-bars, etc., and a retaining or drawing-in bolt which passes through the arbor makes it possible to quickly engage or disengage the tools. The rotary planing equipment consists of a steel milling head about 25 inches in diameter provided with an internal gear, the teeth of which are cut from the solid. The cutters are inserted in the periphery as shown in Fig. 3, and securely clamped.

The port milling attachment, which is shown in use in Fig. 2, may be quickly attached to the squared section of the ram without removing the shaper head. It is provided with a vertical arbor and a train of gearing giving ample power. The spindle is bored to receive a No. 4 Morse taper. This is an efficient attachment for milling cylinder ports, and the operation may be performed when the work is in position for planing the valve seat.

The cylinder chucks, the use and advantage of which will be apparent by referring to Figs. 1 and 2, are attached to movable brackets which are tongued and fitted to one of the slots in the auxiliary base-plate. One of these brackets may be adjusted by a rack and pinion for cylinders of different lengths. These brackets are made to given dimensions so that their surfaces may be used in laying out lines. The chucks are of the three-jawed universal type and make it possible to quickly set a cylinder in alignment, as the jaws

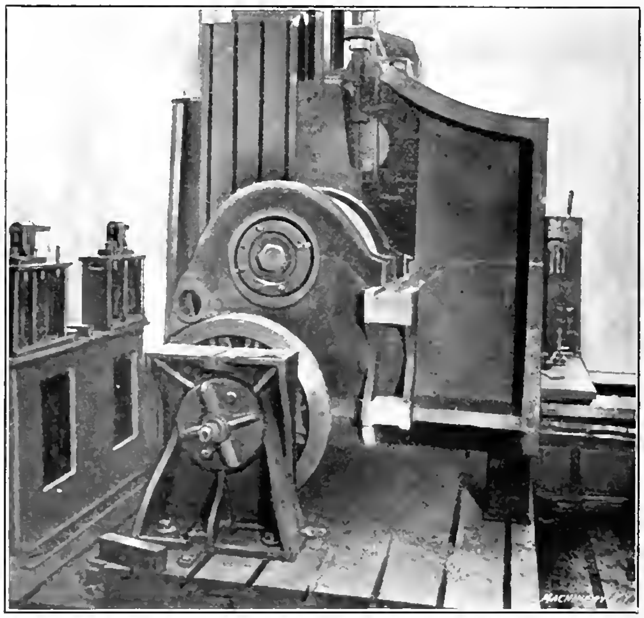

Fig. 4. Boring Attachment of the Cylinder Planer in Use

engage with the finished counterbore. A bolt passing through the cylinder from one bracket to another more firmly aligns and holds in position the work. Parallel blocks are included for supporting a cylinder in various positions and when the work is once chucked, it is not removed until the planing is finished and the bars milled.

This machine has a longitudinal feed of 9 feet and a vertical feed of 60 inches. The extreme height of the machine is approximately 15 feet, the floor space required 14 by 16 feet, and the weight 48,000 pounds.

NEWTON BOLT THREADING MACHINE

The Newton Machine Tool Works, Inc., 24th and Vine Sts., Philadelphia, Pa., has brought out an interesting type of bolt threading machine which we illustrate herewith. This machine, which is built with the duplex die-head shown in Fig. 1, or with a single die-head, has been designed to handle the diversified class of work that the bolt-cutter is usually called upon to do.

The compact design of adjustable die-head with which this bolt-cutter is equipped, constitutes one of the most interesting features in its construction. These die-heads are fitted with four different sets of chasers, as shown in Fig. 2, so that a single head is always ready to cut any one of four bolt sizes. The chasers are of a standard form and are accurate and interchangeable. The four chaser blocks in which the chasers are fitted, are operated universally when adjusting the die, and each is independently locked in its position by a special arrangement which prohibits any movement whatsoever.

To index the chaser blocks when setting the die to a different size, it is simply necessary to throw the lever controlling the head back far enough to completely disengage the locking mechanism; a pin is then inserted in any one of the chaser blocks, which, together with the others, is revolved to the desired position. The head is then closed by means of a lever, and a hand-wheel is adjusted until a pointer is in line with the zero mark on the scale covering the particular size required. By means of separate index scales for each posi-

tion of the chaser blocks, the dies may be set so accurately that it is not necessary to cut trial bolts except when a chaser is first put into operation or when it has been re-hobbed. After the chasers are once set, the head can be indexed as frequently as desired and it can always be brought to the correct position by the pointer and scale referred to. Chasers of the "hobbed" type will be furnished unless otherwise specified, owing to the fact that many desire to re-hob and make their own chasers. These chasers are made of carbon steel ordinarily, but will be made of high-speed steel if preferred.

The general construction of the die-head is simple, there

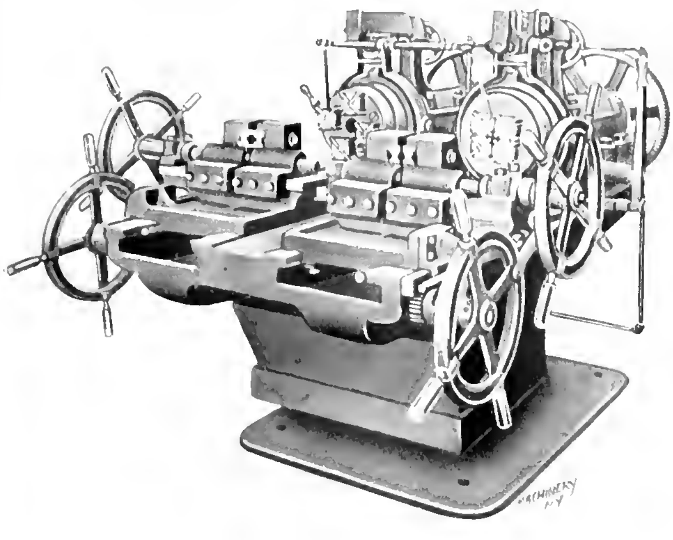

Fig. 1. Newton Duplex Bolt Threading Machine, with Multiple Automatic Die-heads

being few operating parts, all of which are of high-grade material. The head is arranged for automatic opening and closing, or it can be operated by hand. The construction is such that when the opening is done automatically, no fin or burr is left on the thread. The makers claim that this head is as rigid as a solid die, owing to the fact that the in-and-out motion is controlled by a cam and eccentric which give a solid metal-to-metal contact, so that the die is absolutely dependable in maintaining the size of bolt when it is once set. The die-holders are of 50-point carbon steel and the chasers are fitted into slots milled from the solid and have bearings on two sides and the end. The chasers are held in place by a single screw, as shown, and are interchangeable.

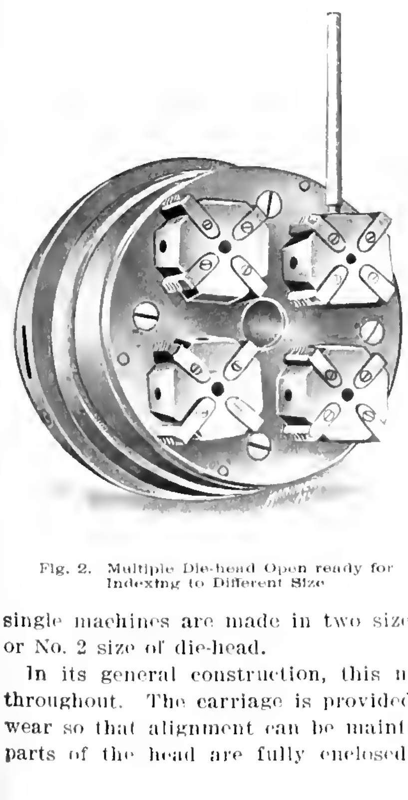

Fig. 2. Multiple Die-head Open ready for Indexing to Different Size

The die-heads are made in two sizes designated as Nos. 1 and 2. The first size will cut $\frac{5}{8}$, $\frac{3}{4}$, $\frac{7}{8}$ and 1-inch bolts, and the No. 2 size, $1\frac{1}{4}$, $1\frac{1}{2}$, $1\frac{3}{4}$ and 2-inch bolts. As the spindle of the machine is hollow, any length of thread may be cut. The duplex machines are made in one size only, and are fitted with heads of each size, thus giving them a capacity for cutting bolts of eight different diameters ranging from $\frac{5}{8}$ inch to 2 inches. The single machines are made in two sizes with either the No. 1 or No. 2 size of die-head.

In its general construction, this machine is heavily built throughout. The carriage is provided with compensation for wear so that alignment can be maintained, and all operating parts of the head are fully enclosed so that all dirt is excluded. The clamping jaws of the vise are reversible and interchangeable, and the machine is fitted with a pump, chip box and drip pan.

NEWCYCLE GAS AND OIL ENGINE

An interesting type of internal combustion engine has recently been placed on the market by the Newcycle Motor Co., 39-41 Cortlandt Street, New York City. The main purpose in the development of this new engine, one design of which is illustrated herewith, has been to secure the advantage of an explosion at each revolution, as with the ordinary two-cycle type. It is also designed to give perfect scavenging without waste of fuel and a full charge of explosive mixture for each revolution.

In the operation of this engine, air only is taken into the crank-case on the up stroke of the piston, through a check valve screwed into the opening *N*, Fig. 2. It will be noted that the piston has two diameters, the smaller end working in the power cylinder and the larger diameter acting as a pump piston, which serves to draw air into the crank-case *C* and also to compress the charge, which is done in the annular space *B* above the enlarged piston end. In the case of an oil engine, space *B* holds air only, which is compressed and used for

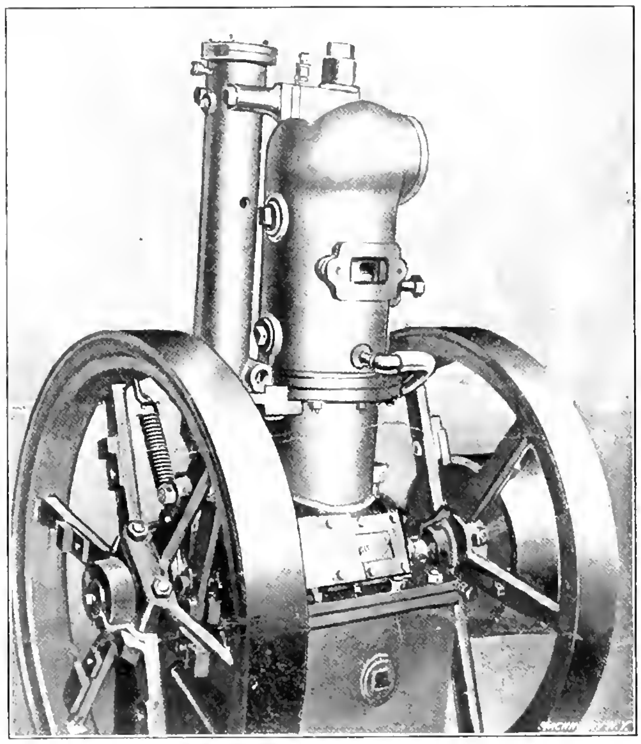

Fig. 1. Newcycle Gas and Oil Engine

injecting the fuel in a blast or spray, while for a gas engine the gas or a rich mixture of gas and air is compressed in this space. When compressed, the charge of air (or gas) enters the valve chest *D* which also acts as a receiver. The admission of air to the annular space *B* is governed by the slide valve *E*, which admits air through the inside port, while the discharge is around the lower edge of valve *E* and up through this valve into the receiver *D*. When the piston is near the end of its downward stroke, it uncovers exhaust port *S* and directly afterward the port *P*, thus releasing the air which has been compressed in the crank-case by the downward motion of the piston. As this air enters, it strikes a baffle-plate *T* on the piston and is deflected upward so that the burned gases are forced downward and out of the exhaust. The volume of the crank-case has been made sufficiently greater than the piston displacement, so that, after allowing for volumetric losses, a charge of air great enough to insure perfect scavenging is injected into the cylinder at the end of each working stroke. The passage of air through the exhaust at this point in the cycle is, of course, immaterial, as the fuel is not as yet mixed with it. Soon after the piston starts on its upward stroke, the valve *F*, which with *E* is actuated by an eccentric, uncovers the port *M* and suddenly releases the air in valve

chest D, which then passes through port M and the check valve H. This is at the time when the exhaust gases have practically all left the cylinder, and when the greater part of the air from the crank-case has passed in through port P. The compression begins, of course, as soon as the ports in the side of the cylinder are closed, and the valve H automatically seats as soon as the pressure is equalized.

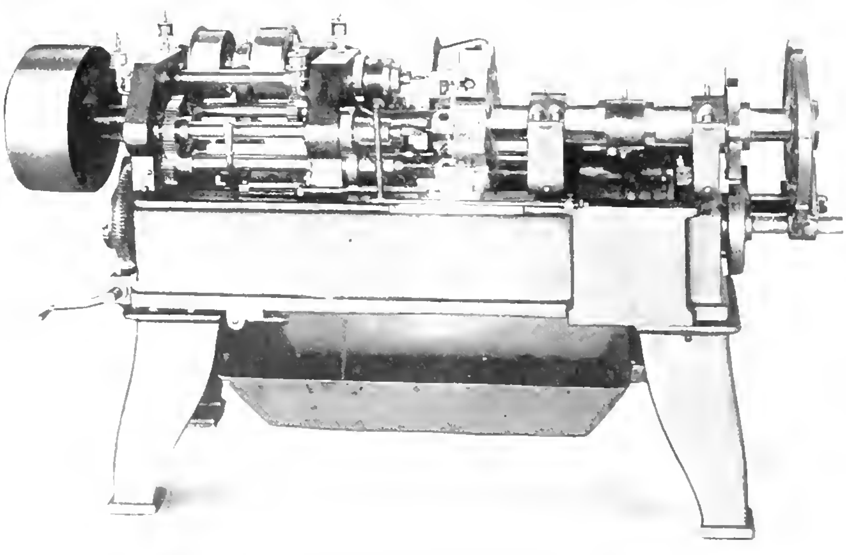
In the case of a liquid fuel engine, the fuel is injected into the passage M by a small pump such as is commonly used on kerosene engines. This pump is under the control of a flywheel governor which regulates its stroke and, therefore, the quantity of oil supplied, according to the load on the engine. As the air in chamber D is under pressure, its sudden discharge at high velocity through port M causes the fuel, which is partly atomized mechanically, to be thoroughly carburetted.

It should be mentioned that the exact construction illustrated is not necessarily to be followed in detail, as modifications will doubtless be necessary to meet different conditions, but the views presented herewith serve to show the cycle of events and the principles involved.

An engine of this type having a 5- by 6-inch cylinder, developed, during a recent test at Cornell University, $6\frac{1}{4}$ horsepower, running at 360 revolutions per minute, and over 7 horsepower during a short period of the time.

PRENTICE FIVE-SPINDLE AUTOMATIC WITH TWO TAPPING SPINDLES

The multiple-spindle automatic turret machine illustrated herewith is a modification of the standard five-spindle automatic built by George G. Prentice & Co., Inc., New Haven, Conn. This machine is arranged especially for the drilling, tapping, etc., of solid castings, forgings and similar work requiring two taps—one under-size for roughing out and the other for finishing. By this method two light cuts are taken, and the breakage of taps of, say, $\frac{3}{8}$ inch or smaller, due to the clogging of chips when using one tap, is overcome.



Prentice Five-spindle Automatic Turret Machine with Two Tapping Spindles

The tapping mechanism consists of a pair of friction pulleys —one for the forward and one for the reverse drive—which are automatically tripped after tapping the required number of threads. The tapping is done by the fourth and fifth spindles, both of which are yoked and geared together and driven by one set of friction pulleys. When starting a new job, the roughing tap is first run through the hole; then the finishing tap is started a few threads by hand into the hole to get the lead. When the collets are tightened, both taps will maintain the same lead.

The machine illustrated has a six-section chuck or work-holder. Five pieces are operated upon simultaneously in this machine while the operator is removing and inserting work at the sixth section of the chuck. The five spindles may be equipped with any arrangement of tooling, including drills, reamers, counterbores, facers, box tools, taps, etc. The machine as shown is equipped with tools and work-holders for drilling, counterboring, and tapping the binder screw holes in automobile clutch-shifter fork forgings.

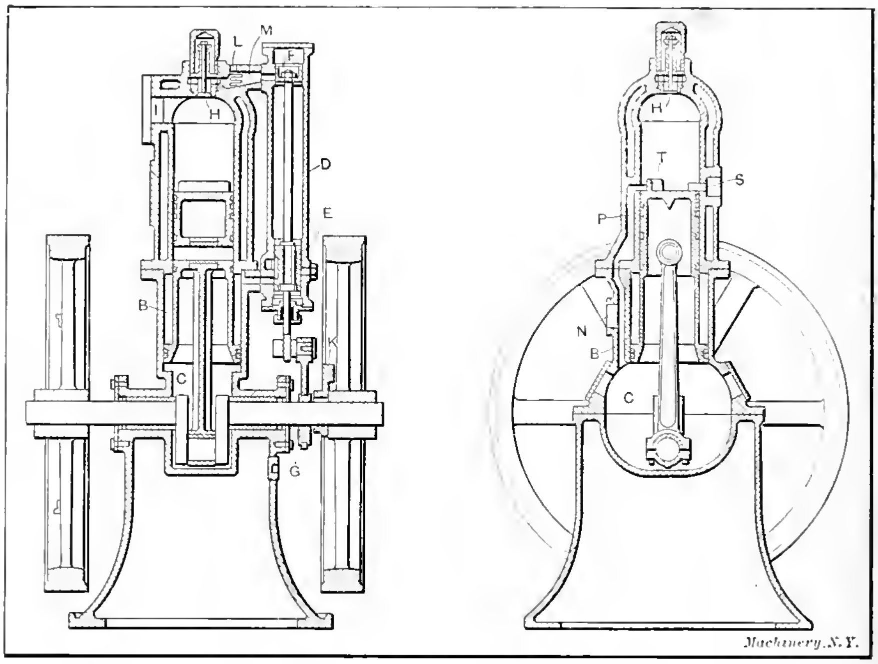


Fig. 2. Sectional Views of the Newcycle Engine

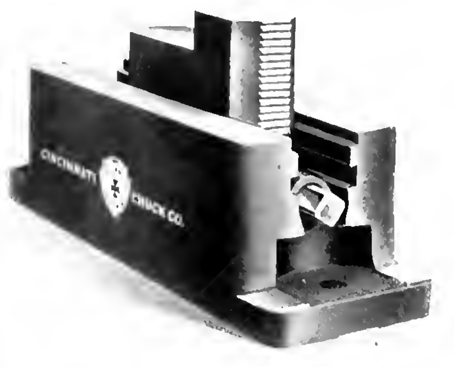
The principle of this machine is the same as in other Prentice single-head automatics. The chuck is automatically advanced towards the revolving spindles by means of a cam on a large drum inside of the bed. There is also a return cam to draw the chuck away from the tools at the completion of the operations. The camming is timed so that the chuck is automatically indexed to the succeeding operation as soon as the longest operation has been completed. A new feature being applied to Prentice automatics, is a differential feed mechanism for speeding up the indexing time of the chuck. By this means the production is increased about 30 per cent.

As all the operations on any piece of work done in this machine are finished complete within the cutting time of the longest operation only, a great saving in time is effected. A further reduction is made on that class of work which requires the drilling of long holes, by drilling one-half the length in one spindle and the remainder in the succeeding spindle. Thus a hole of 2-inch depth could be drilled the entire length, reamed, faced, tapped, etc., in the time that would ordinarily be consumed in drilling a hole one-half that depth. This machine has ample power to drill and tap up to $\frac{5}{8}$ inch in diameter, although the class of work requiring the double tapping arrangement is generally $\frac{3}{8}$ inch and smaller. The net weight of this machine, with countershaft, is about 3000 pounds.

CINCINNATI FACEPLATE JAW

The Cincinnati Chuck Co., Cincinnati, O., is now manufacturing a new faceplate jaw, which we illustrate herewith. The chief feature of this jaw lies in the method of mounting the screws in hardened steel bushings which provide a full bearing for the trunnions of the screws and receive the end thrust on their hardened circular faces, thus minimizing

wear and resultant end play. In the ordinary faceplate jaw, the screws are mounted in semi-circular bearings and receive the end-thrust on semi-circular shoulders formed in the cast iron shell of the jaw, which results in excessive wear that is difficult to overcome. The patented bushings with which these new jaws are equipped will, of course, prove more durable, and when end paly does develop, the construction is such that the bushing can be taken out and replaced by any machinist in a very short time, making the jaw, in this respect, just as good as new. These bushings also serve to hold the screws in absolute alignment with the jaw, thus preventing any tilting of the screw and consequent cutting of the thread. These features are of considerable importance, and overcome most of the jaw troubles commonly experienced.

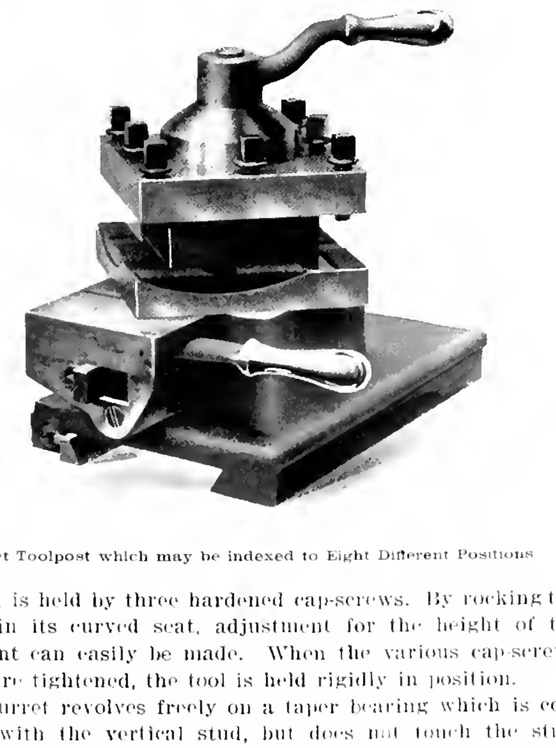


Faceplate Jaw made by the Cincinnati Chuck Co

TURRET TOOLPOST FOR LODGE & SHIPLEY LATHES

The Lodge & Shipley Machine Tool Co., Cincinnati, O., has recently designed a new turret toolpost which may be applied to any size of lathe manufactured by this company. With this new design, the turret can be indexed to eight different positions so that the tools may be set diagonally, as well as at right angles to or in alignment with the cross-slide. Each tool is clamped well forward of the center so as to give a firm support, and the clamping of the binder lever does not appreciably change the position of the turret.

The lower block of this attachment is interchangeable with the compound rest slide and is fitted to the carriage dovetail by a taper gib. A vertical stud is secured in this base and passes up through the turret to carry the binder lever at its top. The toolpost is of steel. Each one of the four tools rests upon a serrated and hardened bolster or rocker, against



Turret Toolpost which may be indexed to Eight Different Positions

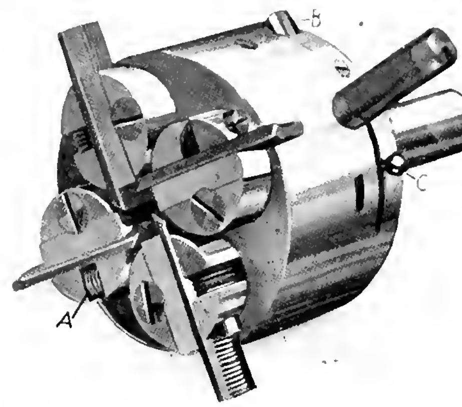
which it is held by three hardened cap-screws. By rocking the bolster in its curved seat, adjustment for the height of the tool point can easily be made. When the various cap-screws shown are tightened, the tool is held rigidly in position.

The turret revolves freely on a taper bearing which is concentric with the vertical stud, but does not touch the stud. A bushing, which is tapered to fit the bearing of the turret, is slipped over the stud. An adjusting nut is threaded to the stud and bears against the upper end of the taper bushing, so that by tightening this nut, the bushing can be pushed down to eliminate play in the bearing. The large collar between the binding lever and the turret, covers the end of the taper bushing and its adjusting nut, so that no chips can get into the bearing. As the large diameter of the taper bearing is at the top, the turret is at all times held against the horizontal bearing of the lower block so that when the binder is clamped, the position of the turret and tools remains unchanged.

The turret is exactly located in any one of the eight positions by a locking bolt which engages notches in an index ring. This locking bolt is withdrawn by the handle seen at the front of the lower block. Compensation for wear in the bearing of the locking bolt is provided for by a taper gib. A coil spring holds the locking bolt against the index ring so that it will at once drop into the notch when the proper point is reached. The screw shown in the illustration just beneath the end of the locking bolt provides adjustment for the tension of this coil spring.

BICKFORD AND WASHBURN TAP THREADING DIE

The die shown in the accompanying illustration, which is manufactured by Bickford & Washburn, Inc., Greenfield, Mass., is intended for the threading of small taps. In this die the well-known milled thread chasers have been used. The advantages of these chasers over the hobbed cutter are in the longer life of the chaser and the shearing cut, which produces a smooth thread when cutting tool steel.



Die for Threading Commercial Taps

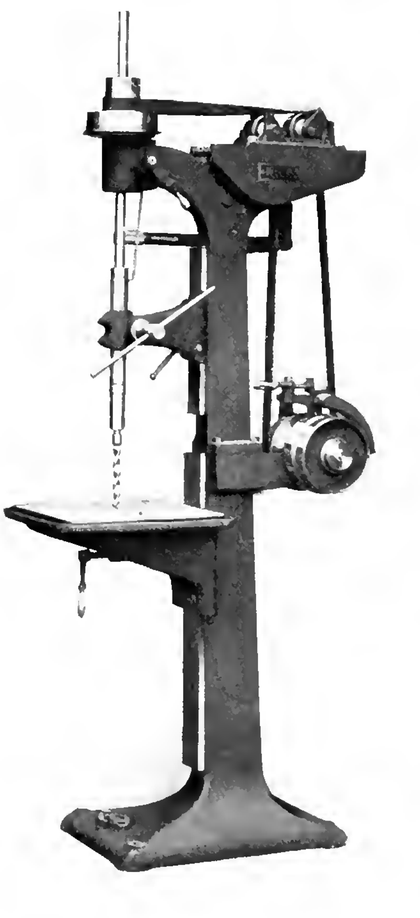
This die, which is designed to be used in a hand screw machine having a lead-screw attachment, has a body 4 inches in diameter, $2\frac{3}{4}$ inches long, and a shank 1 inch in diameter. The shank is hollow and is tapped for a pipe connection so that when the die is in use, a strong flow of oil from the rear keeps the chips well away from the work. The main body is a solid piece of steel accurately bored to receive the cylinders or chaser holders. It is also recessed at the back to make space for short arms which are let in flush at the back end of the cylinders and project across, thus making a bearing to prevent the forward movement of the cylinders. Any backward movement is prevented by the cam plate which comes up directly against the back of the main body and also against the arms referred to. These arms carry pins which are operated by slots in the cam plate, thus opening and closing the die. A collar of the same outside diameter as the main body, is placed just back of the cam plate, and has in its front side a circular recess, into one end of which projects screw *B* which stops the rotation of the cam plate by means of a stud projecting from the plate back into the recess referred to. By turning screw *B* the closed size of the die is determined. The stud in the cam plate is covered by an eccentric sleeve which is operated by the small knob *C*, thus allowing a thick or thin part to come against the end of the screw *B*, so that, by taking a first cut with the knob *C* in the position shown, a very light finishing cut may be taken.

This is a feature in the construction, which will be appreciated by tap makers, as it enables roughing and finishing cuts to be taken. By turning pin *C* to the proper notch for the first cut, it is possible to vary the amount of the finishing

cut as desired. The chasers are held in position by taper gibs which are tightened by the binding screws shown. The necessary adjustment is obtained by means of short worms *A*, inserted in the holders and engaging with the backs of the chasers which are hobbed to receive them. It is possible with this die-head to thread any size of tap within its capacity with the same set of chasers, the proper cutting size being obtained by means of the graduated adjusting screw *B*, as explained.

KERN HIGH-SPEED SENSITIVE DRILL

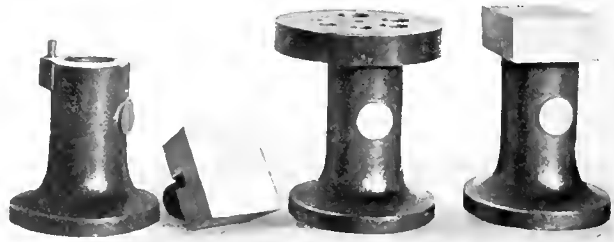
A high-speed, ball-bearing, sensitive drill that is heavily constructed throughout and intended for hard and continuous service, is shown in the accompanying illustration. This machine which is the product of the Kern Machine Tool Co., Cincinnati, O., is exceedingly simple in its design and contains a number of exclusive features. Ball bearings are used throughout, and all cones and ball races are made of steel and are hardened and accurately ground on special machines. The lever at the left of the column near the top controls the idler carriage which is free to move longitudinally. A slight downward pull on this lever loosens the belt and allows speed changes to be instantly made, while an upward movement of the lever tightens the belt to any required tension and automatically locks the idler carriage. The spindle cone, which has two steps, is mounted on a sleeve that is journaled in the column, thus relieving the spindle of any belt pull. This sleeve also serves to raise and lower the cone by means of a rack and pinion operated by the small lever shown on the right side of the column at the top. This vertical adjustment of the spindle cone permits the small or large step to be brought in alignment with the idlers at the rear. Four spindle speeds are available, two being obtained through the two-step cone and the like number by a two-step cone on the countershaft. It will be uoted that the belt-shifting lever is conveniently located and also that the idler pulley is somewhat smaller in diameter than the driving pulley in order to relieve the tension on the belt when the machine is not in use. The upper and lower sections of the column are tongued and grooved to prevent any disturbance of the alignment. The spindle is double-splined and the spindle sleeve is graduated and fitted with an adjustable stop collar. The spindle has a traverse of 15 inches and is bored to a No. 2 Morse taper. The distance from the spindle to the face of the column is 8 inches, and the maximum distance to the table is 32 inches. With a countershaft speed of 800 revolutions per minute, spindle speeds ranging from 600 to 1800 revolutions per minute can be obtained. The table of this machine has a traverse of 21 inches and the head 9 inches. This type of drill can be furnished with any number of spindles up to and including six. The net weight of a single spindle machine is 485 pounds.



High-speed Sensitive, Ball-bearing Drill

CASCADE COMBINATION BENCH ANVIL

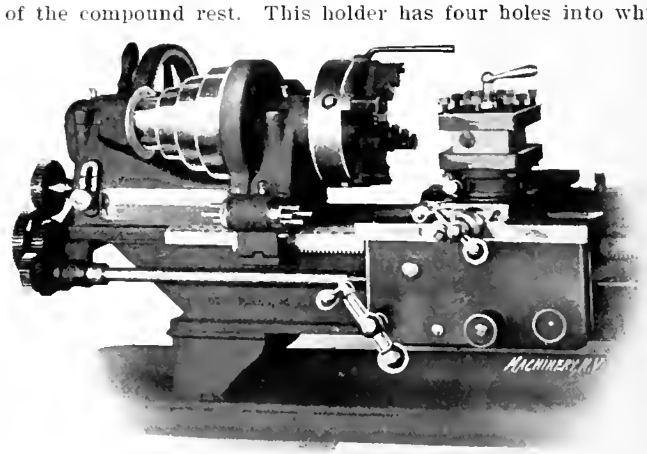
A combination bench anvil that is the product of the Cascade Tool Co., Cohoes, N. Y., is shown in the accompanying engraving. As this illustration is largely self-explanatory, the usefulness of the tool will be at once apparent to the mechanic. The combination consists of a tubular base or stand and an interchangeable anvil and disk, the latter having a series of holes ranging from 1/4 to 1 inch in diameter. The disk has a center hole which engages a pin on the base so that when it is revolved, the holes of various sizes are brought in alignment with the bore of the base for driving arbors, pins, etc. This disk is ground on both sides so that it may be used either side up, and, if desired, one side may be used for rough and the other for finished work. When the disk is not required, it may be lifted off and replaced by the square anvil shown, thus making an excellent bench block for hammering, riveting and similar work. The anvil is also ground on the top and sides, and the supporting base is faced true on the top and bottom. This combination anvil, or a tool of similar construction, could undoubtedly be used to advantage in every shop. In many instances much time is needlessly wasted because of the lack of such inexpensive, but nevertheless, useful tools. The price of this anvil complete with interchangeable anvil and disk is $2.50.



Combination Bench Anvil with Block and Arbor Disk

ATTACHMENTS FOR "STAR" LATHES

In the accompanying engraving two new attachments are illustrated which are intended for use on the well-known 9- and 11-inch "Star" lathes, manufactured by the Seneca Falls Mfg. Co., 330 Water St., Seneca Falls, N. Y. One of these attachments consists of a combination carriage turret and toolpost, which is mounted on the cross-slide of the lathe in place of the compound rest. This holder has four holes into which round-shank tools may be insertea. Binding screws are also provided for holding four regular turning tools. Of course, the tools may be fed either by power, cross or longitudinal feeds, or by hand if desired.



"Star" Lathe equipped with Combination Turret and Toolpost, and Carriage Stop

There is shown clamped to the bed in the illustration another attachment which is used to locate the carriage for shoulder distances, etc., when turning duplicate pieces. This stop, which may be attached to the bed at any desired position, has a revolving cylinder containing four adjustable stop-rods which positively locate the carriage. This cylinder may be re-

volved by hand and is held in position by a detent spring and ball.

These two attachments may, of course, be used singly or together. The advantages of the turret are obvious, and the carriage stop will prove valuable for interchangeable work, as it will eliminate measuring each piece, and insure uniform dimensions.

MORTON SPECIAL DRAW-CUT RAILROAD SHAPER

A shaper of the draw-cut type that has been specially constructed to meet the requirements of railway work, is shown in Fig. 1. This machine, which is the product of the Morton Mfg. Co., Muskegon Heights, Mich., is an improved design in which a number of changes have been incorporated to increase

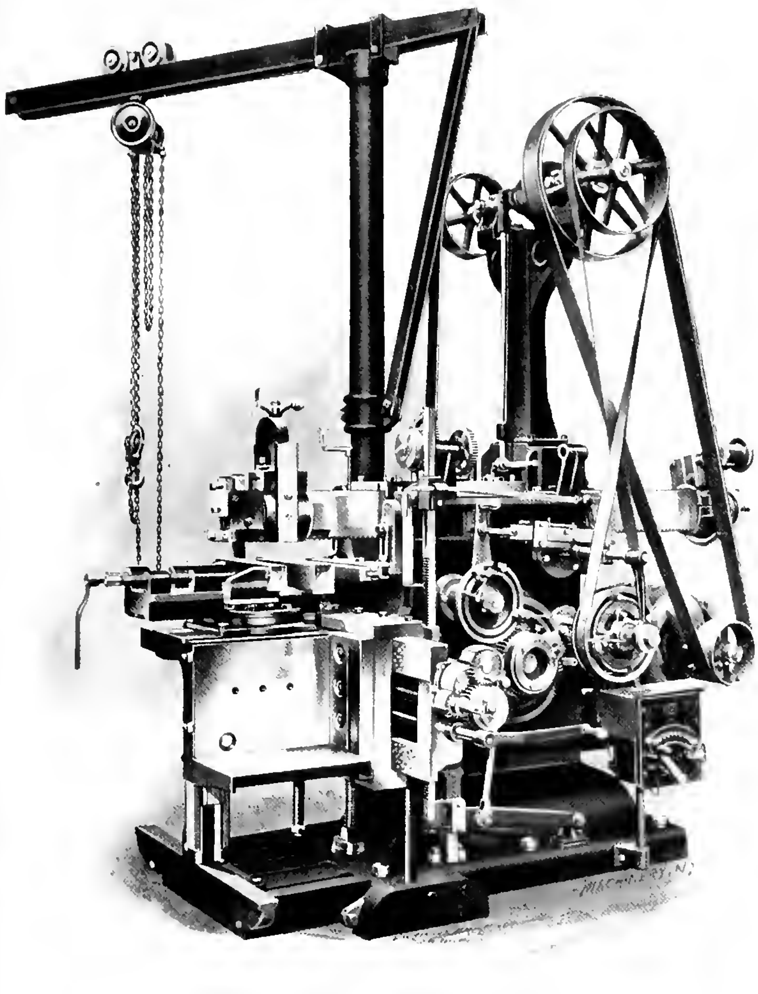


Fig. 1. Morton Special Draw-cut Railroad Shaper

its durability, general efficiency and range of usefulness.

The particular machine illustrated is electrically-driven with a belt transmission which is the form of drive recommended by the makers. As the illustration shows, the motor is mounted on a sliding base at the rear of the column so that the driving belt to the countershaft may be made endless and adjusted for the proper tension. This countershaft has a special friction clutch which may be operated by a conveniently located lever so that the machine may be started or stopped instantly without interfering with the motor. This feature places the machine under complete control of the operator as it enables him to move the ram 1/16 inch at a time, if desired, whenever adjusting or setting the tool. As shown, the drive to the reciprocating clutches is by belts which absorb shocks and tend to protect the motor. The variable speed type of motor with a two or one variation is ordinarily used, but as the cutting speed of this machine is uniform irrespective of the length of the stroke, a constant speed motor may also be used.

The friction clutches, through which, by means of the open and cross belts, the reciprocating motion is given to the ram, are of an entirely new design. The friction surface is made flat, with a revolving disk, which is covered on both sides by vulcanized fiber. The compression is formed by a sliding collar and compression levers provided with set-screws which give ample compensation for wear. The flat disks may be relined at small expense, and being lined with fiber, they never injure the metallic surfaces of the clutches. The reversing mechanism for operating the clutches is also of new design.

The stroke of the ram is adjusted by tappets mounted on a circular disk. Adjustments can be made while the machine is in motion, and the movement of the ram can be reversed by a lever at the will of the operator. The ram has a quick return of $2\frac{1}{2}$ to 1, at a uniform speed.

The friction feed of this machine is of the automatic relieving type, and gives any feed ranging from 1/32 to 5/8 inch, horizontally, and 1/32 to 5/16 inch, vertically. Variations are obtained by moving tappets on a circular disk, which is graduated with suitable index stops.

A power traverse for raising and lowering the cross-rail and moving the apron sideways is supplied. These movements are controlled by a lever which when shifted in different directions moves the apron either to the right or left. As only thirty seconds is required to move the apron the full width of the cross-rail, and forty seconds, for raising or lowering the cross-rail, this feature effects a considerable saving in time when making adjustments.

The ram of this shaper is provided with a rotating arbor, which may be fed automatically in either direction for planing curved surfaces. The rotary-feed motion is transmitted to this arbor from the regular friction, through a gear and ratchet working in conjunction with a vertical bar, connected to a splined shaft, which, in turn, transmits the movement to the arbor. The mechanism is clearly shown in the engraving.

The column of this shaper is of the box type and heavily constructed. All shaft journals, which are mounted in the column, are run in bearings which are fitted in accurately bored holes, thus insuring perfect alignment and rigidity. The knee is of a special design, of the angular bracket

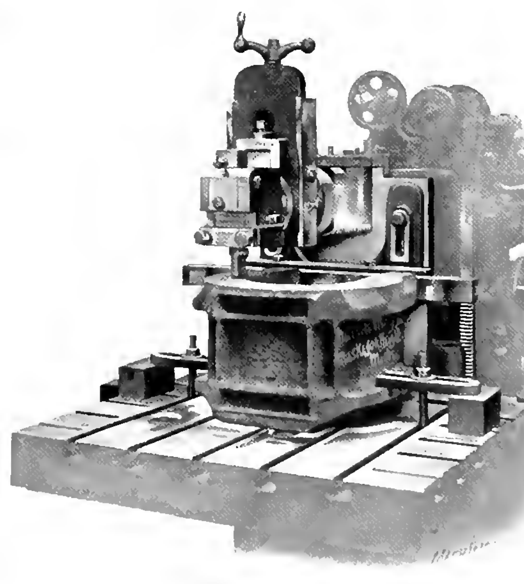

Fig. 2. Planing the Sides of a Driving Box

type that is adjustable vertically on the saddle, so that the distance between the ram and the table may be increased. The table is held in position by a tongue which fits a slot in the knee, and by four bolts, so that it may be quickly removed or placed in position. The vise is of the swivel type and is graduated in degrees. An adjustable back-bearing forms a stop against which work may be placed while being held in the vise or otherwise. This bearing transfers the thrust of the cut directly against the column so that it is not necessary to clamp the part being machined so firmly.

As in previous designs, a crane and hoist is directly attached to the machine, which greatly facilitates the handling of heavy parts. Ordinarily a two-speed hoist of one ton capacity is furnished, that is so arranged that when lifting one-third load, it operates directly and with twice the speed. If desired, the makers are prepared to furnish an air hoist in place of the chain type. This crane will cover a floor space 12 feet in diameter, and the maximum distance from the floor to the hoist is 7 feet.

In order to illustrate the adaptability of this tool to railway work, a number of illustrations showing the machine set up for planing a locomotive driving box and its brass are given. Fig. 2 shows the way the sides of a driving box are planed. As the work is placed against the back-bearing previously referred to, the thrust of the cut is taken directly against the column so that the two small clamps shown are sufficient to hold it in position. For planing the crown brass seat, a double chuck, such

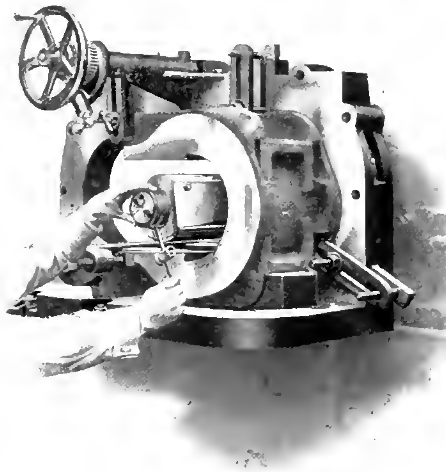

Fig. 3. Gage used in Conjunction with the Ram for Setting Boxes

as is shown in Fig. 3 is used, which has a capacity for two boxes. This chuck is secured to the knee or bracket table of the shaper and it is provided with a back-bearing which transfers the cutting strains to the column. A bracketed bearing is attached at the top which extends forward, thus bringing the operating handwheel in a convenient position. The handwheel is connected to the arbor-rotating mechanism by a universal shaft so that the rotating head may be turned by hand in either direction. Fig. 3 also shows a gage that is used for set-

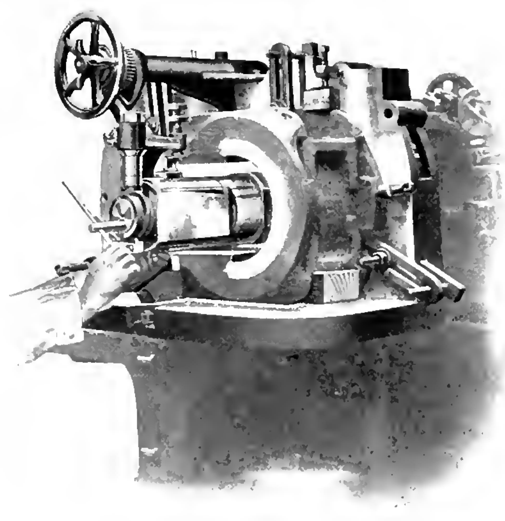

Fig. 4. Setting the Tool by Special Micrometer Gage

ting the box prior to planing. This gage, to which may be attached the scriber of an ordinary surface gage, is accurately fitted to an extension on the rotating head; the extension is also used for holding the micrometer attachment illustrated in Fig. 4, which is used for setting the tool to a given radius. This attachment consists of an arm long enough to meet all requirements, on which there is a scale that enables a sliding bracket to be quickly set to the desired radius. By means of a micrometer screw against which the point of the tool is set, as shown, allowance may be made for the roughing and finishing cuts. After the tool is placed in the proper holder and inserted in its slot from the top, the micrometer

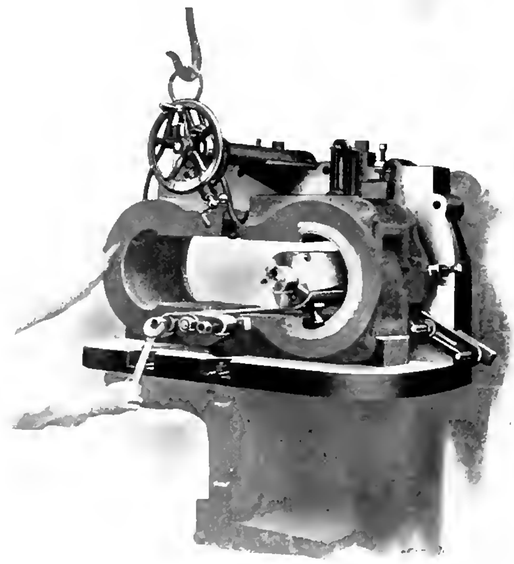

Fig. 5. Placing a Second Box in Position while Planing the First

attachment is placed in position and the tool is raised up to the adjusting screw which has been set inward for the roughing cut. When the tool is being set for a finishing cut, the micrometer screw must be up to the shoulder stop.

The advantage of the double-chuck arrangement is shown in Fig. 5, which illustrates a second box being placed in position while the first is being machined. Obviously the oil cellar fittings may be machined at this same setting of the work if

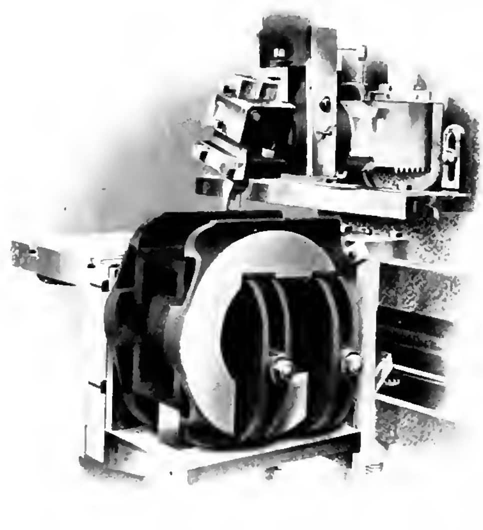

Fig. 6. Method of Holding the Box while Planing Shoe and Wedge Fits

desired. After the crown brass has been forced into the box, it can also be planed for the journal fitting. In Fig. 6, the box is shown in position for planing the shoe or wedge fittings. In cases where single boxes are being finished or when they are being replaned, this machine would undoubtedly handle the work in a very satisfactory manner.

An interesting set of transfer gages for use when fitting the crown brass is shown in Fig. 7. The inner gage, shown applied to the box at the right of the illustration, is so designed that by one or two simple adjustments, the shoes on either side are set to the undercut angles and a central point is brought to bear against the crown so that there are three points for measuring which project beyond the box face. The outer or crescent-shaped gage is next set by these projecting points and then applied to the brass as shown, after the latter is planed on the outside. By means of a scriber, lines are drawn on the end of the brass, thus enabling it to be accurately fitted

to the box. These lines may be quickly and easily set in a vertical position for planing, by means of a special gage.

The attachment for planing the brasses is shown in Fig. 8. This attachment has a tongue fitting a slot in the table so that it is self-aligning. The head is provided with adjusting screws, as shown, which bear against the machine column. The chuck for holding the brass is so constructed that the work may be gripped in any desired position by means of one bolt,

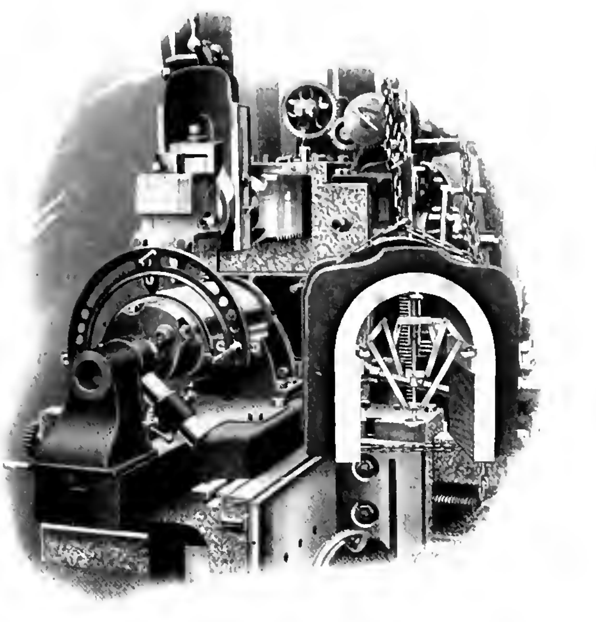

Fig. 7. Inside and Outside Transfer Gages for Crown Brass Work

and as the front head is adjustable, various lengths may be held. The rotary feed is obtained through a worm-gear and flexible shaft which is connected with the regular feed mechanism so that when the ram reciprocates, the chuck is made to revolve intermittently. Fig. 8 also illustrates the use of the micrometer attachment, which is used to scribe a line on the brass at the desired radius. Obviously this line is not broken out by the tool, as the latter begins its cut at this end; this enables the workman to split the line and to produce accurate

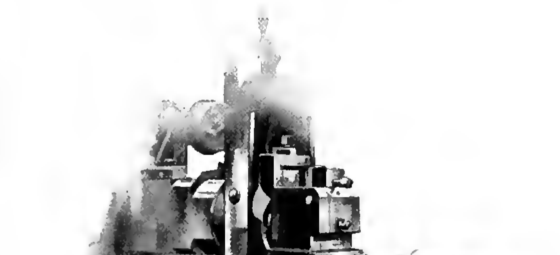

Fig. 8. Use of Micrometer Gage for Sizing Crown Brass

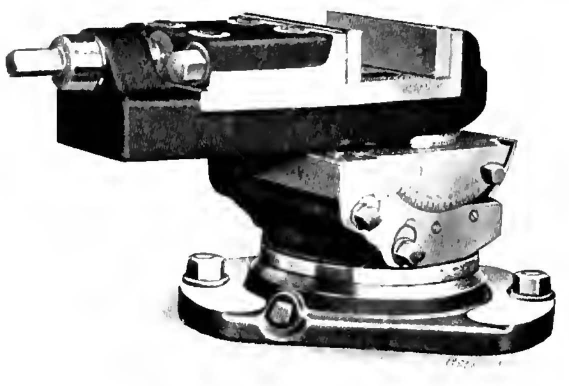
results. The draw-cut also throws the chips away from the operator rather than toward him.

This shaper has a working stroke of 32 inches, a horizontal table feed of 36 inches, and a vertical table feed of 18 inches. The approximate net weight is 10,000 pounds to which 2500 pounds are added when the machine is equipped with a motor drive.

AETNA THREE-WAY VISE

An interesting and useful tool of universal application on the milling machine is illustrated in the accompanying halftone illustration. This device, known as the Aetna three-way vise, is built by the Becker Milling Machine Co., Hyde Park, Mass., and while especially adapted for use with the Becker milling machine, it can be employed, of course, to advantage on milling machines of any type. The vise is provided with adjustments in three planes, so that it can be set practically to any position imaginable within the range of its size. Each of the three adjustments is entirely independent of the others and the respective angles are read in degrees directly from engine-divided dials.

The first adjustment is in a horizontal plane about a vertical axis. This adjustment permits of rotating the work around a full circle, or through 360 degrees. The second movement is at right angles to the plane of the first, and permits of adjustment from the horizontal to the vertical plane through an arc of 90 degrees. The third adjustment, again, is at right angles to the plane of the second, whatever that may be in any one case. The ultimate position of the adjustment of the third swivel which holds the vise proper, depends upon the adjustment of the two previously mentioned. The work can be rotated by this adjustment through an arc of 360 degrees. Although in this manner three joints are introduced from the base to the vise in order to make the device universally adjustable, the tool is so designed as to insure a rigid construction, and is firmly secured to the milling machine table by two bolts. The work to be milled can be clamped in any position



Aetna Three-way Vise for Milling Machines

without disturbing these bolts. The jaws of the vise proper are steel faced.

The capacity of the vise illustrated is as follows: The jaws will open to a maximum width of 3½ inches; the depth of the jaws is 1½ inch, and the width of the vise jaw surface is 5 inches.

WILEY AND RUSSELL THREADING, TAPPING AND CUTTING-OFF MACHINE

A combined bolt cutter, nut tapper, pipe threader, and cutting-off machine, that is especially adapted for railway shops, is shown in Figs. 1 and 2. The headstock of this machine is fitted with a three-step cone pulley and back-gears, through which a special design of work-holding chuck is driven. This chuck has interlocking and interchangeable jaws and is so constructed that it will hold either round or square stock. As the jaws are interchangeable, new ones can be supplied, thus making it unnecessary to secure an entirely new chuck. The spindle is hollow, so that any length of pipe or bolt can be handled. On the carriage, which is operated by means of a rack and pilot wheel, frames for the die-heads are mounted. These frames are connected by a double-threaded shaft so that the dies may be easily opened or closed by means of a handwheel in the front of the machine. Each die-head is accurately fitted in its support and it is held in place by a set-screw that bears against a V-shaped slot, so that the tightening of the screw draws the head against the carrier face. A spring-pin that drops into an opening, prevents the die-heads from turning when the dies are in their proper position. By loosening the set-screw and pulling back the spring-pin, the heads can be

revolved so that any size die within their capacity can be quickly brought into working position. The heads are marked at the top with the size die which is in position for cutting. Each pair of dies has independent stop pins which control its cut. These pins, which are plainly shown in the illustration, can be shortened or lengthened as desired to give the proper diameter of thread. They are made of the very best steel, and are carefully fitted into the circular die-heads. The dies are made in pairs, each of which is properly marked, so that it is a very simple matter to replace them.

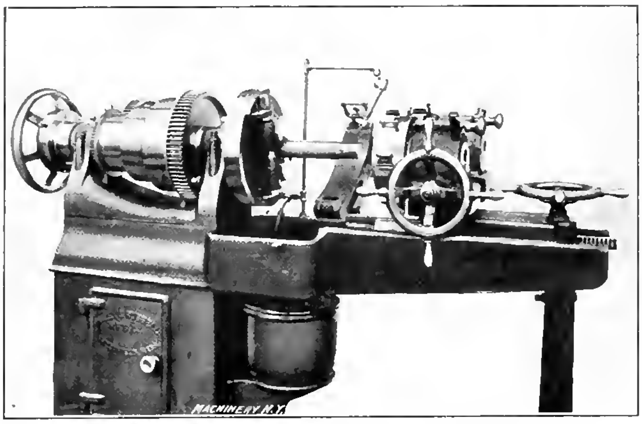


Fig. 1. Combined Bolt Cutter, Nut Tapper, Pipe Threader and Cutting-off Machine

When using this machine for nut tapping, it is only necessary to clamp the tap in the chuck and place the nut in the jaws provided between the carriers that support the die-heads, as shown in Fig. 2. The carriage is then brought up the same as when threading a bolt. It is not necessary to remove the die-heads in order to tap nuts.

A cutting-off attachment, which is plainly shown in Fig. 1, is applied so that it can be swung back out of the way when not in use. This attachment consists of a small carriage with a toolpost and a hand-operated cross-feed. The machine is also provided with a centrifugal oil pump. The lubricant is drained through a screen into a tank below the bed from which it is again pumped to the cutters.

The following figures which relate to the performance of the No. 1 machine, which we illustrate herewith, will serve to

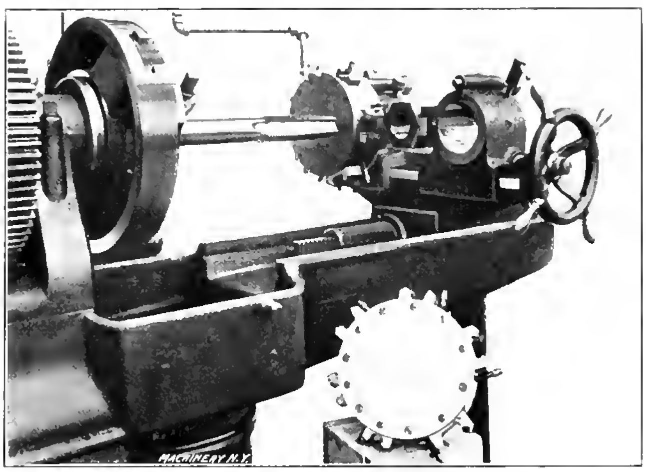

Fig. 2. Machine as used for Nut Tapping

show the possibilities of this type of tool as to output. The threading of ten bolts of the following sizes, $\frac{1}{4}$; 5/16, $\frac{3}{8}$, 7/16, $\frac{1}{2}$, 9/16, $\frac{5}{8}$, $\frac{3}{4}$, $\frac{7}{8}$ and 1 inch, was accomplished in ten minutes. The same machine also cut a thread $6\frac{1}{2}$ inches long on a 1-inch bolt in one minute from the time the workman picked up the stock until the finished bolt was removed from the machine. Ten one-inch bolts were threaded for a distance of $1\frac{7}{8}$ inch, in six minutes, thirty seconds, and threads were cut on eight steel pipes ranging in size from $\frac{1}{4}$ to 2 inches, in fifteen minutes, a little over a minute being required to replace the bolt-cutting die-heads with those for pipe threading.

For roundhouse work this machine offers many advantages. It is also well adapted to the work of the erecting shop, where it is often necessary to quickly thread bolts or to chase a thread that has been damaged. With three sets of die-heads, the machine is equipped for threading practically all sizes of bolts from $\frac{1}{4}$ to 2 inches, as well as piping between the same dimensions. This machine is rigid in its design and wherever miscellaneous threading is to be done, it will undoubtedly prove very efficient. It is the product of the Wiley & Russell Mfg. Co., Greenfield, Mass.

HAUCK KEROSENE BLOW TORCH

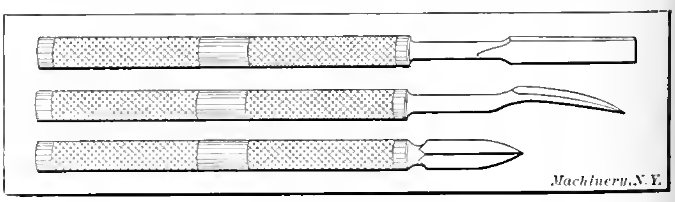
A blow torch in which kerosene is used as a fuel instead of gasoline is shown in the accompanying illustration, being used for brazing cup joints. This torch is said to give better results with kerosene than can be obtained with gasoline. It is adaptable for various heating operations, such as light brazing, tinning, etc. The flame produced is intense and clear, and the construction is such that the tank will remain perfectly cool while the burner is being operated. Only one-pound air pressure is required on the torch, which is obtained by a hand-pump in the usual manner. The flame of this torch will melt a piece of copper $\frac{1}{2}$ by $\frac{1}{4}$ inch, in three minutes and a 1-inch brass rod in two minutes. The particular torch il-

Kerosene Blow Torch being used for Brazing

lustrated has a capacity of $\frac{1}{2}$ gallon, and the consumption per hour is $2\frac{1}{2}$ pints. Larger sizes, however, may be obtained, if desired. The cheapness of kerosene and its comparative safety is, of course, a commendable feature. These torches are simple in design and strongly built to withstand rough usage. They are made by the Hauck Mfg. Co., 140 Cedar Street, New York City.

TOOLMAKERS' SCRAPERS

The scrapers shown in the accompanying engraving are intended for the use of toolmakers or other mechanics who desire something neater and better than a three-cornered or half-round file for scraping. These tools will be found useful in connection with vise work, metal patternmaking, and for similar work. The handles are made of steel tubing and the cutting points of the finest grade of tool steel, which is prop-



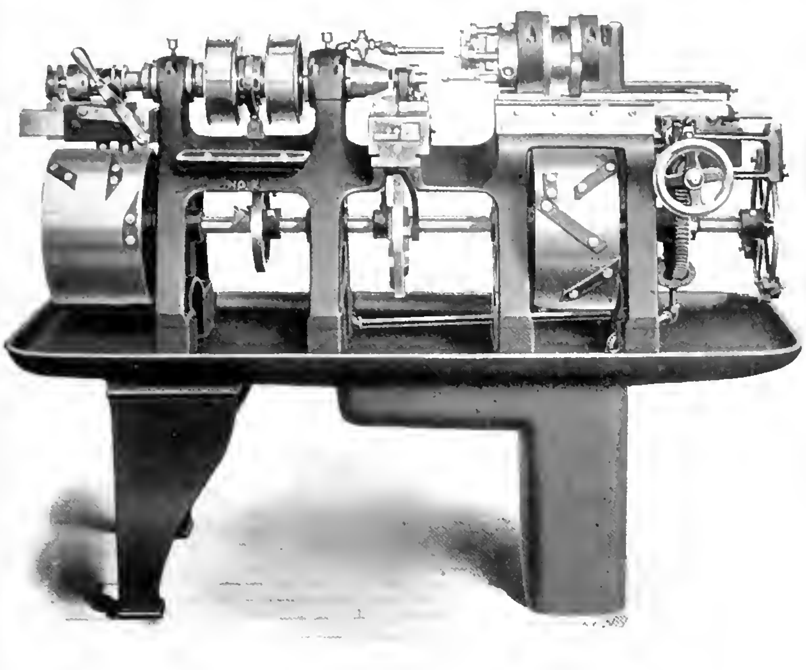
J. E. Poorman Co.'s Scrapers

erly tempered, ground and polished. These scrapers are made in a number of styles, only three of which are shown in the engraving. The upper tool is a small, flat scraper which may be obtained in different widths; the second is of the half-

round, curved type for use in small bearings, etc., while the lower one has a triangular blade which is hollow ground on the sides. These tools are the product of the J. E. Poorman Co., Inc., Bradbury Building, Philadelphia, Pa.

NATIONAL SEWING MACHINE CO.'S AUTOMATIC SCREW MACHINE

The single-spindle automatic screw machine which we illustrate herewith, has been placed on the market by the National Sewing Machine Co., Belvidere, Ill. The distinctive features claimed for the general construction of this machine are: convenience of operation, simplicity in the changing of cams, ease with which adjustments may be made for various classes of work, and low maintenance expense.



National Sewing Machine Co.'s Automatic Screw Machine

The spindle of the machine is driven by a quick-acting friction clutch which is positive and instantaneous in its reverse motion, permitting uniform lengths of thread to be cut when threading. This clutch is operated by a small disk-cam mounted beneath the pulleys on the drum-cam shaft. The stock is fed through the spindle, and the chuck is operated by the drum-cam at the left end of the shaft. Provision is also made for operating the chuck by hand in case this is necessary when setting up the machine.

The turret, it will be noticed, is in a horizontal position, rotation being about a horizontal axis. The location of the locking bolt, which is quick and positive in its action, is such that it engages the turret on a larger radius than that occupied by the tools, which tends to maintain the latter in alignment with the spindle, thus insuring accuracy of the output. The turret is fed to and from the work by a drum-cam.

An accelerated movement for the drum-cam shaft and turret-slide, is obtained through a positive clutch when the tools are not in use, so that they recede from and advance to the work at comparatively high speeds. When the tools are in action, the slower feed then required is obtained through a differential planetary gear system, which reduces the movement between the driving pulley and worm-shaft in the ratio of 18 to 1. The spider disk on the right end of the cam-shaft, controls, by means of dogs on its periphery, the engagement and disengagement of the clutch and consequently the rate of feed. These changes are made instantaneously.

The cross-slide is operated independently to a stop which gives uniform sizes in forming operations. The movement of this slide is controlled by the disk-cam shown beneath it, which engages with the feeding levers shown. These machines are built in two styles, either having a turret or being made plain. The construction of the turret machines is such as to permit the use of taper attachments for turning taper pins and similar work. They are also adapted for thread rolling, knurling, side drilling, slotting and second operation magazine work. The chuck capacity of the No. 2 machine, which is shown in the illustration, is 5/8 inch. The milling length is 3 3/4 inches and the length of feed is 7 1/4 inches. The spindle pulleys are 7 inches in diameter with 1 1/2-inch width of face. The floor space required for this machine is 3 feet by 4 feet 9 inches.

ELECTRIC HOIST FOR MONO-RAIL SYSTEM

An electric hoist, equipped with two hook-blocks that operate together and are driven by the same motor, is illustrated herewith. This type of hoist is undoubtedly superior to the single hook-block hoist for handling a great variety of work, as the two hooks make it possible to carry a lengthy part straight and level and without the swaying incident to the use of a single hook. This feature permits the making of the runway supports narrow and a wide operating space is not required in the storage room or shop. In handling heavy or bulky material, either one or both hooks can be used and either hook has a lifting capacity equal to that of the hoist.

This hoist is furnished with a seat, as shown, or with a cage if desired. When a seat is used, the operator attaches the work, thus making a helper unnecessary. This hoist is very rigidly constructed throughout. The truck wheel frames, which are made of steel castings, are interlocked with the main frame and made to swivel when rounding a curve. By means of handled ropes which hang near the operator's seat, all movements are controlled. The hoist is provided with an automatic load or mechanical brake for lowering, that is entirely enclosed and operates in a bath of oil; there is also an

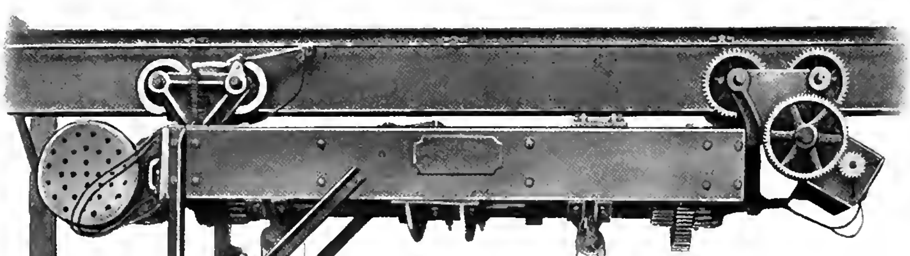


Fig. 1. Electric Hoist with Two Hook-blocks which operate simultaneously

electric brake on the motor. The motor is of the enclosed type, commonly used for crane service. Electric connection to the motor is made by a trolley which is in contact with a conductor attached to one side of the rail as shown. The winding drums have a diameter equal to thirty times that of

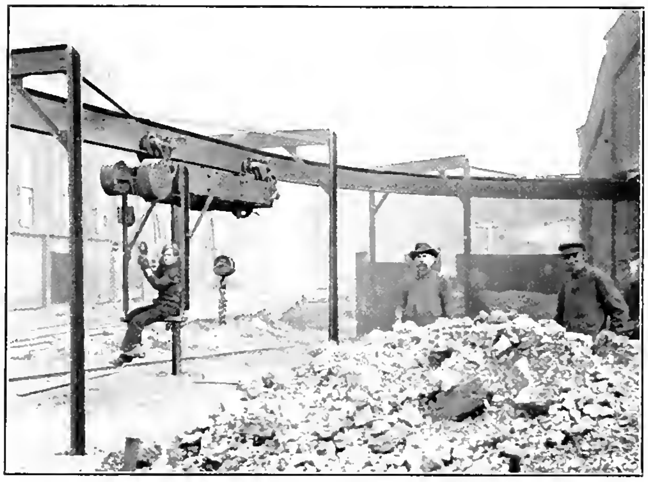

Fig. 2. View showing the Electric Hoist and Runway

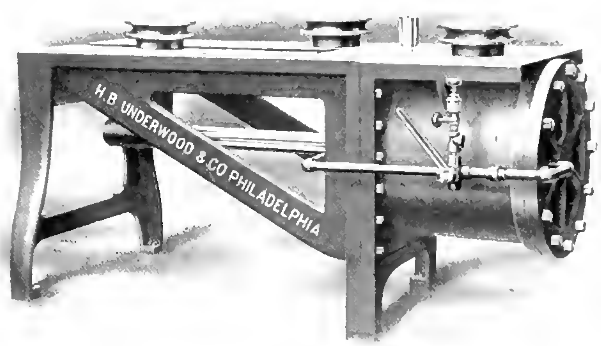
the rope. The gearing used is of cast steel and the teeth are all cut. All the bearings are bushed with bronze. These hoists are made by the Johnston & Jennings Co., Cleveland, O., in two-, four-, and six-ton capacities.

UNDERWOOD PIPE BENDER

The pipe bender shown in the accompanying illustration, besides being efficient for the bending of pipes, may also be used as a power bender and bulldozer. This tool has a stroke



Machine for Power Bending built by H B Underwood & Co

of 15 inches, and the control is very flexible. The work-table is rectangular and is provided with numerous holes for the convenient location of dies or pins. As the top of the table is perfectly flat, it offers no obstruction that will in any way interfere with the work. Innumerable shapes can be bent without the necessity of having a large number of dies, by simply changing the position of the resistance studs. The ram, which is beneath the table, slides in a strongly constructed guide and has projecting above the table a stud on which a roller of suitable size may be placed. Either steam or compressed air may be used to operate the machine. For the former a metallic packing is used on the piston rod and for the latter a leather packing. The use of compressed air is recommended, when available, as it offers many advantages over steam. The cylinder is 20 inches in diameter, and the power of the machine is limited only by the pressure applied to the piston. This piston has air on both sides of it at all times, connection from one side to the other being made by the pipe shown, which connects with the operating valve. This valve is so constructed that only the amount of air required for the actual bending escapes. The air is transferred from one side of the piston to the other, depending on the direction of movement desired. Owing to the unequal areas on the two sides of the piston by reason of the space occupied by the piston rods, the piston is given a sensitive control and it may be moved when necessary only a fraction of an inch. The ram may also be held perfectly stationary to allow measuring or the placing of templets on the work. Such nicety of control is, of course, very desirable, and is particularly useful for straightening work. This machine is manufactured by H. B. Underwood & Co., 1025 Hamilton St., Philadelphia, Pa.

WILLIAMSON PORTABLE GRINDER

A self-contained, motor-driven grinder, which is portable and can be used for grinding inserted-tooth face milling cutters on either a horizontal or vertical milling machine without removing the cutter from the spindle, is illustrated herewith. Mr. H. C. Williamson of the H. C. Williamson Engineering Co., Industrial Building, Indianapolis, Ind., has perfected and applied for a patent on this device.

The machine is shown in Fig. 1 in the position in which it would be used for grinding an inserted tooth cutter on a horizontal spindle. The motor, which is specially designed and

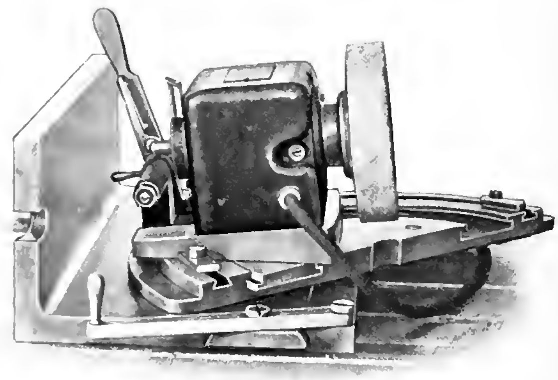


Fig. 1. Williamson Electrically-driven Portable Grinder

may be driven from an electric lighting circuit, is provided with adjustable bearings. It drives a 6-inch cup-wheel and is mounted on a plate having a fixed angle of 5 or 7 degrees, as may be desired, which gives the teeth the proper clearance. This plate is attached to a slide which travels in the circular T-slot of the base shown. The distance of the travel is governed by two stops, which are inserted in an outer dovetailed

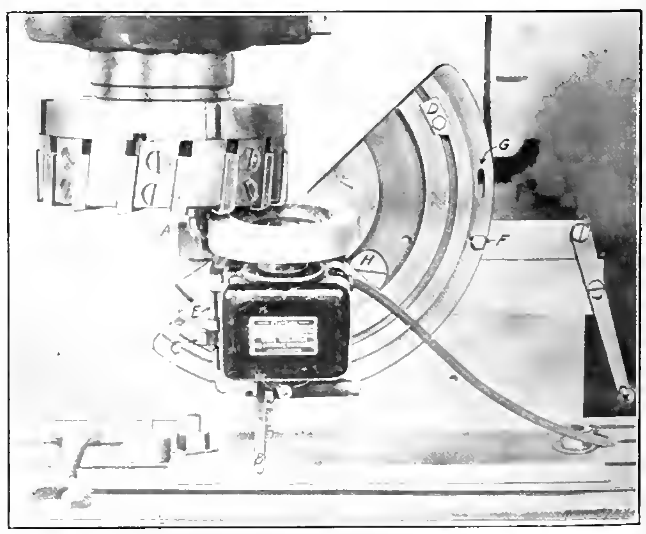

Fig. 2. Wheel in Position for Grinding Ends of Teeth

slot. This circular base is fastened to a slide which can be moved forward or back in the angle plate by the lever shown attached to it. Movements in the opposite directions are obtained by the lever shown pivoted near the back end of the wheel spindle. This lever is used for feeding the wheel up to a tooth for grinding, and its movement is controlled by a positive stop so that each tooth may be ground absolutely the same.

Fig. 2 shows the grinder set up in position for grinding a

10-inch cutter on a vertical milling machine. When the tooth is indexed against finger *A*, the wheel is brought up in contact by lever *B*. By means of the adjusting screw *E*, which comes against a stop, as shown, and controls the movement of the wheel, an equal amount is ground from all the teeth. The stop *C* controls the angular position of the wheel in one direction when grinding the bottom of the cutter. By swinging the motor and wheel around until contact is made with stop *D* (as shown in Fig. 3) the complete cutting edge of the tooth is ground at one sweep. The adjusting screw *E* can be set up so as to give any desired radius for the corners of the

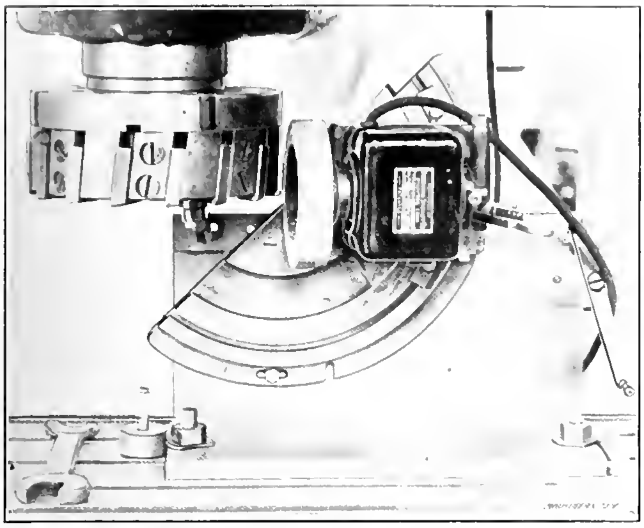

Fig. 3. Wheel swung around for Grinding Sides of Teeth

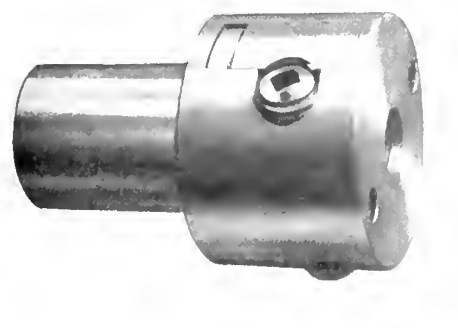
teeth, from practically a sharp corner to $\frac{1}{2}$ inch radius or larger. The semi-circular base on which the motor and wheel are mounted, swivels on the stud *H* so that its position may be changed for grinding right- or left-hand cutters. This base is secured to the angle-plate by bolts inserted in the slots *F* or *G*, one set being for right-hand and the other for left-hand cutters.

As the illustrations indicate, it is an easy matter for a workman to set up this machine for either horizontal or vertical grinding, and when a cutter is ground while in place, every tooth will run true and do its share of the cutting. This same device can be used in connection with a stand or column so that cutters may be removed and sharpened if desired, and there is no limit to the diameter of the cutter which may be ground.

PRATT TURRET LATHE CHUCK

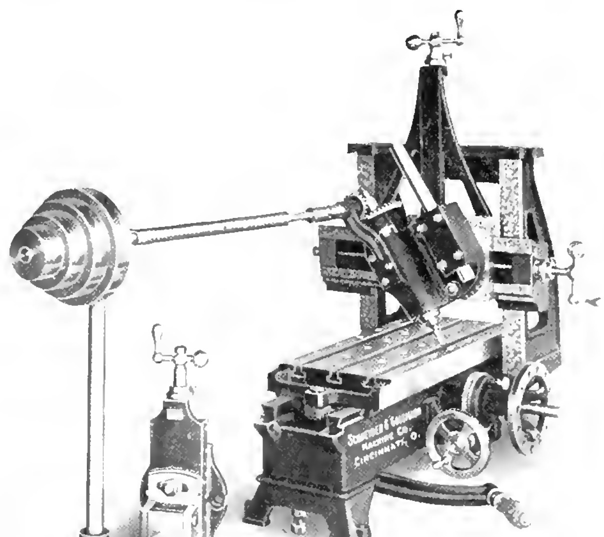
A chuck that has been designed especially for use in turret lathes, turret heads of screw machines, etc., for holding such tools as reamers, drills, outside finishing tools, etc., is now being manufactured by the Pratt Chuck Co., Frankfort, N. Y. This chuck is equipped with the company's patented equalizing driver, which gives a positive rotation to the tool, independently of the chuck jaws. This positive driver is self-adjusting, permitting the jaws to center and align the tool shank accurately in the chuck, so that it is true and at the same time positively held. On finishing cuts, the jaws of the chuck can be partially tightened, thus permitting the tool to float, as the equalizing driver will prevent it from turning and allow it to assume a position in line with the spindle of the machine, thus insuring uniformity of product. These chucks are made in sizes ranging from $2\frac{1}{4}$ to $6\frac{3}{4}$ inches in diameter and with drill capacities from $\frac{1}{2}$ to 2 inches.



Turret Lathe Chuck with Positive Equalizing Driver

SCHNEIDER & GOOSMANN HAND PLANER MILLING ATTACHMENT

The Schneider & Goosmann Machine Co., 20 E. 9th St., Cincinnati, Ohio, has designed a power-driven milling attachment that is intended to be used in conjunction with a small hand bench planer which the company manufactures. This attachment is particularly adapted for handling the numerous small milling jobs that come up in the toolroom and in experimental die, jig and similar work. It is attached to the planer saddle in place of the regular tool-slide, and is driven by a cone pulley mounted on an independent stand fastened to the bench as shown. This cone pulley is connected to the spindle of the attachment by a universally jointed shaft and bevel gears. These gears give a 2 to 1 reduction in order that the spindle will be driven with ample power, though gears with a 1 to 1 ratio can be furnished for high speed or light milling operations. The spindle has a taper bearing, and is provided with compensating collars to take up wear. There is a No. 7 Brown & Sharpe taper hole in the spindle, and a draw-in rod for tightening the cutter arbor. The table feed for milling is through a worm and worm-gearing, allowing micrometer adjustment. Micrometer dials are also provided on the cross and vertical feeds. The worm or feed box can be easily attached to the side of the planer bed with very little fitting. Once attached it can remain there, and may be engaged or disengaged by the in or out movement of a pin which fits in any one of a series of holes in the side of the worm-wheel, thus making it possible to quickly traverse the table in either direction. This milling head is very quickly applied to the planer, and it has a wide range of usefulness in addition to ordinary horizontal and vertical milling operations, as the



Schneider & Goosmann 10-inch Hand Bench Planer with Power-driven Milling Attachment

swiveling head allows the cutter to be set to any angle.

The planer itself, which was described in the department of New Machinery and Tools of December, 1909, has a width of 10 inches between the housings and a maximum distance under the cross-rail of $8\frac{1}{2}$ inches. The table is reciprocated, when the machine is being used for planing, by a small handwheel which is mounted directly on the driving shaft which, in turn, is connected with the table rack by a steel pinion. This handwheel, as the illustration shows, has a series of holes drilled in its rim to receive a pin located in the arm of the driving crank. This feature allows the crank to be used in whatever position is most convenient to the operator.

MODERN 20-INCH DRILL PRESS

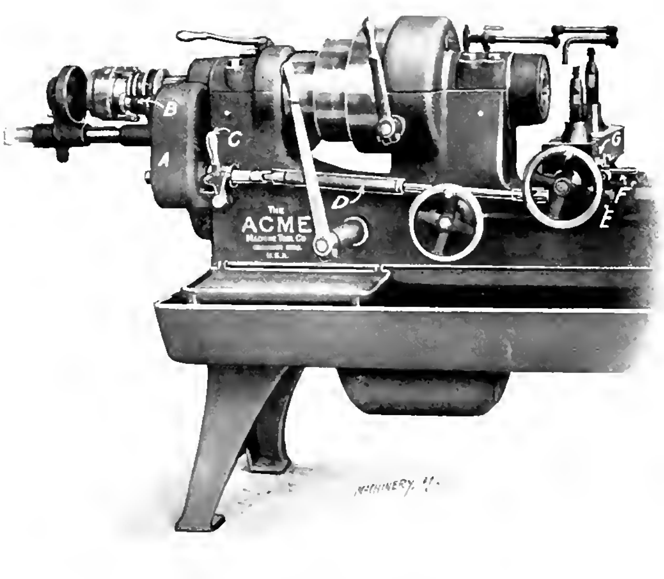
The 20-inch drill press which we illustrate herewith, is built by the Frontier Iron Works, Letchworth and Grant Sts., Buffalo, N. Y., and is designed along the same general lines as the 21-inch machine of the tilting-table type built by this company. The frame of the drill is heavily constructed and the bearings are lined with a special alloy to withstand hard usage

under all conditions. The spindle is of high-grade steel, and it is bored for a No. 3 Morse taper. The teeth of the bevel gears are cut by the generating process, and the gears are practically noiseless in operation. A steel elevating screw is provided for the knee that is operated by a handle connected to it with bevel gears. The machine as illustrated, is equipped with a lever feed and ratchet mechanism which permits the lever to be shifted to the most convenient position. There is also a quick return for the rapid adjustment of the spindle. If desired, a wheel feed can also be furnished at slight additional cost. A treadle form of belt shifter is attached to the base and provides convenient means for starting and stopping the machine. The height of this drill is 62 inches, and the floor space required, 42 by 15 inches. The table has a traverse of 13¾ inches and the spindle, 7½ inches. The diameter of the table is 15¼ inches and the diameter of the column 5 inches. The shipping weight is 650 pounds, to which 100 additional pounds are added when the machine is boxed.

Twenty-inch Drill Press built by the Frontier Iron Works

CROSS-SLIDE POWER FEED OF THE ACME SCREW MACHINE

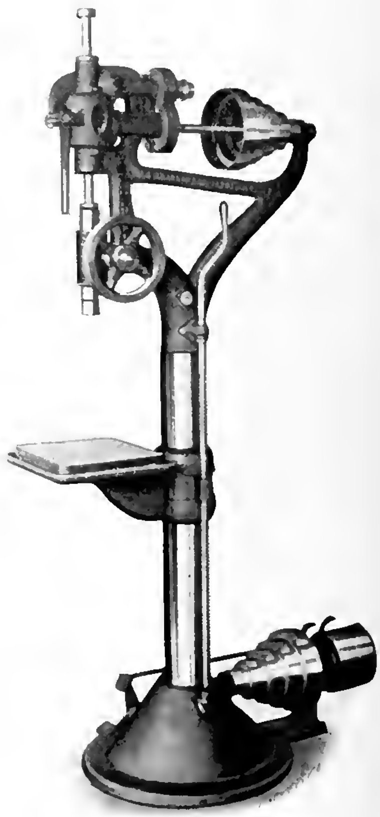
The power feeding mechanism for the cross-slide of the turret lathe or screw machine manufactured by the Acme Machine Tool Co., Cincinnati, Ohio, is illustrated herewith. The feed changing mechanism, which is of the slip key type, is located in the bracket *A*, which is bolted to the end of the head, suitable holes being provided in all machines for this purpose. Three rates of feed may be obtained by the movement of lever *C*, which has attached to it an index showing plainly the rate of feed being used. The motion is transmitted from the feed-change box to the carriage by a universal shaft which drives a worm located in worm-box *E*. This worm engages with a worm-wheel on the cross-slide screw. The feed is thrown in or out by the lever *F* which may be operated by hand or automatically by dogs *G*, the latter being set to trip the feed as required. This power feed is found very useful for facing large castings, forgings, etc., and work of a similar nature, and it is also used in connection with the cutting-off tool. When so ordered, it can be made with a very fine feed, which is suitable for forming operations and similar work.



View showing Power Feed Mechanism for Cross-slide on Acme Screw Machine

BARNES 15-INCH DRILL

The W. F. & John Barnes Co., 231 Ruby St., Rockford, Ill., has brought out a new drill, intended for light and medium work and particularly adapted for tapping operations. The lever, by which the tapping attachment is controlled, is located just in front of the spindle in a position that enables the operator to reverse the tap without releasing his hand from the feeding wheel, thus making the control as convenient as possible. This lever also serves to start and stop the spindle instantly while the machine is in motion, without shock or jar. The reversals are obtained through a clutch, mounted on the spindle between two bevel gears, which revolve in opposite directions. When the clutch is shifted and engaged with the upper of these gears, the reverse movement is obtained. The tapping attachment may be disengaged by the movement of a lever, so that the gearing of the attachment is only running while it is in use, thus reducing the wear. The wheel for the hand-feed is provided with holes in its periphery, so that the operator has a choice between a lever or wheel feed. This machine is equipped with extra long bearings, solid steel forged gearing for both the bevel and spur gears and hardened steel clutches, all of which insure strength and endurance. The particular drill illustrated has a 15-inch swing, but the geared tapping attachment can be furnished on the 22, 22½, 25, 26, 28, 34, 42 and 50-inch drills manufactured by this firm. The height of this machine is 65 inches and the distance from the spindle to the base 47 inches. The spindle has a travel of 7 inches and is bored for a No. 2 Morse taper. The maximum distance from the spindle to the table is 31 inches, and the table has a working surface of 10 by 12 inches. The floor space required for this tool is 20 by 31 inches and the weight is 290 pounds.



Barnes Fifteen-inch Drill with Geared Tapping Attachment

BAIRD DOUBLE OBLIQUE TILTING TUMBLER

In the May number of MACHINERY, in the department of New Machinery and Tools, we illustrated and described a large tilting tumbler which is a product of the Baird Machine Co., Oakville, Conn. This firm has now brought out a new tumbler of the duplex type which we illustrate herewith. This machine, which with others of its class, is used largely for the polishing and grinding of various articles, has been designed particularly for concerns which have considerable work of this kind, and which have heretofore found it necessary to employ

a number of single and independently driven units. This tumbler, as is evident from the illustration, takes up less room than two single machines, and it has the additional advantage of being driven by a single belt. The movements of the barrels, however, are entirely independent, so that one can be emptied and refilled while the other is in motion.

The driving pulley is located between the two barrels, and the drive is direct through bevel pinions, which are mounted on each end of the shaft and which mesh with corresponding gears on the barrels. As the engraving shows, these barrels may be tilted either for dumping the contents, inspecting the work, or to an angle which will give the best results. These angular adjustments may be made while the machine is in motion through a crank and gear mechanism which is easily operated. The tumbler is shown with one barrel in the dumping position and the other in the operating position. These barrels are interchangeable and they can be made of wood, cast iron, steel, sheet or cast brass. The main bearings in which the barrel shafts rotate are fitted with ring oilers affording good lubrication, and bushing bearings which may be removed when worn and replaced by new ones. The end-thrusts of the barrels are taken by adjusting screws and washers, thus relieving the gears of any unnecessary strain. Obviously, cutting down or burnishing compounds, or water

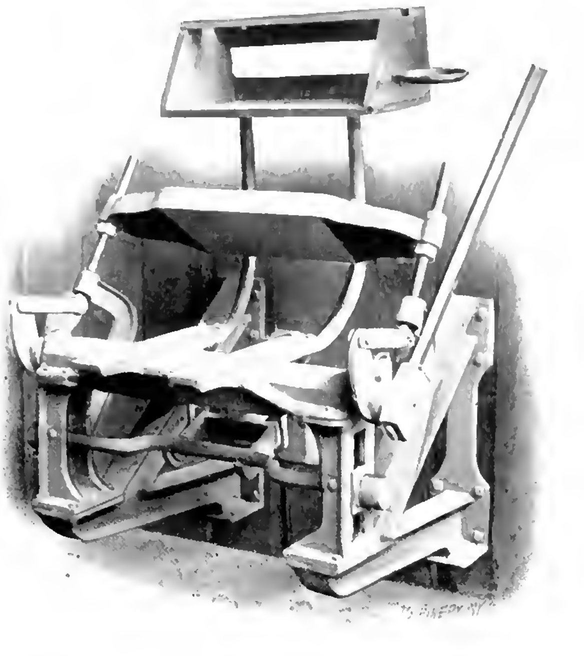
Baird Tilting Tumbler of the Duplex Type

for the purpose of cleaning the work, can be introduced into the tumblers while they are in motion.

These machines are built in two sizes, designated as Numbers 1 and 2. The first machine takes barrels ranging from 16 to 22 inches in diameter at the base, and the No. 2 machine, barrels from 22 to 36 inches in diameter. The smaller size, with 22-inch barrels, occupies a floor space of 45 by 64 inches, while the No. 2 machine with 28-inch barrels, requires a floor space of 66 by 81 inches. The respective weights of the two sizes without the barrels, are approximately 500 and 1000 pounds.

FARWELL SQUEEZER TYPE MOLDING MACHINE WITH WALL BRACKET

In the May number of MACHINERY, in the department of New Machinery and Tools, we illustrated and described some of the new molding machines recently brought out by the Adams Co., 842 White St., Dubuque, Iowa. This company has now added another type of Farwell squeezer to its line, that is designed to be attached to the wall instead of being mounted upon legs. The principal advantage of this type is that it occupies very little space, and where the floors are crowded, makes it possible to put up one or two more rows of molds. This machine would, of course, be unsuitable on long floors where considerable space is covered with molds and where a day's work is poured off at one time. It is adapted, however, for malleable foundries and other foundries in which heats are taken several times a day and where pouring is continuous. When pouring is done once a day, the molds accumulate to such an extent, that the portable type of machine is the most desirable. In fact, the ordinary portable type of squeezer is better adapted to the work of most foundries, for, by moving it several times a day, a great deal of the work of carrying molds and moving the sand is eliminated. When floors are very narrow, the broad-gage type of portable machine which

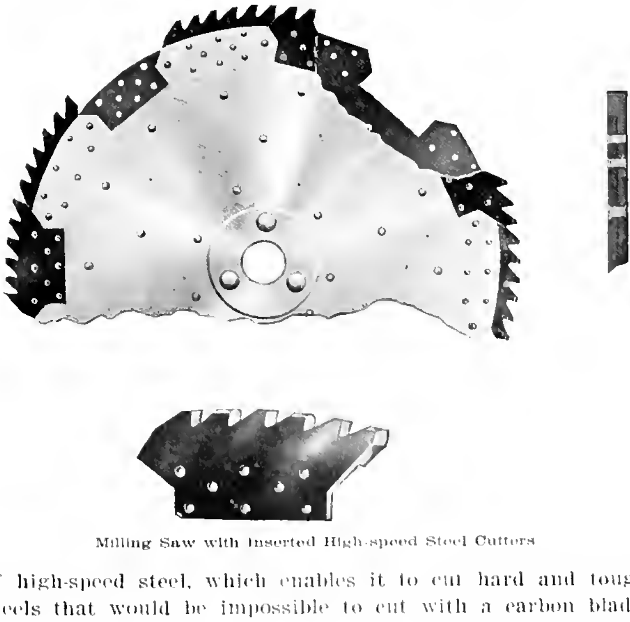


Farwell Squeezer-type Molding Machine with Wall Bracket

straddles the sand heap may be used, but such a machine must be moved quite frequently and necessitates a constant cleaning of the floor so that it is not recommended by the manufacturers where the regular portable machine can be used. The accompanying illustration shows a 30-inch machine, this dimension being the distance between the side rods, but this bracket type of squeezer will also be built in 24-, 34- and 38-inch sizes. The addition of these four sizes of bracket squeezers brings the number of molding machines manufactured by this company up to seventy-two, of various styles and sizes. It should be understood that this new machine is not intended to take the place of the stationary Farwell squeezers, or any of the other types, as it is a special design that is adapted to certain conditions.

HUTHER BROS. INSERTED TOOTH MILLING SAW

The inserted tooth milling saw shown in the accompanying engraving, is equipped with teeth made from the best grade



Milling Saw with Inserted High-speed Steel Cutters

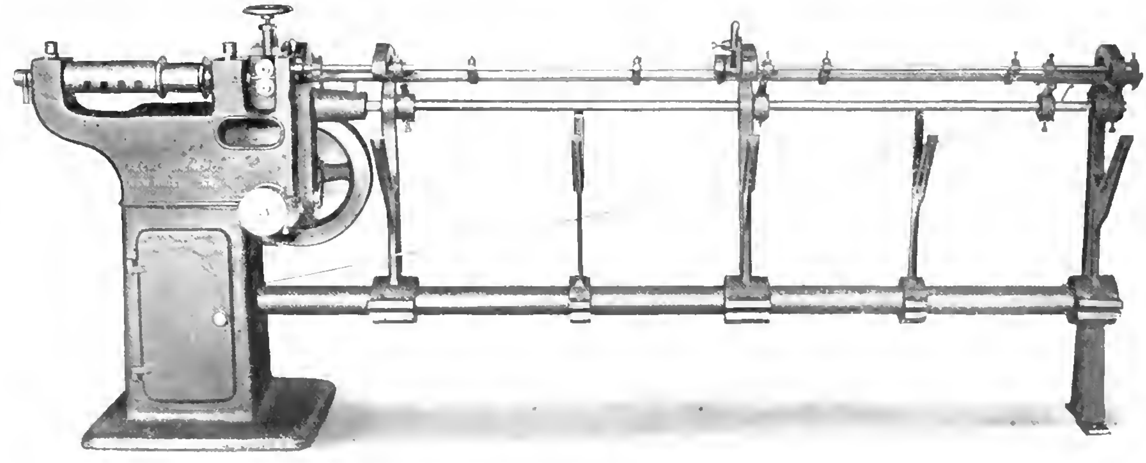
of high-speed steel, which enables it to cut hard and tough steels that would be impossible to cut with a carbon blade. The body of this saw is constructed of two crucible steel plates

which are firmly riveted together as shown. The pockets into which the teeth are inserted are cut into the plates alternately and the teeth are inserted in these pockets and securely riveted to the plates from alternate sides. The location and shape of these pockets is plainly shown in the engraving, the dotted lines indicating these in the back-plate. This method of attaching the teeth permits them to be replaced when worn, and the thickness of the saw is comparatively small which is very important, as a thin blade will cut with less strain and require less power than a thicker one. It is claimed that this saw will not fracture, as the plates are made of the best crucible steel and are given a very tough temper. Saws of this type, 32 inches in diameter and 5/16 inch thick, also 24 inches in diameter and 1/4 inch thick, are being used in steel mills with satisfactory results. This construction insures a tough and rigid blade, and these saws are recommended by the manufacturers to any firm requiring high-speed steel saws, ranging from 20 to 36 inches in diameter.

GREINER AUTOMATIC WIRE STRAIGHTENING AND CUTTING MACHINE

The automatic wire straightening and cutting machine shown in the accompanying engraving, is one of a line of various sizes manufactured by the Charles Greiner Co., New Haven, Conn. The particular machine illustrated, which is one of the smaller sizes built by this company, is capable of cutting wire of 1/8 inch diameter or less, directly from the bundle into lengths up to and including 6 feet. The wire first passes through straightening rolls which are located above the column at the left of the machine. It is then fed by a roller feed past the cutting-off tool which is automatically operated by the engagement of a clutch controlled by a gage that may be adjusted for obtaining various lengths.

The operation of this machine is as follows: A shaft, which is about as long as the machine's capacity for cutting, is attached to the fulcrum of the cutting-off lever and rotates simultaneously with this lever. A guide-bar that is situated above and in front of this shaft is connected both with the shaft and the cutting-off lever. This guide-bar has a groove running its entire length in which is located the adjustable gage, which is connected at its outer end by a wire with a clutch on the camshaft. The wire to be cut is drawn through the rotary straightening device by feed rolls until its end strikes against this gage. The clutch, which operates the cutting-off lever, is then automatically engaged and the wire is severed. At the same time, the rotary action of the shaft throws a cover off the groove in the guide-bar by means of arms on it, and the cut wire drops into forked holders which are mounted on a piece of wrought-iron pipe. This pipe is fastened into the base of the machine at one end and it is supported at the other by a floor stand as shown in the illustration. Some of the holders extend upward and support the shaft, guide-bar and other necessary parts, thus giving strength and rigidity to the cutting-off extension. These machines are made to cut wire to almost any length in the following sizes: 1/16, 1/8, 3/16, 1/4, 3/8, 1/2, 5/8, and 3/4 inch.

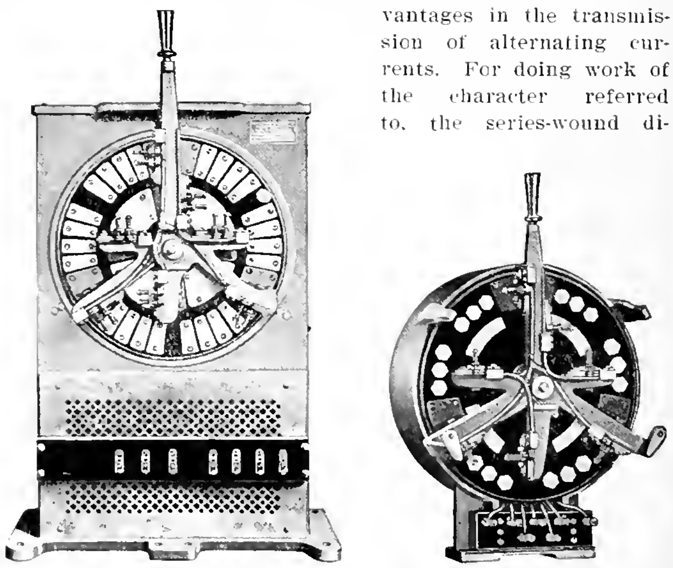


Automatic Wire Straightening and Cutting Machine

Each machine is capable of handling smaller diameters of wire than that indicated as its size, by equipping it with the necessary feeding and cutting-off tools. This line of tools is rigidly constructed and is designed to withstand long and continuous service. They may be used on all kinds and qualities of brass or copper, and also on tinned, black and galvanized iron, or steel wire, and for plated and highly finished wire, with satisfactory results.

ELECTRIC CONTROLLER AND MFG. CO.'S ALTERNATING CURRENT CONTROLLERS

Direct current motors, which formerly were used almost exclusively for operating electrically-driven cranes, mill machinery, etc., have been replaced in many instances, by motors of the alternating current type because of the well-known advantages in the transmission of alternating currents. For doing work of the character referred to, the series-wound direct current motor has the very desirable characteristic of a high starting torque. In alternating current motors, this feature is more often found in the slip-ring type than in the squirrel-cage type; therefore, for the operation of cranes and similar work, the development of the alternating current motor has been toward the slip-ring type.



Controllers for the Slip-ring Type of Alternating Current Motors

The speed and torque control of this motor is obtained by inserting and varying the resistance of the secondary winding by means of controllers. A complete line of manually-operated controllers of this type, ranging in capacity from 1 to 100 horsepower, has been developed by the Electric Controller & Mfg. Co., Cleveland, Ohio. These controllers, two sizes of which are illustrated herewith, follow, as closely as possible, the design and construction of the direct current controllers made by this company, and they may be used in connection with reversing slip-ring motors, operating on either the two- or three-phase system. The resistance is entirely self-contained, and it is necessary to connect only seven leads to the controller. Where heavy currents are to be handled, cast

grids resistance is employed, and unusual precautions have been taken to insure insulation which will be permanent. All the contacts, which are of heavy copper and reversible, are mounted on a vertical slate face so that dust cannot settle between the segments and cause short circuits. The use of screws or bolts with special threads has been avoided, and so far as possible, the wearing parts have been designed so they can be replaced by the user. The operation of these controllers is by a lever motion, which the manufacturers consider advantageous for crane and mill service.

AMERICAN SPEED VARIATOR FOR PLANERS

A planer speed variator of the cone-pulley type, which is now being applied to the planers of the American Tool Works Co., 300-350 Culvert St., Cincinnati, Ohio, is shown in Figs. 1 and 2. This device gives four speed changes, which are obtained through a pair of opposed four-step cone pulleys that are mounted upon a substantial platform on top of the housings. These pulleys are connected by an endless belt which is shifted from one step to another by a pair of belt forks that are moved alternately along guide rods by means of two cylindrical cams; these cams are revolved alternately by intermittent gears, operated by the handwheel shown at the rear. One revolution of this wheel shifts the belt from one step to another, and a stop pin indicates the complete revolution. The cam rolls have spiral slots milled in their peripheries and the belt forks are moved along the guide rods through the medium of a roller operating in the spiral slots. The relation between

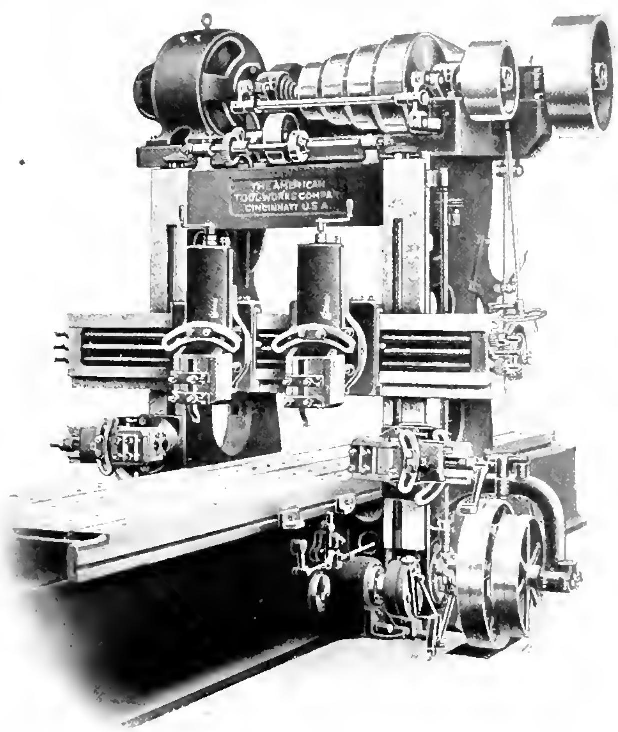


Fig 1. Planer equipped with Speed Variator

the cams and forks is such as to shift the belt off the high step of one cone before placing it on the high step of the opposing cone. The tension of the belt is controlled by the vertical lever shown at the rear, which operates a pair of bell cranks through link connections. These cranks serve to slide the driven cone towards the driver, thus slackening the belt. This feature, together with the mechanical belt-shifting device and the fact that the steps of the pulleys are beveled on the edges so as to offer no resistance to the passage of the belt, permits the making of speed changes rapidly.

After the belt is located for the desired speed, it is tightened by moving the hand lever to a point where the tension is sufficient for the work, after which the lever is securely clamped by a binder handle. As the driven cone is moved toward the driver, which carries the planer driving belts, the tension of the vertical driving belts is not disturbed when making speed changes. The speed changes can be made with this variator without stopping; in fact, it is easier to make the changes while the machine is in motion.

The driving pulleys have flywheel rims, the momentum of which reduces to a minimum all shocks to the driving mechanism due to intermittent cutting and reversing. They also insure a steady, even drive during the cut, and as they are perfectly balanced, the vibration is eliminated even on high speeds.

All the shafts of this variator are of large diameter, accurately ground and run in massive phosphor-bronze journals which are lubricated by the ring or "dynamo" system of oiling. The journals are supplied with liberal oil wells and return ducts, thereby preventing the oil from escaping and coming in

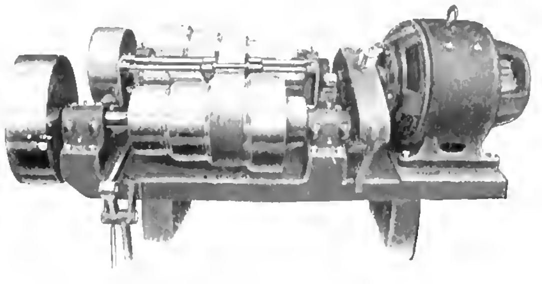

Fig. 2. View of Speed Variator from above

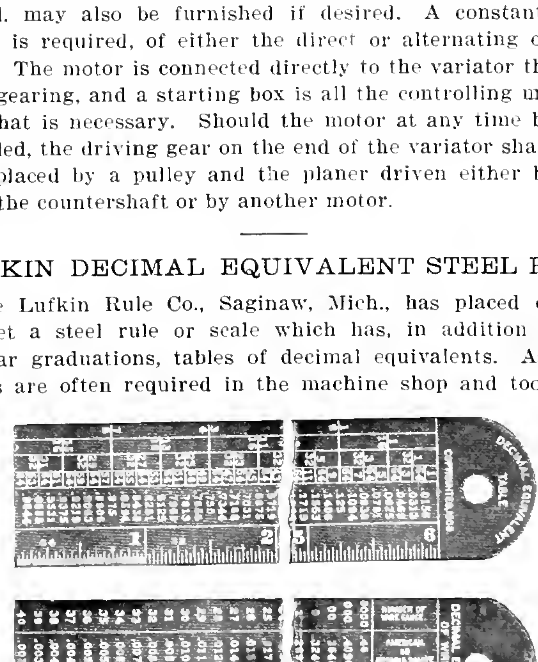
contact with the belts. The bearings are of the ball-and-socket type, thus insuring perfect alignment at all times.

The cutting speeds can be arranged to suit individual requirements, but, as regularly furnished, the variator gives speeds of 20, 30, 40 and 50 feet, with a constant return speed of about 80 feet. A belt drive is regularly furnished with this variator, the tight and loose pulleys being applied to the rear of the countershaft. The drive can be obtained direct from a lineshaft, provided it has sufficient speed, but slow shafts making about 150 revolutions per minute require an intermediate or jackshaft. The construction is such that it is a simple matter to convert the belt drive into a motor drive at any time after the machine is installed. The electric drive, as illustrated, may also be furnished if desired. A constant-speed motor is required, of either the direct or alternating current type. The motor is connected directly to the variator through spur gearing, and a starting box is all the controlling mechanism that is necessary. Should the motor at any time become disabled, the driving gear on the end of the variator shaft may be replaced by a pulley and the planer driven either by belt from the countershaft or by another motor.

LUFKIN DECIMAL EQUIVALENT STEEL RULE

The Lufkin Rule Co., Saginaw, Mich., has placed on the market a steel rule or scale which has, in addition to the regular graduations, tables of decimal equivalents. As such tables are often required in the machine shop and toolroom,



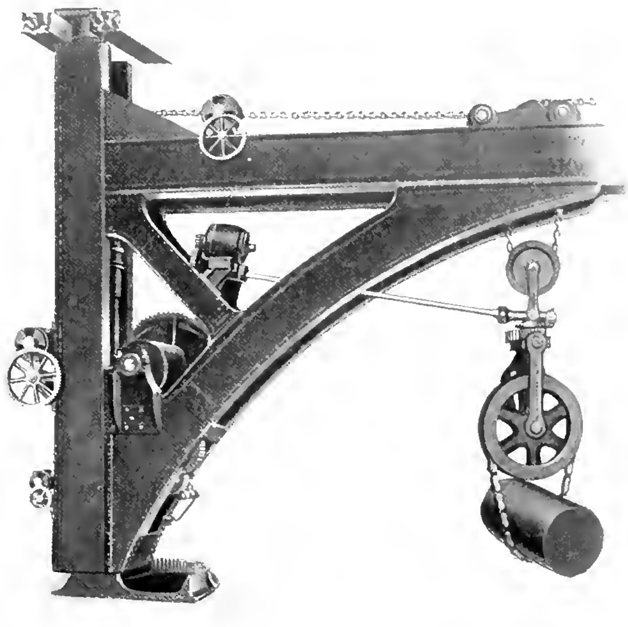
Steel Rule with the Decimal Equivalents of Fractions and Wire Gages

this rule will doubtless be appreciated by machinists and toolmakers. Both sides of the rule are shown in the accompanying illustration. One side has, in addition to a 6-inch scale with one inch graduated in 64ths and the remainder in 32nds, the decimal equivalents of all the fractional parts of an inch

by 64ths. The other side is marked with the decimal equivalents of wire gages and also a 6-inch scale graduated in 16ths. These rules are made of tempered steel and are machine divided. The surfaces are polished, and the figures and graduations are black so that they are distinct and easily read.

JOHNSTON & JENNINGS CRANE BILLET ROTATOR

The Johnston & Jennings Co., of Cleveland, Ohio, has recently designed a device for forge shop cranes, that is used for rotating billets or ingots under the hammer. The rotating mechanism of this device is power-driven, so that its use decreases the number of helpers required on the hammer crew, as it is only necessary to steady the end of the billet by balancing tongs. The drive between the motor and rotating mechanism is so arranged that it does not prevent obtaining any movement that is available with the ordinary crane, it being possible to operate the hook-block and sling chain close to the hammer or in any position on the boom. The billet and sling chain can be swiveled entirely around, as all joints in the hook-block are universal. A sprocket wheel is used for the sling chain so as to obtain a positive drive. By removing a



Crane equipped with Electrically-driven Billet Rotating Mechanism

small pin, the chain wheel can be disconnected and used without power when desired. The mechanism is very rigid and compact and is heavily designed to absorb the shocks without damage. The motor does not receive any shocks due to hammering, nor can it be injured by the billet being fast or refusing to rotate. All parts are made of either steel castings or steel forgings, and the gears are provided with cut teeth. All the bearings are bushed with bronze bushings which are self-lubricating. The lubricant is such as to withstand the heat of the billet without burning. This mechanism can be operated by the crane-man at the base of the crane, or, if desired, the crane and rotator controllers can be located near the hammer-man's position. The particular crane illustrated, which has a capacity of 25 tons, is equipped with an electric drive, but steam may be used if desired. This rotating mechanism is made for cranes of any capacity, and for either the jib or traveling type. It is effective for handling eccentric shafts, such as crankshafts, etc., as well as for round forgings, and its use would undoubtedly result in a greater output because of the increased speed of rotating and handling the work. This device enables the heaviest billets to be turned through a complete revolution in from 2 to 5 seconds.

CORRECTION

The weight of the Gardner Machine Co.'s pattern-shop disk grinder, a description of which appeared in the May number of MACHINERY, was erroneously given as 12,000 pounds. The correct weight of this grinder, complete with countershaft, is about 1200 pounds.

NEW MACHINERY AND TOOLS NOTES

Lathe Tool-holder: Lowe Tool & Machine Co., Ansonia, Conn. This is a holder of the inserted-blade type with which seven high-speed steel cutters ground to shape are furnished. These cutters are so held in the holder that they may be clamped in any one of four positions, thus adapting them to various purposes. They are made from stock sizes and may readily be obtained in the bar.

Thread Snap Gage: K. L. Herrmann, Detroit, Mich. This device consists of two hardened and lapped jaws provided with threads fastened to a C-frame. It is intended for the rapid inspection of threaded work, especially for work of large diameter and a great number of threads per inch, such as is commonly found in automobile work. The gage indicates inaccuracy in pitch, diameter and angle of thread.

"Star" Grinding Wheel Dresser: C. H. Stephan Specialty Co., Dayton, O. This tool, for truing grinding wheels, consists of a tapered tube which is filled with an abrasive. The abrasive instead of being baked in position is first made as a vitrified stick, which is afterward united to the taper tube by a metallic substance which holds it firmly. A wooden handle is inserted in the end of the tube and the dresser is used in the usual manner.

Toolmaker's Pin Vise: A. S. Koch & Sons, 143 Nevin St., Lancaster, Pa. This device is so arranged that it can be opened by one hand, while the other hand holds the work in place between the jaws. The handle consists of a sliding sleeve with a tapered end which engages the back ends of one jaw and clamps the jaw lightly against the work. A short lever which actuates an eccentric is then operated and the jaws closed firmly on the work.

Micrometer Plug Gage: Nash Engineering Co., 248 Gates Ave., Brooklyn, N. Y. This tool is intended for measuring small holes or slots with great precision. The barrel is graduated to read by thousandths and by means of subdivisions to ten-thousandths of an inch or less. This tool is nearly as rigid as a solid plug and has the advantage that intermediate sizes can be measured with accuracy, each instrument having a range of about 1/32 inch above and below its nominal size.

Hinge-joint Belt Fastener: Webb Hinge Belt Hook Co., Boonton, N. J. These fasteners are of the hinge-joint type and consist of a series of wire hooks which are inserted in the belt from both sides and clinched. The hinged connection is made by inserting a pin through eyelets or turns in the hooks which come between the belt ends. Made-up fasteners are furnished in sizes from 1 to 4 inches in width and for any thickness of belt. For wide belts a number of sets may be used.

Drill Socket: Sager Drill Socket Co., West Albany, N. Y. This drill socket is designed for holding shanks with broken tangs by the tapered part of the shank without the necessity of cutting a keyway or a flat, or using any other driving means. The socket is split and a taper sleeve screws onto the lower end of the socket. By means of this sleeve the drill shank can be firmly tightened or clamped in place. The sockets are made in several sizes for drills from ¼ to 3 inches diameter.

Measuring Device: C. J. Root Co., Bristol, Conn. This device has been designed for measuring the linear lengths of various materials during the process of manufacture. A measuring wheel mounted in a bracket rests upon the material to be measured, while a flexible shaft extends from the wheel to the counting register. The device is applied to machines through which the material passes while in the manufacturing processes. Wheels for measuring units of 12, 20 and 36 inches are furnished.

Swaging Machine: Coulter & McKenzie Machine Co., Bridgeport, Conn. This machine embodies certain improvements recently patented by Andrew Berg and is especially intended for making file tangs. The operation of forming file tangs can be accomplished in about four seconds. All the operator has to do is to place the heated stock between the dies, close the chuck mechanism and press a foot treadle. After the swaging of one tang, the swaging dies automatically open to receive another blank.

Variety Saw for Pattern Shop: B. M. Root Co., York, Pa. The countershaft by which this saw is driven, is mounted at the rear on an extension of the base. An endless belt may be used for transmitting motion to the saw arbor, as the latter with the table is adjustable horizontally. Instead of vertical adjustment for the table, the saw itself is raised or lowered by a handwheel conveniently located. The table tilts to an angle a little greater than 45 degrees and is provided with suitable graduations. This machine can be fitted with a foot-operated boring attachment if desired.

Double Back-geared Lathe: Prentice Bros. Co., Worcester, Mass. The quick-change gear mechanism of this lathe gives 36 changes of lead for screw cutting from 1 to 16 threads per inch. The lead-screw, which is large and of coarse pitch, is rotated when screw cutting only. The spindle of this machine has a $2\frac{1}{2}$-inch hole through it and runs in bearings of hard bronze. The tailstock is of the offset type, permitting the compound rest to be set parallel with the bed. The feed

is automatically thrown out at any point by a stop which disengages a clutch on the feed rod. A taper attachment can be furnished, if desired, at extra cost.

Worm-gear Hobbing Attachment: Garvin Machine Co., Spring and Varick Sts., New York City. This attachment, which may be placed on the maker's milling machine tables, will permit of the cutting of two worm-gears at a time. While two gears are being cut, two previously finished gears can be taken off and new gear blanks put in place, the device having provision for the simultaneous holding of four gears. When the worm-gears are being cut, they are positively rotated; they are driven from the spindle of the machine by worm gearing to a positive clutch. The hobs are driven from the spindle by being held in an ordinary collet chuck.

Gearless Reversing Countershaft: Carl M. Wheaton, 9 Calendar St., Providence, R. I. This is a countershaft of the reversible type that is driven by a single belt and is without gears. The reverse movement is obtained by a short endless rope belt which, by passing over idlers, connects the belt pulley with the one giving the reverse motion. The desired direction of rotation is obtained by means of a clutch which connects the shaft direct to the belt pulley or indirectly through the rope drive. All parts are self-oiling and the same general constructional features employed for the regular two-pulley countershafts manufactured by the builder, are retained.

Relieving Attachment: Lodge & Shipley Machine Tool Co., Cincinnati, O. This attachment, which may be applied to this company's patent head lathe, can be used for relieving either straight or taper work, having any number of flutes ranging from 3 to 16 inclusive. A special relieving rest is furnished, which is reciprocated by a single-throw cam that is actuated from the headstock by longitudinal and cross-shafts connected by bevel gears. Multiple cams are not required as the indexing to relieve different numbers of flutes is accomplished by change gears. Three cams are furnished to give variations in the depth of relief of 1/32, 1/16 or 1/8 inch. Cams giving other throws may, of course, be easily made by the purchaser if desired.

Friction-driven Sensitive Drill Press: Barry & Zecher Co., Lancaster, Pa. This machine may be driven direct from the countershaft, as the necessary speed variations are obtained through a friction disk drive. By means of a treadle at the base, the drill is started or stopped by disengaging the friction disk, while a second treadle controls the position of the driver on the friction disk and consequently the speed of the spindle. Speed changes can be made while the machine is in motion and the available speed variations for the spindle range from 250 to 1800 revolutions per minute. The drill has a capacity for holes up to 9/16 inch in diameter. The maximum distance from the spindle to the table is 36 inches, and from the center of the spindle to the column, 13 inches.

Drawing and Broaching Press: Standard Machinery Co., 7 Beverly St., Providence, R. I. This is a press for drawing tubes in brass, gold, silver, platinum and copper, or for redrawing and broaching cups and tubes of heavy metal. The machine is designed to give a uniform pressure on the work and to draw stock evenly. It has a maximum stroke of 24 inches which may be varied to suit the work being done. The speed of the press may also be varied either by means of the lineshaft or through change gears located on top. By the use of roller thrust bearings which take the thrust of the screw and ram on both the upward and downward strokes, a considerable saving in the power required to operate the machine is said to be effected. The floor space required for this press is 3 feet, 2 inches by 7 feet, 6 inches and the extreme height is 9 feet.

Vertical Boring and Turning Mill: Betts Machine Co., Wilmington, Del. This company has brought out a new line of vertical boring mills, ranging in size from 5- to 20-foot swing. Both the vertical and horizontal movements of the heads of these machines are controlled by levers located on the heads so that the latter may be started or stopped without the operator's leaving them. The feeds may also be controlled from the heads or, if more convenient, from either side of the machine. These machines can be arranged to be driven either by motor or by belt. The cross-rail is raised and lowered and the heads rapidly traversed by a constant-speed motor mounted on the distance piece between the uprights. Each tool is independently counterbalanced by weights which do not need to be changed for any position of the cross-rail or head. On the 7-foot mill, eight feeds are provided ranging from 0.023 inch to 1 inch per revolution, which are obtained through positive clutches. All sliding surfaces are of rectangular section, the bearings are bushed with bronze, and no gears are used having less than 11 teeth.

Steam and Air Flow Meter: General Electric Co., Schenectady, N. Y. This company has developed a recording steam flow meter, two types of indicating steam flow meters, and an indicating air flow meter, each of which will accurately measure the rate of flow of steam, air or other gases under any conditions of pressure and temperature met in commercial practice. The principle governing the action is a modification of that of the Pitot tube. A brass nozzle is screwed into the pipe at the point where measurements are to be taken, having two sets of openings so arranged in relation to the direction of flow that the impingement of steam against one set results in a pressure equal to the static pressure plus the pressure due to the velocity head, while the second set is acted on by the static pressure less that due to the velocity. The difference in these values is a measure of velocity, and for constant temperature and pressure, gives the rate of flow. The pressures existing in the two sets of openings are transmitted through separate longitudinal tubes, to the outer end of the plug and from there by pipes to the meter.

Heavy-Duty Radial Drill: Edwin Harrington, Son & Co., Inc., 17th and Callowhill Sts., Philadelphia, Pa. In the design of this drill, particular attention has been given to the matter of strength and convenience of operation. The arm is rigidly constructed with cross-ribs and a large strut to prevent deflection, and it is carried on the saddle by ball thrust and roller bearings. The saddle has a vertical power traverse and a long bearing on the column. The drive is from a variable speed motor by belt to a shaft at the top of the column. Speed variations, with and without the back-gears, are obtained through a drum type controller, which is mounted on the column. When particularly slow speeds are required, they may be obtained through special gearing. Positive tooth clutches are provided in the head for reversing the drive and for engaging the back-gears, which are operated by levers located on the head. Six changes of feed are provided, ranging from 0.0051 to 0.04 inch per revolution. The spindle-reversing clutch on the horizontal shaft permits tapping without the use of an extra attachment. These drills are made in two sizes having 5- and 6-foot arms. A 20-horsepower motor is supplied with each machine, and the respective weights are 17,000 and 18,000 pounds.

Sprue Press: Standard Machinery Co., 7 Beverly St., Providence, R. I. This is a press that has been designed to meet the needs of brass founders and other manufacturers for a machine to cut the sprues or gates from soft metal castings. It is a modification of the company's style D power press. Both a treadle and hand lever are furnished for controlling the clutch mechanism, so that when necessary the operator can have both hands free to hold and guide the work, the machine stopping automatically at the upward end of the stroke. The cutters are made of open-hearth tool steel, and are two inches square in section, so that they may be made from plain bar stock. Provision is made for adjusting these cutters so that they may be accurately set to just cut off a gate without touching each other, thus preserving the cutting edges. When it is found more convenient to present the work from the side of the machine, the cutters may be turned at right angles to the normal position. The patented instantaneous clutch with which this press is fitted is so designed that the machine can be run continuously or stopped instantaneously after each revolution. This clutch, which is of the Horton type, illustrated in an article on "Clutches for Power Presses," in the November, 1908, number of MACHINERY, operates so quickly that there is less than 1/32 inch travel on the periphery of the flywheel, after the clutch mechanism is engaged or disengaged, thus insuring efficient operation.

Turn-table Lathe: Pratt & Whitney Co., Hartford, Conn. The tool-carrying cross-slide of this machine is provided with a plain rotary table of hexagon shape onto which the tools are clamped. The machine derives its name from this rotary table. It is intended for the machining of bar stock, castings and forgings, and it has a capacity for bar stock up to $2\frac{1}{2}$ inches diameter and turns a maximum length of 26 inches. The swing over the bed is 20 inches and the swing over the forming slide is 11 inches. The machine is provided with a geared head and single-pulley drive, the gearing in the head giving eight speed changes for the spindle, the speed ranging from 10 to 251 revolutions per minute. An automatic chuck and rod feed mechanism of the same design as that provided on the Pratt & Whitney open turret lathe described in MACHINERY July, 1907, is also applied to this machine. A feed gear box is placed beneath the head in front of the machine. This gear box provides for six feed changes. The stops for the cross-slide are arranged in a similar manner as on the maker's regular turret lathes, six regular and three supplementary stops being provided. Power and hand feed are provided for the cross-slide in both directions. The turn-table or top of the cross-slide is indexed either automatically when the carriage is run back or directly by hand. The machine can be either belt- or motor-driven, the motor being $7\frac{1}{2}$ horsepower.

Universal Triple-Geared Radial Drill: American Tool Works Co., 300-350 Culvert St., Cincinnati, O. This is a powerful triple-geared radial drill of the universal type, designed to meet the demand for a tool having a wide range of usefulness and at the same time the required power, rigidity and durability to withstand the heavy duty imposed by the use of high-speed steels. One of the striking features is the design of the arm, which has been made exceptionally rigid to resist the combined strains of torsion and deflection. This arm is made in the form of upper and lower tube sections which are bound together in the back by a double wall of metal and further reinforced by heavy transverse ribbing. By means of a worm-

wheel, which engages with teeth cut in the flange of the arm, the latter may be rotated in a complete circle. This movement in connection with the angular adjustment of the head makes it possible to drill and tap to any angle radiating from the center of a sphere. The head of this machine is very compact in its design and is equipped with powerful steel triple gears. The spindle is provided with 24 speed changes ranging from 19 to 314 revolutions per minute in geometrical progression. The tapping mechanism is interposed between the triple gears and the speed box, being mounted in the column end of the arm. By placing the tapping mechanism in this position, it receives the benefit of the triple gear ratio, thus making possible unusually heavy tapping without undue strains and at the same time permits the backing out of taps at an accelerated speed. The lever for operating it is placed on the front of the saddle and controls the starting, stopping and reversing of the spindle. The speed box is of the cone-and-tumbler type and provides eight changes of speed, any one of which is instantly available by shifting the tumbler gear lever to the proper position. By means of an auxiliary train of gearing placed between the pulley and cone shafts, the cone gears are automatically rotated when speed changes are being made, so that undue shocks to the gears are avoided. The driving mechanism is further protected by a flexible coupling or cushion interposed in the line of drive for the purpose of absorbing shocks.

* * *

NATIONAL ASSOCIATION OF MANUFACTURERS' CONVENTION

The fifteenth annual meeting of the National Association of Manufacturers was held in New York, May 16, 17, and 18, the Waldorf-Astoria being the headquarters. The registered attendance, including members and visitors, was 321. The proceedings of this association are largely of a semi-political character, questions of governmental policy, foreign relations, the tariff, patents, immigration, internal commerce, waterways, merchant marine, conservation of resources, etc., being subjects of committee reports. Industrial accidents, means of prevention, and liability insurance, which are of direct and vital importance to every manufacturer, were very practical matters that received attention, however. The program included the following, bearing on them:

An illustrated lecture by Prof. Frederick R. Hutton, "The Prevention of Industrial Accidents";

Address by Henry L. Rosenfeld, "Cooperation and Compensation vs. Compulsion and Compromise in Employers' Liability";

Address by Miles M. Dawson, "True Economy in Compensation for Industrial Accidents," etc.

The report of the committee on industrial indemnity insurance comprising insurance against accidents, sickness and old age; home acquirements, safety appliances and prevention of accidents, etc., probably is one of the most thoroughgoing documents on the subject ever presented. It is authoritative, and represents a large amount of labor in the collecting of the information from manufacturers, government statistics, reports, and other sources. The workings of the present liability insurance system were denounced, and an employers' mutual indemnity insurance system, providing for accidents, sickness and old age was recommended. Liability insurance is a wasteful system of protecting the manufacturer. The defense of damage suits clogs the courts; it is said that from one-third to one-half the time of the state and federal courts is taken up with accident damage suits, and that less than 30 per cent of the premiums paid by employers reach the injured or the dependents of the killed. The report recommended that annual prizes of $10,000 be offered for the safest plants and the best means of accident prevention.

Honor was paid to the late James W. Van Cleave, former president of the association, by a memorial service at 4 o'clock May 17, when the funeral was being held in St. Louis. Glowing tributes were paid to his courage and aggressive qualities.

John Kirby, Jr., president, and F. H. Stillman, treasurer, were both re-elected.

Nearly 400 attended the banquet at the Waldorf-Astoria Wednesday evening at which Speaker Joseph G. Cannon, of the House of Representatives, was the principal speaker.

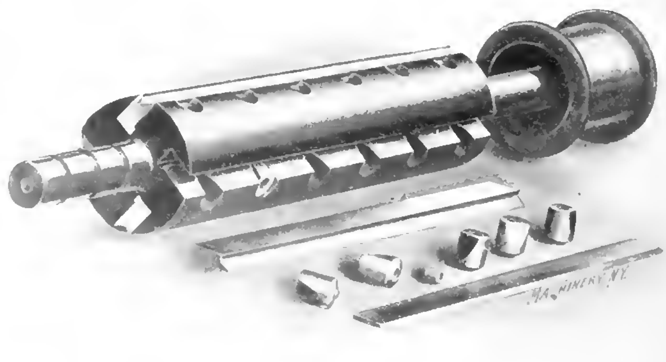
Flaming arc lamps are used for interior lighting with great success by the H. H. Franklin Mfg. Company, Syracuse, N. Y.

SAFETY HEAD FOR WOODWORKING MACHINE

A simple method of safeguarding workmen from the knives or cutters of a jointer, has been developed by the Crescent Machine Co., Leetonia, Ohio. This company has applied to machines of this type, a cylindrical cutter head, such as is shown in the accompanying illustration, which, by reason of its shape, is much safer than the square type commonly used. In case the hand gets in contact with the knives of this new safety head, as it has been appropriately called, a flesh wound



Cylindrical Cutter Head for Jointer, designed to minimize Injuries

would be about the limit of the injury, whereas with the square type of head, there is great danger of the hand being drawn in, resulting in the loss of fingers or in a more serious injury. The reason for the comparative safety of this new head is plainly indicated by the illustration. In conjunction with this head, there is also used a protective shield or guard, which is intended to cover the unused portion of the cutters. The safety head affords protection, however, even though the workman neglects to use the guard, as it minimizes the extent of the injury.

BORING AND MILLING OPERATIONS ON ALUMINUM CRANK-CASE

An interesting machining operation that is performed on the crank-case of the "Cino" motor in the shops of Haberer & Co., Cincinnati, Ohio, is illustrated herewith. The casting is of aluminum and all the operations of boring and milling are done on the horizontal machine shown. The first operation is that of milling the top face. The piece is then put in a jig where all the holes are drilled, after which it is returned to the horizontal boring machine where the crank-shaft holes and

Milling Aluminum Crank-case on Horizontal Boring and Milling Machine

cam-shaft holes are bored by means of a double boring-bar. The next operation is that of facing the ends of the crank-shaft holes, which is accomplished in the manner illustrated. Six straddle mills are mounted on a bar with adjustable spacing collars between them. Each mill takes a cut ¼ inch wide, with a feed of 0.0155 inch per revolution of the spindle, on each of the six faces at the same time. The spindle runs at 30 revolutions per minute, which gives a peripheral speed to the cutters of about 85 feet per minute. This particular operation on the crank-case takes only fifteen minutes, which includes the time of setting up and taking down. The machine on which this work is dene is built by The Fosdick Machine Tool Co., Cincinnati, Ohio.

HERRICK BALANCED ROTARY ENGINE

A new type of rotary engine that promises to be of commercial value in connection with marine work, if not in other fields, was formally exhibited at the Waldorf Astoria, Saturday evening, May 21, before a large gathering of engineers. This new engine, which is the invention of Mr. Gerardus P. Herrick, differs from the countless designs which have preceded it, principally in an ingenious method employed for counterbalancing the radial load on the bearings, which in other rotaries has resulted in serious loss of power through

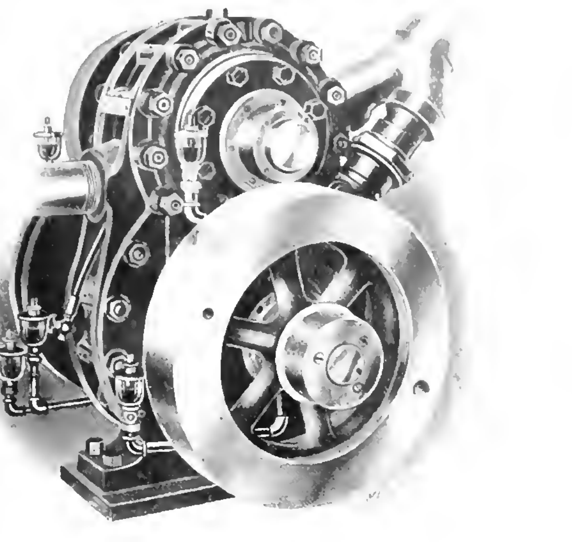

Fig. 1. The Herrick Rotary Engine

excessive friction. The way in which this counterbalancing effect is obtained, as well as the operation of the engine itself, will be explained in connection with the accompanying illustrations, Figs. 1 and 2, which show, respectively, general and sectional views of the experimental motor.

This engine has two rotating cylindrical members A and B,

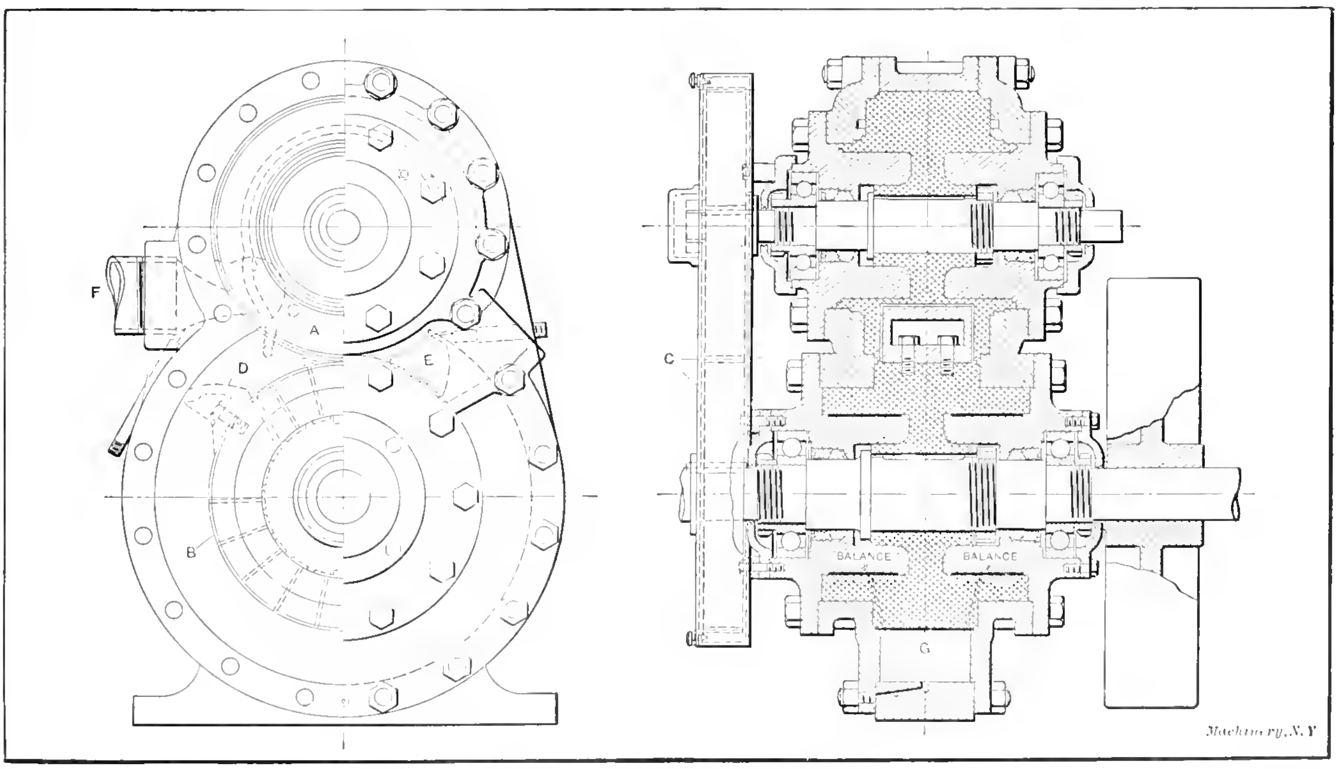

Fig. 2. Elevation and Section of the Herrick Rotary Engine

which are mounted in bearings placed just far enough apart to obtain a rolling contact between the peripheries. The lower part B is the rotor to which is attached a single impeller blade against which the steam acts. The upper part A is, in reality, a valve which controls the admission of steam. This valve also serves, by its contact with the rotor, to separate the steam and exhaust spaces of the cylinder. The rotor and valve are connected by herringbone gears C of the same size which give these two parts synchronous movements. A circular recess is cut in the periphery of the valve, as indicated by the dotted lines in the elevation, which meets the impeller blade D at each revolution and allows it to pass without contact. When this recess moves around to the point where it connects with the steam port which communicates with the pipe F, steam is admitted to the space between the blade D and the contact point between the rotor and valve. When the valve moves to the position shown in Fig. 2, the steam is cut off and used expansively throughout the remainder of the revolution. As soon as the impeller blade passes port E, the exhaust takes place. The recess in the valve has then moved around to allow the blade to pass, which completes the cycle.

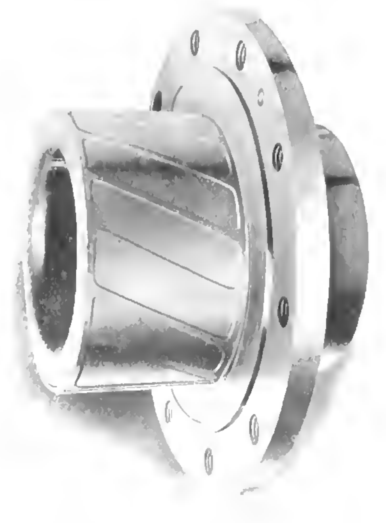

Fig. 3. Enlarged View of Balancing Plug showing Balancing Chambers

The casing which forms the cylinder, has side plates bolted to it, to which are attached, concentric with the valve and rotor shafts, what are known as "balancing plugs." These plugs fit closely into annular spaces on each side of the central webs of both the valve and rotor, and contain the packing and bearings. They are also provided with shallow chambers on their peripheries, as shown in the enlarged view, Fig. 3. The way these plugs are utilized in balancing is as follows: As the steam enters the cylinder, a small amount passes through holes located just back of the impeller blade (these are indicated at G in Fig. 2) to a chamber of the balancing plug, and then to successive chambers as the rotor revolves, thus introducing into each chamber a film of steam, the pressure of which gradually decreases as the steam expands. As these balancing plugs are lengthened sufficiently to compensate for their small diameter, theoretically the radial thrust from the pressure on part of the exterior surface of the rotor, is counter-

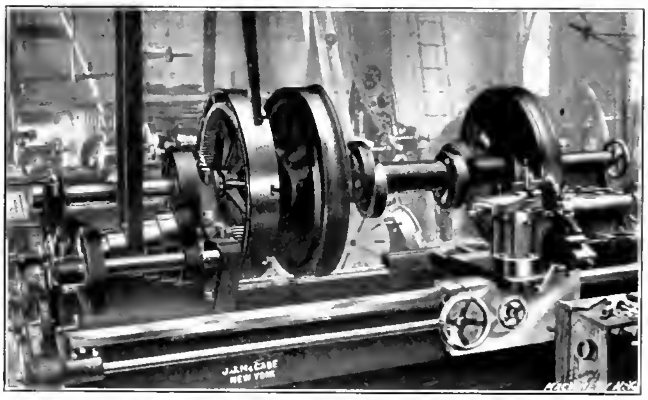
balanced by this inner steam film which rests against the inner wall of the rotor. It will be seen that as the pressure area on the outside of the rotor increases, the balancing area between the plugs and the inside of the rotor also increases.

Mr. Luther D. Lovekin, Chief Engineer of the New York Shipbuilding Co., has suggested that this engine could be advantageously used in connection with turbines for ship propulsion. The plan is to use a three-shaft installation, the two wings or outer shafts being driven by turbines and the central shaft by a rotary engine interposed between the boilers and turbines. By this arrangement, high-pressure superheated steam, which cannot be used economically in turbines without greatly increasing their weight and size, could first be utilized in the rotary, from which it would be exhausted at the most suitable pressure for economy in the turbine. This plan has been indorsed by Captain A. B. Willis, U. S. N., who further recommends that three separate rotaries (not compounded) with impeller blades located 120 degrees apart, be used in order to obtain a better balance and a steadier steam flow to the turbines. The construction of this new rotary is such that the rotating surfaces do not come into actual contact within the steam space, which, while it reduces the friction, results, of course, in some leakage. Such leakage, however, with the roto-turbo combination will pass out through the exhaust and be utilized in turbines. Mr. Lovekin estimates that by this arrangement a water rate of ten pounds per brake horsepower per hour, can be obtained.

* * *

TURNING LOCOMOTIVE DRIVING WHEELS IN A McCABE DOUBLE-SPINDLE LATHE

An excellent example of the adaptability of the double-spindle lathe, particularly for shops handling a large variety of work with a more or less limited tool equipment, is shown by the accompanying engraving. The particular work illustrated, is that of re-turning the tires of a pair of locomotive driving wheels in the Empire Machine Works of Brooklyn, N. Y., on one of the J. J. McCabe double-spindle lathes. These



Turning the Tires of a 48-inch Driving Wheel in a McCabe Double-spindle Lathe

wheels are 48 inches in diameter, the width of the tire is 6 inches, and the approximate weight is 7000 pounds. As they had been in constant service both night and day for two years, they were not only badly worn, but extremely hard, owing to the chilled spots due to the braking action and the slippage between the wheels and the rails. By doing this job in the machine referred to, it was unnecessary to send the wheels to Philadelphia to be turned ou a regular wheel lathe as formerly. By the use of an auxiliary tool-stand that may be attached to one side of the saddle, two tools were used simultaneously to cut down the ridges on either side, which reduced the time required for the turning operation.

* * *

LAUNCHING OF THE FLORIDA

The U. S. S. *Florida*, which, when completed, will be the largest battleship in the United States Navy, was launched at the Brooklyn Navy Yard on Thursday, May 12. The *Florida* will have a normal displacement of 21,825 tons, which exceeds the displacement of the *Connecticut* by 5825 tons, and that of the *Oregon* by 11,537 tons. Her length over-all is 521 feet, and her width of beam, 85 feet. The armament consists of ten 12-inch rifles in the main batteries, and sixteen 5-inch rapid-fire guns, four 3-pounders, two 1-pounders, and a number of machine guns in the secondary batteries. There are also two 21-inch submerged tubes for torpedoes. The broadside fire will be 20 per cent greater than any battleship in commission in our navy. The engines are of the turbine type and are designed to develop 28,000 horsepower, which will give an estimated speed of approximately 22 knots. Propulsion is obtained through four propellers, being arranged in tandem on each side of the twin shafts. When launched, the *Florida* weighed approximately 8700 tons, and she was 65 per cent completed. Her estimated cost at completion is $6,000,000.

* * *

THE NEW CINCINNATI PLANER PLANT

Five of the largest concerns connected with the Cincinnati machine tool industry have formed an industrial colony at Oakley, Ohio, which is only a few miles out of Cincinnati. These concerns are the Cincinnati Planer Co., Cincinnati Milling Machine Co., Cincinnati Bickford Machine Tool Co., Triumph Electric and Ice Machine Co. and the Modern Foundry Co., and they all own a power plant in common, the stock ownership of which is proportioned to the amount of power used. This power plant furnishes power, light, service water, sprinkler water, compressed air, steam line and hot water for heating plants. As noted elsewhere, the Triumph plant is already in complete operation; so too are the Modern Foundry Co. and the Cincinnati Planer Co., the latter having entirely vacated its old plant in Cincinnati.

Fig. 1. Colony Power Plant and Modern Foundry Co.'s Plant, Oakley, Ohio

Pictures of the Modern Foundry's Co.'s plant and the common or colony power plants are shown in Fig. 1 and in Fig 2 is the Cincinnati Planer plant. A general view of the shop interior of the latter place is given in Fig. 3 and shows the magnificent lighting, and the crane system; in the lower left-hand corner are shown the tops of freight cars which are run into the shop on depressed tracks, capable of holding two 40-foot cars, which bring the floor of the cars on a level with the shop floor.

Fig. 2. Cincinnati Planer Co.'s Plant, Oakley, Ohio

Each department is driven by individual motors, the line-shaft being in sections. Hyatt roller bearings are used on all shafts and the method of mounting the motors is somewhat

unusual. In the first place the shop floor is composed of about eight inches of cinders, eight inches of concrete, then creosoted sleepers imbedded in concrete, next $1\frac{5}{8}$ inch of oak and lastly a layer of easily renewable $\frac{7}{8}$-inch oak flooring. The motor foundations are built up like a big concrete box, directly from the eight-inch concrete foundation. These hollow motor foundations average about three feet in height and are filled with cinders, on top of which is placed four inches of oak as shown at *A*, Fig. 4. The motors are bolted down solidly by bolts imbedded in the concrete. The construction of the motor foundations in this way does away with the vibration present when

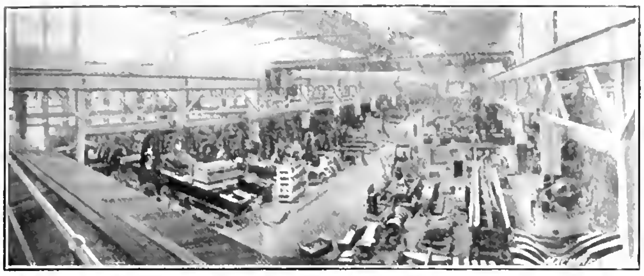


Fig. 3. Interior View of Cincinnati Planer Co.'s Shop

they are placed on platforms in the usual way, and it also provides means of oiling and inspecting without using a ladder. This engraving also shows one of the short shafts at *B* used for testing planers in position before shipping.

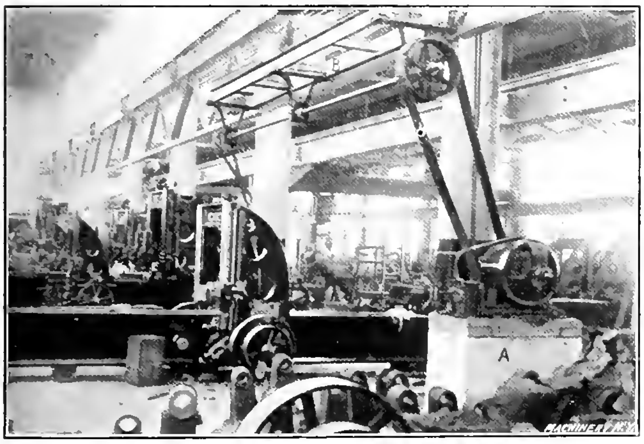

Fig. 4. Motor Foundation and Test Shaft in Shop

Fig. 5 shows a small section of the individual locker and wash-bowl system, which is only one of the many features of the plant designed to provide for the comfort of the employes.

* * *

Cement will resist a temperature of 500 degrees F. for an indefinite period, but a continuous temperature of over 700 degrees F. is disastrous. The heat-resisting power of cement is due to the amount of moisture chemically combined, being from twenty to twenty-five per cent of its weight. At a high temperature this chemically-combined water is driven

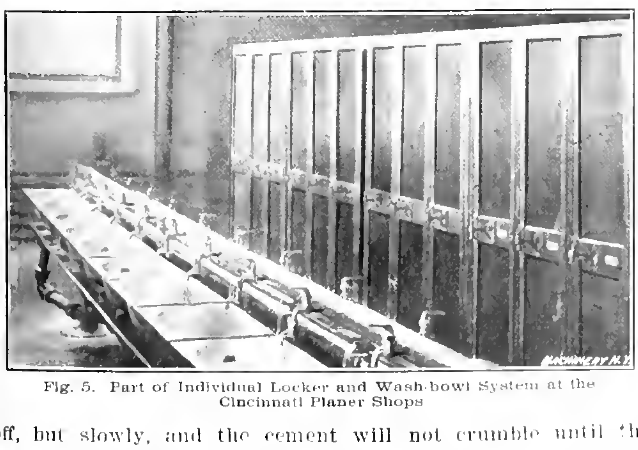

Fig. 5. Part of Individual Locker and Wash-bowl System at the Cincinnati Planer Shops

off, but slowly, and the cement will not crumble until the water has been evaporated. The slowness of evaporation is probably the cause of the ability of concrete to resist high temperatures for a short period, while a much lower temperature, long continued, will ultimately disintegrate it.

OPENING OF NEW PLANT OF TRIUMPH ELECTRIC CO. AND TRIUMPH ICE MACHINE CO.

A special B. & O. railway train carried 350 visitors from Cincinnati to Oakley, Ohio, to the opening of the Triumph Electric, and Triumph Ice Machine Co.'s new plant, Saturday, April 30. In addition to these about 150 more made the trip in

New Machine Shop of Triumph Electric Co. and Triumph Ice Machine Co., Cincinnati, Ohio, 300 feet long, 140 feet wide, Center Bay 60 feet

automobiles and street cars. Buffet lunch was served, after which John L. Shuff, acting as chairman, introduced W. N. Hobart, the venerable head of the concern, who made a short speech. He was followed by James J. Heekin, president of the Chamber of Commerce; A. J. Conroy, president of the Business Men's Club; President Egan of the Industrial Bureau; W. F. Robertson of the Manufacturers' Club, and R. K. LeBlond of the Metal Trades Association. After the close of the speeches, all of which were brief and to the point, the guests were divided into groups with a guide at the head and shown over the plant.

An interesting feature of the plant is the position of the various store-rooms which are situated in the middle gallery either directly above, or directly below, the department which they are to serve, thus reducing the trouble of getting stock promptly, to a minimum. The view reproduced herewith shows the main machine shop, which is 300 feet long and 140 feet wide. The center bay is 60 feet wide.

* * *

SPRING MEETING OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS

The program of technical papers for the American Society of Mechanical Engineers' convention, which will be held in Atlantic City, N. J., May 31 to June 3, is as follows:

"The Shockless Jarring Machine," by Wilfred Lewis.

"A Comparison of Lathe Headstock Characteristics," by Prof. Walter Rautenstrauch.

"The Strength of Punch and Riveter Frames Made of Cast Iron," by Prof. A. L. Jenkins.

"The Mechanical Engineer and the Textile Industry," by H. L. Gantt.

"The Elastic Limit of Manganese and other Bronzes," by J. A. Capp.

"The Hydrostatic Chord," by R. D. Johnson.

"The Resistance of Freight Trains," by Prof. Edw. C. Schmidt.

"A Regenerator Cycle for Gas Engines Using Sub-adiabatic Expansion," by Prof. A. J. Frith.

"Gas Engines for Driving Alternating Current Generators," by H. G. Reist.

"Two Proposed Units of Power," by Prof. William T. Magruder.

"Some Operating Experiences with a Blast Furnace Gas Power Plant," by H. J. Freyn.

"Improvements in Lineshaft Hangers and Bearings," by Henry Hess.

"Experimental Analysis of a Friction Clutch-Coupling," by Prof. William T. Magruder.

"An Improved Absorption Dynamometer," by Prof. C. M. Garland.

"Critical Speed Calculation," by S. H. Weaver.

NATIONAL MACHINE TOOL BUILDERS ASSOCIATION CONVENTION

The semi-annual convention of the National Machine Tool Builders' Association at Rochester, N. Y., May 24 and 25, was the most successful spring meeting ever held, the attendance breaking the record for a semi-annual convention. Twenty-one new members joined—the largest number of accessions at any meeting.

F. A. Geier, president of the association, called the meeting to order and in a few well-chosen remarks congratulated the members on the progress made and the mutual good feeling engendered. He contrasted the members' relations with the conditions existing abroad, especially in Germany, where practically no cooperation whatever exists, and where almost every machine tool builder regards his competitors with suspicion and distrust. Great regret was expressed for the illness of W. P. Davis, president of the W. P. Davis Machine Tool Co. of Rochester, through whose efforts, largely, the meeting was held in Rochester.

After the transaction of the routine business came the reports of committees, the first being that of the committee on standardization of motors, of which Paul A. Montanus, of the Springfield Machine Tool Co., Springfield, Ohio, was chairman. The report gave the substance of the conference of the committee with a similar committee appointed by the American Association of Electric Motor Manufacturers. Fifteen principal points of discussion were presented, of which eight had been agreed on, the remainder having been left for further discussion. The results of the committee work will be published when it has been completed.

The Committee on Uniform Costs, of which E. J. Kearney, of Kearney & Trecker Co., Milwaukee, Wis., was chairman, was represented by S. H. Reck of the Rockford Drilling Machine Co., Rockford, Ill., in the absence of Mr. Kearney. A communication from the latter expressed satisfaction with the uniform costs system installed in the Kearney & Trecker plant.

The Apprenticeship Committee, of which E. P. Bullard, of the Bullard Machine Tool Co., Bridgeport, Conn., was chairman, was represented by F. L. Eberhardt, who read a paper giving an outline of the apprenticeship system in operation in the plant of Gould & Eberhardt, Newark, N. J.

The Tariff Committee, of which J. B. Doan, of the American Tool Works Co., Cincinnati, Ohio, was chairman, rendered a report which briefly reviewed the work and gave some statistics of the present tariff, including the minimum and maximum features.

The cancellation of machine tool orders was ably discussed by C. Wood Walter, C. A. Johnson, Murray Shipley and William B. Reid, the first three taking the manufacturer's side. It was practically agreed that present trade practice is unsound, too much looseness existing in the character of orders and in permitting cancellations without adequate cause. Parallel conditions exist in no other industry. The privilege of cancellation is abused. Customers and dealers place orders on chance. If the business materializes the machines are accepted, but if not, the orders are countermanded without thought of the hardship inflicted on the machine tool builder. The injurious effects of this system of doing business are so obvious that no great argument was necessary to prove them. Mr. Reid, representing the dealers, conceded much that had been said. He stated, however, that 80 per cent of the machine tool trade is done through dealers and that grave practical difficulties prevent any radical change in a system that has become strongly established by custom. If the builders were unwilling to practically carry stock in the dealers' warerooms in good times, through permitting cancellations at will, they should not in justice ask the dealers to order stock in dull times.

Prof. F. B. Dyer, superintendent of Cincinnati public schools, described the work of the Cincinnati continuation school and illustrated the character of instruction with stereopticon views. (See MACHINERY, May, 1910, for abstract of similar paper.) His talk evoked hearty applause and many members evinced great interest in the school work, which undoubtedly is a forerunner of one of the most important educational works that has been undertaken in America along industrial lines.

Robert Pierpont, works manager of the Olds Motor Works, Detroit, Mich., read a paper on the future of the automobile business with reference to machine tools, in which he set forth some very practical ideas developed from experience in the management of one of the large automobile factories. He advocated special machinery and simpler standard tools. In his opinion individual motor drive is best adapted to special machines in which the power consumption is practically a fixed quantity. On standard tools, where the power requirements vary widely, the motor equipment is necessarily greater in power than the total required for a group of the same machines when driven by a motor direct connected to the lineshaft. He advocated cone drive in preference to gear drive as the latter is likely to be noisy and inefficient. Suggestions were made regarding milling machines, lathes, grinders, drilling machines, screw machines, gear cutters, and special machinery.

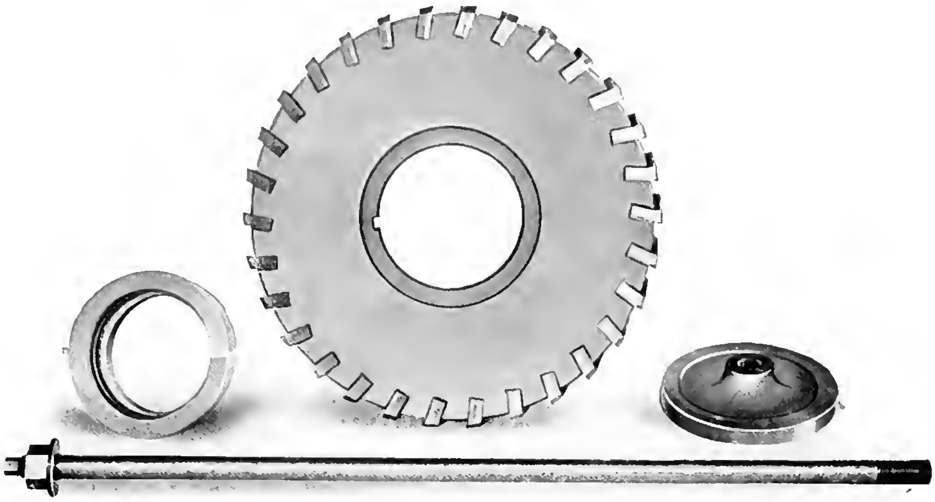
R. K. LeBlond of the R. K. LeBlond Machine Tool Co. and William Lodge of the Lodge & Shipley Machine Tool Co., discussed the relative merits of cone drive and gear drive, the former advocating the cone drive and the latter the gear drive. Mr. LeBlond claimed that all the advantages that can possibly be secured with the gear head can be better obtained with a variable speed motor and comparatively few mechanical changes, because the changes can be obtained with small friction loss. In his opinion the great difficulties of all gear-driven machines are lack of efficiency, expensive maintenance and increased first cost. It was pointed out that the single-pulley gear-drive 16-inch lathe required a one-horsepower motor to turn it over, and fully one-half horsepower is absorbed in friction loss under actual working conditions. With the cone pulley drive on direct speeds an efficiency as high as 85 per cent is obtained and in the extreme cases of transmitting power through the back gears the efficiency is seldom lower than 75 per cent.

Mr. Lodge conceded that for light work the cone pulley drive can be used to advantage, but advocated the gear drive when taking heavy cuts at high rates of speeds, the power consumption then being increased from two to five times the ordinary ratings.

William R. Wood of Cincinnati, Ohio, read a paper advocating a court of patent appeals. He referred to the importance of patents in the machine-tool manufacturing business and the hopeless discrepancies between the means provided for securing patents and for protecting the patent when secured. The Patent Office represents one piece of the patent machinery and the United States courts the other. The application for a patent receives the most careful scrutiny, and thorough examination is made into the state of the art before the patent is granted. The time required for securing a patent may vary from six months to six years and when granted it is supposed to give the inventor a monopoly for a period of seventeen years. After all the elaborate precautions have been taken by the examiners, we have the glaring inconsistencies of the courts in passing on the validity of the patents so cautiously obtained. The United States courts have exclusive jurisdiction in patent suits and, with all due respect to the attainments of the learned judges comprising the court, it must be conceded that they have not the experience that qualifies them to pass on many questions of purely mechanical merit. The American Bar Association, the Washington Bar Association and many members of the patent bar, are in favor of creating a patent court of appeals composed of five judges selected from the thirty regular circuit judges with special view of their fitness, to whom all patent suits shall be taken. A bill has been introduced to the Senate, known as Senate Bill No. 4982, and a similar bill has been brought before the House of Representatives, known as House Bill No. 14,622.

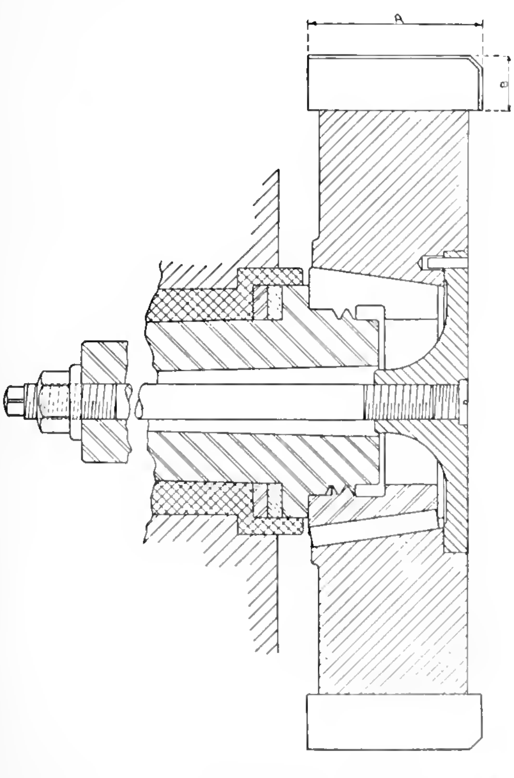
A new and original feature, and one of the most interesting in the proceedings to the newspaper men, was the discussion of the value of what was called "Direct Advertising," represented by A. H. Hitchcock of *Hitchcock's List*, and "Trade Paper Advertising," by John A. Hill of the *American Machinist*. A raised platform for the participants, equipped with buckets of water, boxing gloves and sponges created great merriment as the members assembled in the hall. The speakers were placed in chairs. Charles G. Allen of Barre, Mass., seconded

Why do you keep a large number of face milling cutters on hand when you can use one on several sizes of machines?



B. & S. Inserted Tooth Face Milling Cutters

can be used interchangeably on machines of different sized spindles and so greatly reduce the number of cutters necessary to keep on hand.



The cutters are made to fit over a split sleeve which screws on to the nose of the spindle. When it is desired to use one cutter on different sized spindles, the internal diameter of the sleeves varies to fit the different spindles but the external diameter of the sleeves is the same.

Another advantage of the cutters is the fact that the sleeves are made with a taper that will allow for ready release when it is desired to remove the cutter.

The theory of the cutter allows for taking the heaviest cuts, as all danger of jamming the cutter on the nose of the spindle is eliminated. Thus the capacity of the cutter is limited only by the full power of the belt.

Send for our new Cutter List.

BROWN & SHARPE MFG. CO., Providence, R. I., U.S.A.

Mr. Hill and A. E. Newton of Worcester, Mass., Mr. Hitchcock. Edward Rivett of Brighton, Mass., acted as referee. Our limited space prevents an extended report of the papers, but those who are acquainted with the speakers will agree with us that both sides were ably presented, the discussion being declared a drawn battle by the referee.

One function of the trade journal, and an important one, which is sometimes lost sight of by advertisers who consider direct results only, is the educational and informative work the best trade journals perform in their respective fields, and which indirectly brings more and better results to manufacturers than their advertising. We need only point to the progress of the machinery trade in this country, which is coincident with the development of the trade journals in this field, to prove the necessity for their existence, even if they brought no returns whatever to an advertiser.

The social event of the meeting, long to be remembered with pleasure by those participating, was the reception, Tuesday evening, given by Miss Kate Gleason and brother, William Gleason, of the Gleason Works, Rochester, at their "Spanish castle" home "Clonos" on East Ave., Pittsford, a suburb of the city. About 180 machine tool builders, friends, guests and ladies were taken there by automobile. The unique architectural features of "Clonos" inspired the liveliest interest, and the entertainment left nothing to be desired.

There are now 116 members in the association including the new members added at this convention, the names of which are as follows:

Adams Co.	Dubuque, Iowa.
Baker Bros.	Toledo, Ohio.
Becker Milling Machine Co.	Hyde Park, Mass.
Bridgeford Machine Tool Works	Rochester, N. Y.
Betts Machine Co.	Wilmington, Del.
Bryant Chucking Grinder Co.	Springfield, Vt.
Foster Machine Co.	Elkhart, Ind.
Edwin Harrington Son & Co., Inc.	Philadelphia, Pa.
Landis Tool Co.	Waynesboro, Pa
Leland, W. H. & Co.	Worcester, Mass.
Moline Tool Co.	Moline, Ill.
Morton Mfg. Co.	Muskegon Heights, Mich.
New Haven Mfg. Co.	New Haven, Conn.
Oesterlein Machine Co.	Cincinnati, Ohio.
Pratt & Whitney Co.	Hartford, Conn.
Rochester Boring Machine Co.	Rochester, N. Y.
William Sellers & Co., Inc.	Philadelphia, Pa.
Taylor & Fenn Co.	Hartford, Conn.
Universal Boring Machine Co.	Hudson, Mass.
Walker Grinder Co.	Worcester, Mass.
Waltham Watch Tool Co.	Springfield, Mass.

The officers and committees are to be congratulated on the results of the work, which has greatly strengthened the association, and which undoubtedly has contributed materially to general information on technical and practical matters of great moment to the members. The fall meeting will be held in New York City.

* * *

PERSONALS

E. A. Murray, general foreman of the C. & O. R. R. shops at Covington, Kentucky, has been promoted to the position of master mechanic of the Lexington shops.

J. H. Nash, master mechanic of the Illinois Central Ry. shops at Paducah, Kentucky, has just been given the position of superintendent of the Burnside shops of the same road.

J. E. Parker, formerly connected with the H. Mueller Mfg. Co. of Decatur, Illinois, has taken a position as steel expert and traveling salesman with the Crucible Steel Co. of America, his headquarters being at Philadelphia.

Martin S. O'Connor has been promoted from the position of foreman in the Avis, Pa., shops of the Pennsylvania division, New York Central Lines, to that of general foreman of the Highbridge, N. Y., shops of the Putnam division.

A. F. Cook, general car foreman of the Chicago division of the C. B. & Q. R. R., has taken charge of the car department of the Chicago & Western Indiana R. R. and the Belt Ry. Co. of Chicago, with headquarters in Chicago.

Dr. William H. Tolman, director of the Museum of Safety, New York, sailed for Europe May 12 with a commission from the National Electric Light Association to investigate European methods of protection of life and limb in electric plants.

John R. Back has resigned his position as instructor in the Worcester trade school, Worcester, Mass., and Mr. M. L. Carroll has been elected to the position. Mr. Back, who was for many years superintendent of the F. E. Reed Co., has entered the employ of Prentice Bros. Co., Worcester.

J. B. Comstock, for six years with the Westinghouse Electric & Mfg. Co. at its East Pittsburg Works, and for four years manager of its publication department and printing plant, severed his connection with that company in April to take a similar position with the P. & F. Corbin Co. of New Britain, Conn. Prior to Mr. Comstock's connection with the Westinghouse Co. he filled the position with the Corbin Co. that he has recently been recalled to assume.

S. Noda, president of Roku-Roku Shoten, Inc., machinery merchants, 3 Shinsakancho Kyopashiku, Tokio, Japan, visited a number of American machine tool manufacturers in May, whom he will represent in Japan. He sailed the last of May for Germany with the intention of attending the Brussels Exposition. Mr. Noda has thoroughly equipped himself for handling machine tool business in Japan. He speaks English and German fluently. His brother is spending three years in the machine shops of the United States to obtain a thorough practical knowledge of machinery manufacturing and operation, particularly the latter. It is his intention to cooperate with his brother in selling machine tools. His practical experience will enable him to get the best possible results from American machinery. In many cases, at present, machine tools are being operated in Japan very inefficiently, no one in charge being competent to work them to the best advantage.

OBITUARIES

Thaddeus W. Tyler, the original of Longfellow's "Village Blacksmith," died at Lynn, Mass., in April, aged seventy-six years.

John I. Kinsey, who for forty years was master mechanic of the Lehigh Valley R. R. shops at Easton, Pa., died in Easton, April 28, aged eighty-three years.

Charles W. Gage, an expert draftsman, employed by the George H. Bushnell Press Co., Thompsonville, Conn., died at his home in Thompsonville April 15, aged forty years.

Leonard B. Spence died in New York, April 16, aged seventy-two years. Mr. Spence was a pioneer manufacturer of mowing machines and made, in Worcester, Mass., some of the first machines for cutting grass produced in New England. He had been connected with the New York Aquarium for fifteen years as a scientist.

James W. Van Cleave, president of the Bucks Stove & Range Co., St. Louis, Mo., and former president of the National Association of Manufacturers, died at his home in St. Louis, of heart disease, May 15, in his sixty-first year. A memorial service was held by the association, which was in convention at the Waldorf-Astoria hotel in New York, at four o'clock, May 17, just at the time the burial was taking place in St. Louis. Van Cleave will be remembered as one of the great fighters of unions and union labor. His labor troubles undoubtedly shortened his life.

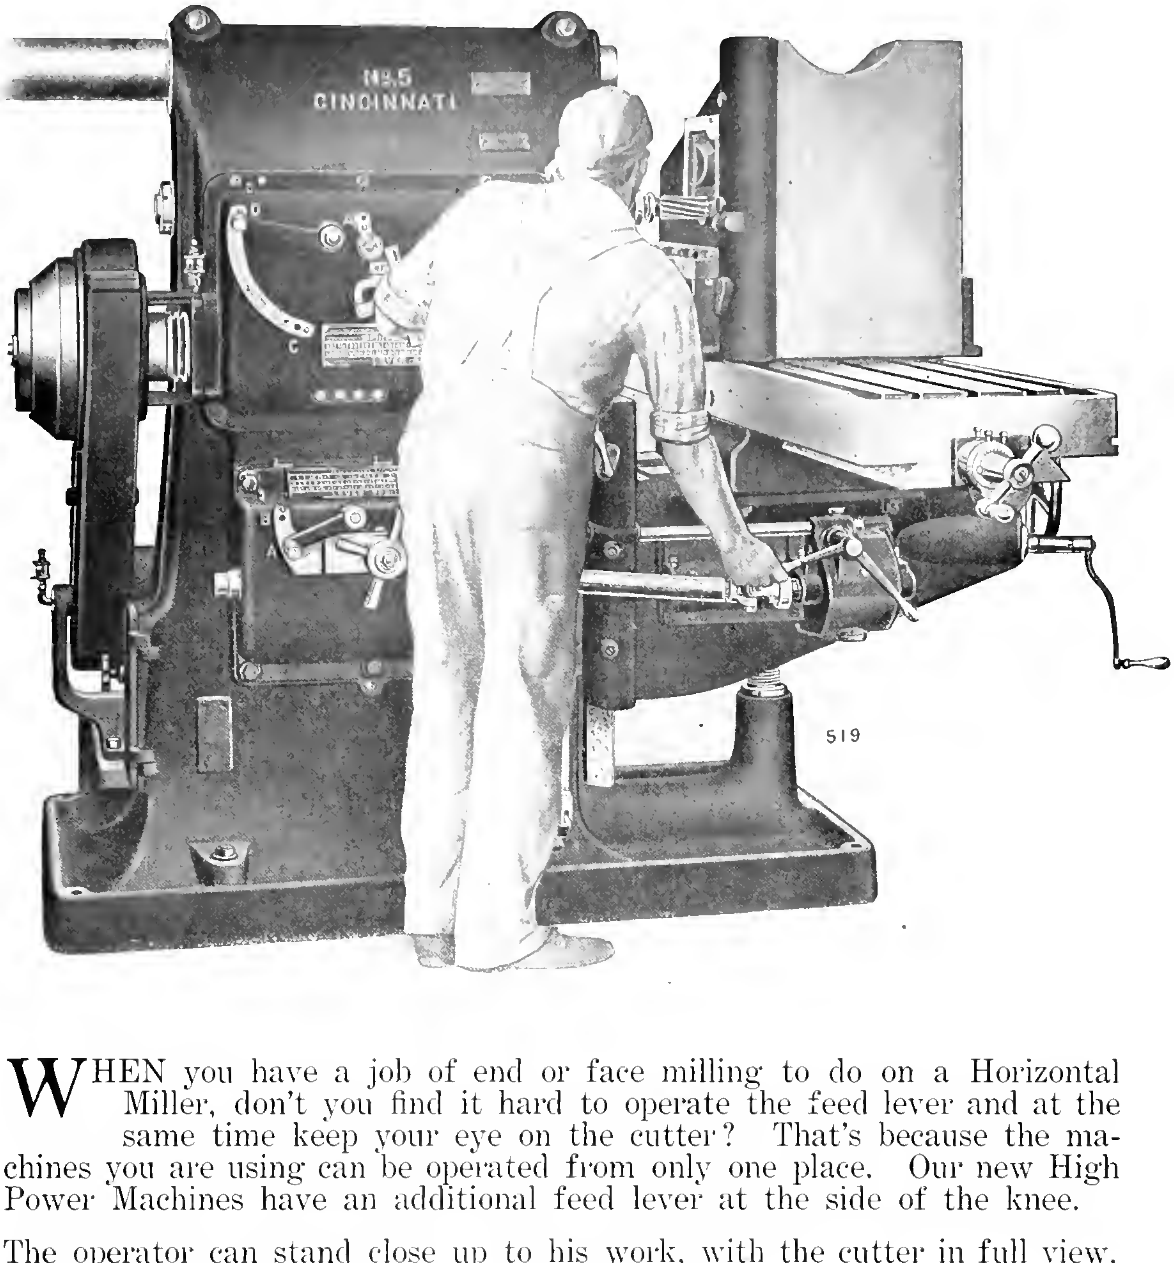
John Wilson Wheeler, president of the New Home Sewing Machine Co., Orange, Mass., died at his home in that town May 2, aged seventy-seven years. Mr. Wheeler left the mercantile business in 1867 to engage in the manufacture of sewing machines in Orange, Mass. Mr. Thomas White, of the White Sewing Machine Co., Cleveland, Ohio, is the only survivor of the company. These pioneers began the business in a very small way, making small hand sewing machines. The business in Orange grew from this small beginning to the present capacity of 600 machines a day and the employment of over 800 people. Mr. Wheeler worked unceasingly to build up the business, first as secretary and treasurer, and then as president for the past ten years.

John H. Converse, president of Burnham, Williams & Co., Philadelphia, Pa., died suddenly of heart disease at his suburban home in Rosemont, May 3, aged sixty-nine years. Mr. Converse was born in Burlington, Vt., and graduated from the University of Vermont in 1861. His first employment was in newspaper work as an editorial writer on the *Burlington Times*, where he stayed for three years. He then went to Chicago, where he engaged in railroad work for two years with the Chicago & Northwestern Ry. Co. In 1866 he went to Altoona, Pa., to work for the Pennsylvania R. R. Co. In 1870 he became a member of M. Baird & Co., Philadelphia, afterwards Burnham, Parry, Williams & Co., and now Burnham, Williams & Co., builders of Baldwin locomotives. The growth of the company during Mr. Converse's regime was enormous, the production increasing from less than one locomotive a day to seven or eight a day in the most prosperous times.

WALTER CRAIG KERR

Walter C. Kerr, president of the Westinghouse Church Kerr & Co., 10 Bridge St., New York, died on May 8 at Rochester, Minn., where he had gone two months previous to undergo an operation for cancer. Mr. Kerr was born at St. Peter, Minn., in 1858. He received his early education in the public schools of his birthplace and took a course in mechanical engineering at Cornell University, graduating in the class of 1879. After his graduation he remained at Sibley College as an instructor and assistant professor until the organization of Westinghouse Church Kerr & Co. was effected in 1884, when, from the first, Mr. Kerr was one of the officers of that

Cincinnati Handiness



WHEN you have a job of end or face milling to do on a Horizontal Miller, don't you find it hard to operate the feed lever and at the same time keep your eye on the cutter? That's because the machines you are using can be operated from only one place. Our new High Power Machines have an additional feed lever at the side of the knee.

The operator can stand close up to his work, with the cutter in full view, and control the machine from this position.

With this one lever he can operate and reverse table, cross or vertical feeds.

The main starting lever is immediately in front of him and the speed and feed changers are at his elbow, so that the entire machine is under complete control from here.

Ask for the Catalog.

AUSTRALIAN AGENTS—Thos. McPherson & Son, Melbourne.

Walter Craig Kerr

firm. Much of the credit for the growth and success of this company, of which Mr. Kerr was long president, was due to him.

Mr. Kerr was one-time vice-president of the Westinghouse Machine Co., and at the time of his death was a director of the Electric Properties Co. Since 1890 he had been a trustee of Cornell University. He was a member of the American Society of Mechanical Engineers and of various other engineering societies and clubs. He is survived by a widow, one son and three daughters.

COMING EVENTS

May 31-June 3.—Spring meeting of the American Society of Mechanical Engineers, Atlantic City, N. J.

June 1-4.—Second annual state convention of Pennsylvania engineers, for the furtherance of the organization of the Engineers Society of Pennsylvania, Hall of Representatives, Harrisburg, Pa. Engineers Society of Pennsylvania, Gilbert Building, Harrisburg, Pa.

June 6-10.—Convention and exhibition of the Foundry and Manufacturers' Supply Association, Detroit, Mich. C. E. Hoyt, secretary, Lewis Institute, Chicago, Ill. Cadillac Hotel, Detroit, headquarters of the association convention week.

June 7-9.—Convention of the American Foundrymen's Association and American Brass Founders' Association, Detroit, Mich. Headquarters, Hotel Ponchartrain. Richard Moldenke, secretary, American Foundrymen's Association, Watchung, N. J. W. M. Corse, secretary, American Brass Founders' Association.

June 13-16.—National Gas and Gasoline Engine Trades Association convention at Cincinnati, Ohio, Hotel Sinton, headquarters. Albert Stritmatter, Cincinnati, Ohio, secretary.

June 15-17.—Annual convention Master Car Builders' Association, Atlantic City, N. J. J. W. Taylor, secretary, Old Colony Building, Chicago, Ill.

June 20-22.—Annual convention of the American Railway Master Mechanics' Association, Atlantic City, N. J. J. W. Taylor, secretary, Old Colony Building, Chicago, Ill.

June 20-July 6.—Detroit Industrial Exposition, Detroit, Mich., under the auspices of the Detroit Board of Commerce to accelerate the city's industry and commerce. The exposition grounds will be on the Detroit River where a large exposition building is being erected to be used in conjunction with the Wayne Pavilion. W. G. Rose, manager, Detroit Board of Commerce, Detroit, Mich.

July 26-29.—Joint meeting of the American Society of Mechanical Engineers and the British Institute of Mechanical Engineers in Birmingham and London, England.

August 16-19—Annual convention of Traveling Engineers' Association, Clifton Hotel, Niagara Falls, Canada. Subjects to be discussed are: "Fuel Economy," "Superheating," "Education of Firemen," "Development of Air Brake Equipment," "Locomotive Lubrication," and "New Valve Gears." W. A. Thompson, secretary, N. Y. C. Car Shops, East Buffalo, New York.

NEW BOOKS AND PAMPHLETS

Cost of Living to Railways. By Edward W. Harden. 8 pages, 6 x 9 inches. Reprinted from the *Outlook*, New York.

National Vitality; Its Wastes and Conservation. By Irving Fisher. Document No. 419 issued from the Government Printing Office, Washington, D. C.

Tests of Washed Grades of Illinois Coal. By C. S. McGovney. Bulletin No. 39. 146 pages, 6 x 9 inches. Published by the University of Illinois Engineering Experiment Station, Urbana, Ill.

The bulletin presents the results of an elaborate series of boiler tests made in connection with a 210-horsepower brick set water-tube boiler, equipped with chain grate stoker. A description of the method employed and the results of the tests are given in detail.

Study in Heat Transmission. By J. K. Clement and C. M. Garland. Bulletin No. 40. 17 pages, 6 x 9 inches. Published by the University of Illinois Engineering Experiment Station, Urbana, Ill.

The bulletin describes the method of studying the effect of agitation of a medium in contact with metal walls upon the heat conducted through these walls and to or from the medium. Experiments were made on a one-inch steel tube through which water flowed at different velocities. A record of the amount of heat transmitted was obtained from the weight of the water and rise in temperature while passing through the tube.

Ornamental Concrete Without Molds. By A. A. Houghton. 132 pages, 5 x 5½ inches. 30 illustrations. Published by Norman W. Henley & Son, 132 Nassau St., New York. Price \$2.

The process of making ornamental concrete without molds has long been held a secret, it is said. It is now given to the public in a practical treatise and is said to be the only work issued which explains simple and practical methods whereby concrete-workers are enabled, by using wooden and metal templets of different designs, to mold or model in concrete any cornice, archivolt, column, pedestal, base, cap, urn or pier in monolithic form. Full directions are given for making templets at very slight cost of time and labor.

Dynamo Building for Amateurs. By A. J. Weed. 83 pages, 5 x 7½ inches. 64 illustrations. Published by Norman W. Henley & Son, 132 Nassau St., New York. Price \$1 in cloth, and 50 cents in paper.

The book gives a general description of a 50-watt dynamo and describes its building in detail, telling of the tools and material required. Separate chapters are devoted to side-bearing rods, field punchings, bearings, commutator, pulley, brush holders, connection board, armature shaft, armature, armature winding, field winding, connections and starting. The book is one that should enable an amateur to proceed intelligently in the making of a working dynamo capable of lighting six 6-candle lamps. Various operations are made plain by halftone illustrations and drawings.

Self-Taught Mechanical Drawing and Elementary Machine Design. By F. L. Sylvester, with additions by Erik Oberg. 333 pages, 5 x 7½ inches. 218 illustrations. Published by Norman W. Henley & Son, 132 Nassau St., New York. Price \$2.

This comprehensive and well-prepared work has been published to meet the demand for an elementary treatise on mechanical drawing, including the first principles of machine design. The opening chapters are devoted to mechanical drawing pure and simple, taking up instruments and materials, definitions of terms used in geometrical and mechanical drawing, geometrical problems, projection, and working drawings. The following chapters are on algebraic formulas, elements of trigonometry, elements of mechanics, first principles of strength of materials, cams, sprocket wheels, general principles of gearing, calculating the dimensions of gears, cone pulleys, bolts, studs and screws, couplings and clutches, shafts, belts and pulleys, flywheels for presses, punches, etc., trains of mechanism and quick-return motions. The work should be well-suited to the class for which it is intended. The mathematics are simple and readily understandable. It can be specially recommended to those desirous of improving their mechanical education by home study.

Safeguards for the Prevention of Industrial Accidents. Edited by David Van Schaak. 174 pages, 6¾ x 9¾ inches. 168 illustrations. Published by the Aetna Life Insurance Co., Hartford, Conn. Price 50 cents.

The importance of promoting the movement for the prevention of industrial accidents has been fully realized by the great accident and liability insurance companies and a concerted movement is being made to induce manufacturers to supply guards for gears, belts, moving chains, elevators, set-screws, and other potentially dangerous things. Accidents may be attributed to the following principal causes: Ignorance, carelessness, unsuitable clothing, insufficient lighting, defects of machinery and structures, insufficient room, unclean conditions, and lack of good air. The work treats of these subjects and gives general suggestions for safeguarding all classes of machinery. A large number of illustrations are given, showing methods of guarding gears on slitting machines, rolling mills, slotting machines, gear cutters, lathes, wall-paper printing machines, tumbling barrels, pipe threading machines, boring mills, twisters, baling machines, looms, etc. Chapters are devoted to flywheels, driving belts, set-screws, sprocket wheels, rolls and knives, punch presses, stairways, platforms and runways, elevators, contracting, bake-shops, and miscellaneous. The concluding chapter is on rules and regulations, instructions, warning notices, etc. The book is one that every manufacturer, superintendent and shop foreman should read and study. If the suggestions contained therein were followed, most of the distressing industrial accidents would be avoided.

CATALOGUES AND CIRCULARS

Bristol Co., Waterbury, Conn. Bulletin No. 124 illustrating Bristol's atmospheric recording thermometer.

Terrell's Equipment Co., Grand Rapids, Mich. Folder illustrating steel wardrobes, steel lockers, and steel shelving and bins.

Peter Gerlach Co., Cleveland, Ohio. Catalogue of circular and cylinder saws, stave beading and barrel machinery, and saw and logging tools.

American Blower Co., Detroit, Mich. Catalogue of "Sirocco" electric fan and air purifier for insuring absolute ventilation in offices all the year round.

Northern Engineering Works, Detroit, Mich. Catalogue of the Newten cupola having a differential adjustable tuyere system and an all-steel air chamber.

Wiley & Russell Mfg. Co., Greenfield, Mass. Circular of "Green River" opening die bolt cutter, nut tapper, pipe threader and cutting-off machine No. 55.

Landis Machine Co., Waynesboro, Pa. Catalogue of bolt threading, pipe and nipple threading, bolt pointing and nut tapping machinery, and special threading machines.

Crocker-Wheeler Co., Ampere, N. J. Bulletin No. 124 superseding No. 112 on exhaust fans. The motors of these fans are built for durability and are practically "fool-proof."

Dodge Mfg. Co., Mishawaka, Ind. Pamphlets entitled "Friction Clutches," "Safe Construction and Speeds for Flywheels," "From Log to Lineshaft," and "Dividends and Drives."

T. R. Almond Mfg. Co., Ashburnham, Mass. Circular of Almond three-jaw geared drill chuck made in two sizes having capacities from 0 to 5/16 inch and 0 to ½ inch respectively.

Crocker-Wheeler Co., Ampere, N. J. Bulletin No. 119 superseding No. 107 on direct-current lighting and power generators; also Bulletin No. 121 on small engine type direct-current generators.

Joyce-Cridland Co., Dayton, Ohio. Catalogue of lifting jacks, including hydraulic jacks, lever jacks, automatic jacks, geared automatic jacks, screw jacks, traversing jacks, journal jacks, navy jacks, etc.

Bickford & Washburn Inc., Greenfield, Mass. Catalogue of thread milling machines, index centers for fluting taps and reamers, open die for threading small taps, solid adjustable die and upright threader.

Pawling & Harnischfeger Co., Milwaukee, Wis. Folder illustrating line of horizontal drilling and boring machines, recommended for drilling all classes of work. The drill capacities range from ⅜ inch up to 3 inches.

Lucas Machine Tool Co., E. 99th St., and L. S. & M. S. Ry., Cleveland, Ohio. Circular No. E-2 of No. 21 precision boring, drilling and milling machines, illustrating the cone drive, and constant-speed drive and gear box types.

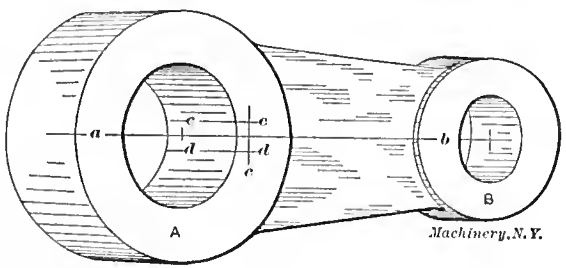
National-Acme Mfg. Co., Cleveland, Ohio. Leaflet illustrating a piece formed complete on the Acme multiple-spindle automatic screw machine on which circular forming, taper forming, drilling and facing operations are performed.

Supplement to MACHINERY, July, 1910

Operations for the Article in this number entitled "Machine Shop Practice—Chipping"

SHOP OPERATION SHEET NO. 139

Oscar E. Perrigo MACHINERY, July, 1910



Laying Out the Keyway in a Crank Hub

NOTE.—It is assumed that the crank shown in the illustration is to have a keyway cut through the bore and that there is no suitable machine available for doing the work, which makes it necessary to cut the keyway by hand. It is first necessary to lay out the keyway in its correct position with relation to the bore.

1. Rub moistened sulphate of copper ("blue stone"), in the bore and at the ends where the keyway is to be laid out, so that the scribed lines will show more distinctly.

2. With a straightedge and scriber, draw a centerline *a—b*, passing through the centers of the shaft bore and crankpin bore. The straightedge may be set central at each end by adjusting it until the distance from its edge to the sides of the two holes, as measured by a scale, is equal to the radius of each respective hole. If the faces *A* and *B* are not in the same plane, the work may be laid on a surface-plate in the position illustrated and a surface gage used to advantage for scribing a center line, after the centers of both holes have been set to the same height from the plate.

3. With the dividers set to one-half the required width of the keyway, set off each side of centerline *a—b*, the location of the side lines, *c* and *d* and scribe these lines parallel with the centerline. If a surface gage has been used for drawing the centerline, it can also be employed for laying off the side lines c and *d*.

4. With the dividers set as explained in Step 3, mark the depth of the keyway on the lines c and *d*, and scribe the depth line *e*.

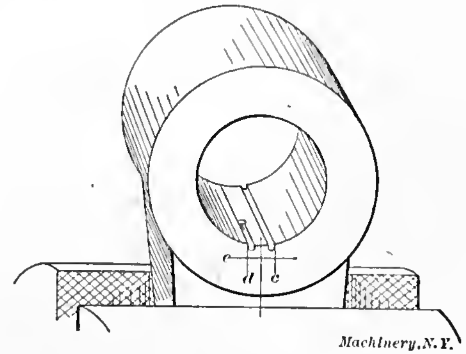
5. Pass the blade of a square through the bore, and holding the stock firmly against the face of the crank, scribe the center and side lines through the bore.

6. As the keyway is to be chipped half way through from each side of the hub, repeat the laying out operation on the opposite side, locating side and depth lines as before. If the key is to be tapered on top, allowance should be made for this when locating the depth lines.

NOTE.—The keyway is here placed in its usual position. If a certain location is prescribed, it will be laid out, of course, with the given point as its center. In the case of a wheel or pulley, it is customary to locate it opposite one of the arms. The keyway is usually located adjacent to the strongest part of the piece.

SHOP OPERATION SHEET NO. 140

Oscar E. Perrigo MACHINERY, July, 1910



Chipping the Keyway in a Crank Hub

NOTE.—The keyway is supposed to have been laid out as described in the previous sheet, its width being indicated by lines through the bore, and its width and depth shown by lines on both faces. On this sheet, the operation of finishing the keyway by chipping and filing will be described.

1. If the keyway is comparatively large as to width and depth, begin by taking a light cut just inside one of the side lines. Use a round-nosed cape chisel, or what is sometimes known as a grooving chisel, and carry the cut back steadily to about the center of the work. Take a similar cut on the opposite side of the keyway, and then with a straight-point cape chisel, continue to take light cuts in each groove until they are nearly down to the depth line. By using a grooving chisel, as described, for cutting the first grooves, the cast iron does not tend to break over the line as it would be likely to do if a straight point were used.

2. With a wider chisel, cut out the central rib between the two channels, taking as many cuts as are necessary to cut down nearly to the depth line. To prevent chipping below the line when in from the face, measure the depth of the keyway at the sides with a small scale.

3. From the opposite face of the crank, repeat the cuts described in Steps 1 and 2, meeting the cuts taken from the first side.

NOTE.—The method of procedure when chipping a keyway, depends somewhat upon its size. A small keyway, for example, would be cut by chipping a single groove with a chisel having a width slightly less than that of the keyway.

4. With a square, coarse cut file, straighten the keyway by filing it on each side, closely to the side lines and down to the depth line.

5. Finish the sides of the keyway with a flat second cut file, so that the key to be used will crowd tightly to the bottom at all points in its entire length. Also file the bottom side straight.

NOTE.—The following requirements should be borne in mind when finishing a keyway in a hub: The sides should be parallel with each other and also with a radial line passing through the center of the keyway; the keyway should be parallel with the axis of the bore, and the correct width, depth, and taper when taper is given.

SHOP OPERATION SHEET NO. 141

Oscar E. Perrigo MACHINERY, July, 1910

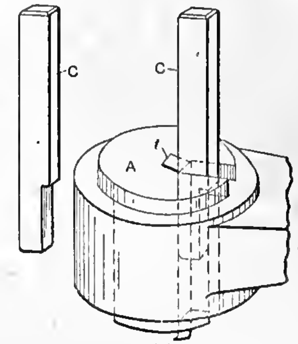


Fig. 1

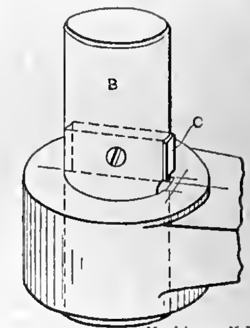

Fig. 2

Broaching the Keyway in a Crank Hub

NOTE.—Two methods of cutting a keyway in a hub by hand will be given in the following, either of which is quicker than the one described in the previous sheet; their use, however, necessitates special tools which are not always available. By the first method, illustrated in Fig. 1, a mandrel *A* is used which fits closely the bore of the hub and which is splined to receive a cutter *C* that is driven through the hub and fed out for each successive cut by placing thin strips of metal back of it. By the second method, illustrated in Fig. 2, a closely fitting mandrel *B* is also used, but the cutter *C*, in this case, is attached to the mandrel and the two are driven through the bore together.

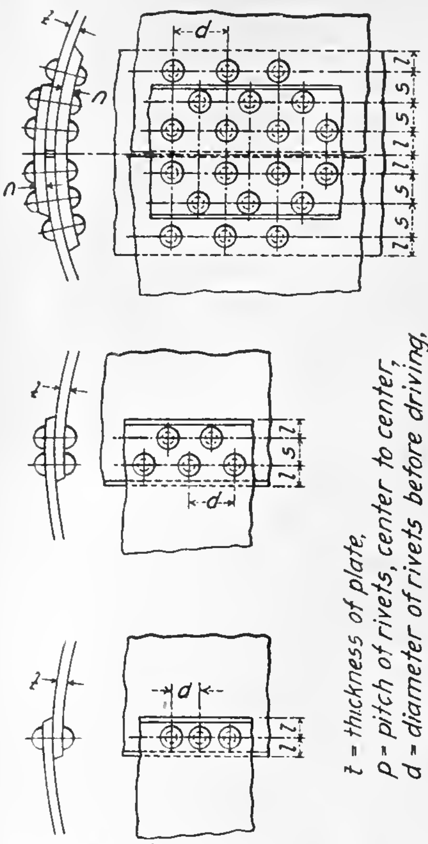
1. Lay out the keyway as described on Sheet No. 139, omitting the lines through the bore and also those on one side.

2. Select a guiding mandrel *A* (Fig. 1) and cutter *C* of the required size, and insert the mandrel in the bore of the hub. Support the work on blocks so that there is plenty of clearance beneath it for the cutter *C* and drive the latter through the bore. Before taking the first cut, care should be taken to turn the mandrel so that the cutter coincides with the lines indicating the position of the keyway.

3. After removing the cutter from below, insert a strip *t* of tin or other thin material, having a length somewhat greater than that of the mandrel, in the spline and again drive the cutter through. It will be seen that by repeating this operation of adding additional liners each time the cutter is driven through, that the latter will gradually be fed to the required depth. After a number of thin liners have been used, it is well to replace them by a thicker one which will be more rigid.

4. By the second method, a closely-fitting mandrel *B* is also essential, and the work must be blocked up so that the mandrel may be removed at the bottom. Set the cutter *C* to take a light cut, turn the mandrel to the correct position and with a soft hammer drive it through the hub. A screw or hydraulic press may also be used for this work if one is available. Return the mandrel to its original position and again drive it through the work after the cutter has been set out for a second cut. Repeat this operation until the depth line is reached.

STANDARD PROPORTIONS OF RIVETED JOINTS FOR PRESSURE TANKS—I



t = thickness of plate,
p = pitch of rivets, center to center,
d = diameter of rivets before driving,
D = diameter of hole,
s = distance between lines of rivets,
l = distance from edge of plate to first line of rivets,
u = thickness of strap,
E = efficiency of joint in per cent.

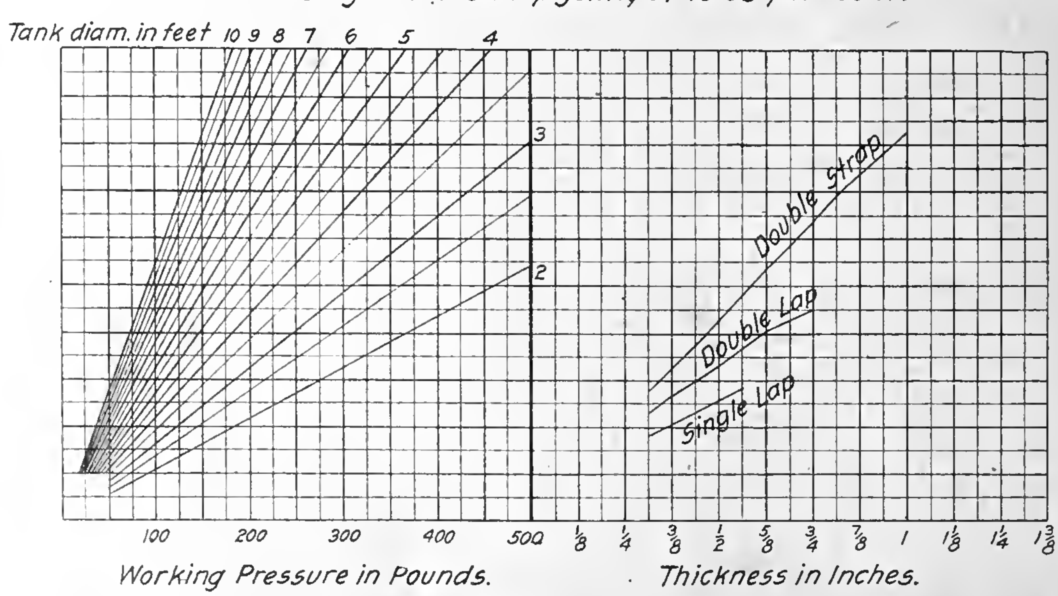
PLATE THICKNESS FOR PRESSURE TANKS II

$$\text{Thickness in inches} = \frac{(\text{factor of safety, 5}) \times 100 \times \text{working pressure in pounds} \times \text{diam. in inches}}{2 \times (\text{breaking stress, 55000}) \times \text{efficiency in per cent}}$$

$$= \frac{0.004545 \times \text{working pressure in pounds} \times \text{diam. in inches}}{E}$$

Efficiency E = for double strap, triple riveted butt joint, 83 to 85 per cent,
for double riveted lap joint, 60 to 74 per cent,
for single riveted lap joint, 51 to 59 per cent.



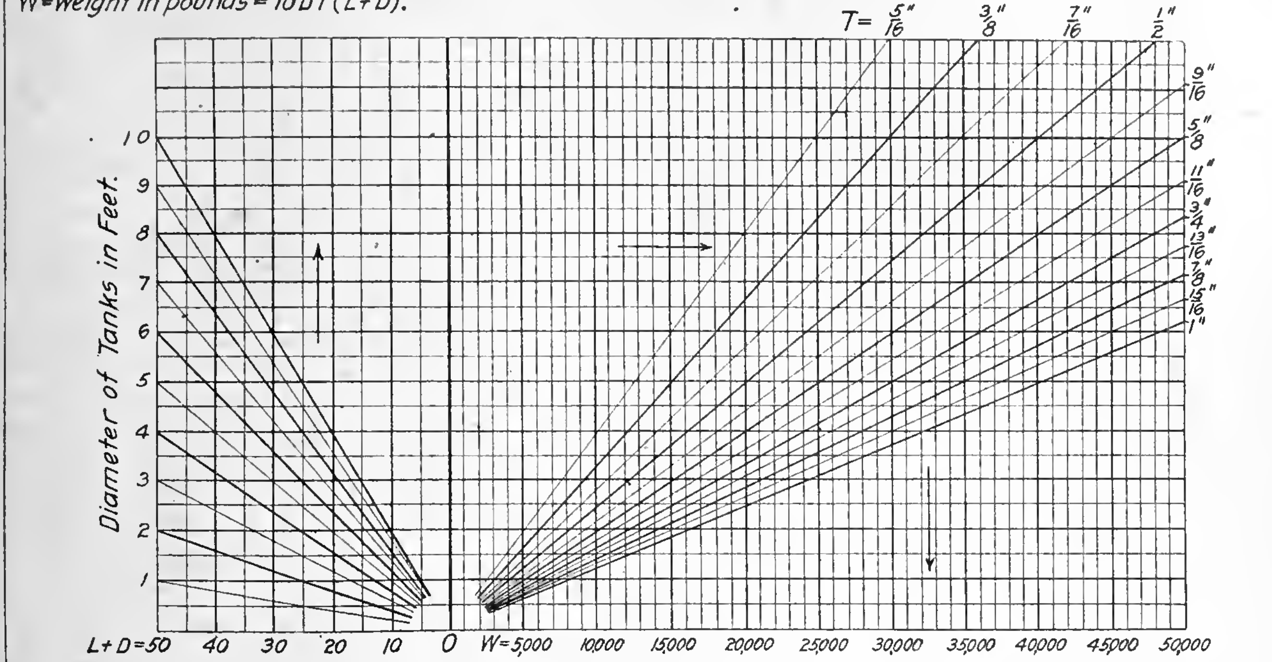
Contributed by C. R. Whittier

WEIGHTS OF CYLINDRICAL PRESSURE TANKS—III

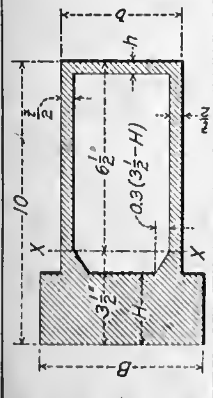
Average shipping weights of cylindrical pressure and discharge tanks with dished heads $\frac{1}{16}$ inch thicker than shell, and with manholes, nozzles and inside pipes, compiled from actual tanks.

L = length in feet,
D = diameter in feet,
T = thickness in 16ths of an inch,
P = pressure per square inch,
W = weight in pounds = $10DT(L+D)$.

For double strap, triple riveted long. seams, $T = 0.01DP$ (min. $= \frac{5}{16}$) $W = P\left(\frac{G}{60} + 0.1D^3\right)$,
For lap joint double riveted long. seams, $T = 0.013DP$ (min. $= \frac{5}{16}$) $W = P\left(\frac{G}{46} + 0.13D^3\right)$,
For lap joint single riveted long. seams, $T = 0.016DP$ (min $= \frac{5}{16}$) $W = P\left(\frac{G}{37} + 0.16D^3\right)$,
G = capacity in gallons $= 6LD^2$



PROPERTIES OF SECTIONS FOR PUNCH AND SHEAR FRAMES—IV



S_c = Section Modulus for Compression,
S_t = Section Modulus for Tension,

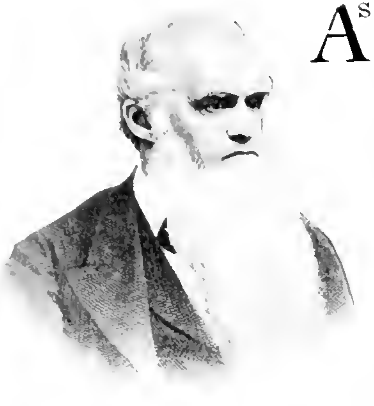
MACHINERY

July, 1910

HISTORY OF THE INVENTION OF THE UNIVERSAL GRINDING MACHINE

By LUTHER D. BURLINGAME

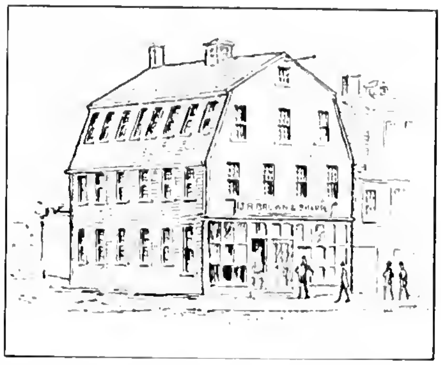


Joseph R. Brown, born January 16, 1810, died July 23, 1876

As far as the writer knows the early history of the universal grinding machine has never been recorded in print. This machine is one which has had such an influence on modern machine methods and has done so much to raise the standard of workmanship and to increase economy of production that it is believed that its history should be recorded while the records still exist and while the memory of living men can be drawn upon for the facts necessary to complete it.

In investigating this matter it has been interesting to trace the progress from the crude grinding lathe of the early 60's, step by step, to a complete universal machine, a progress with which Mr. Joseph R. Brown, senior member of the firm then doing business under the name of J. R. Brown & Sharpe, was intimately connected in all its steps.

The grinding machine as first built at the Brown & Sharpe works was for the accurate and economical manufacture of their own products without thought of putting the machines on the market. In this respect, its origin and development were very much like the origin and development of the universal milling machine and other machine tools which have originated in the works of this company. The first work for which the grinding machines were designed was for grinding needle bars, foot bars, and shafts of the Wilcox and Gibbs sewing machine. This was done by mounting an emery wheel on the carriage of a lathe and traversing it back and forth past the work.



Old Shop in South Main St., Providence, R. I., where the Universal Grinding Machine was invented and first built

In 1864 and 1865 drawings were made and machines built using parts of a 14-inch Putnam lathe, mounting a wheel stand as above mentioned and adding a feeding mechanism including a reverse. One of these early machines is still in use in the Brown & Sharpe works, although the feed mechanism and footstock have been removed. It is now used for grinding the faces of dies. This machine in its present form is shown in Fig. 1. It bears an old brass plate stamped "Grinding Machine by J. R. Brown & Sharpe." The construction of the wheel stand and feed mechanism of this machine is shown in Fig. 2 and Fig. 6 reproduced from the original drawings.

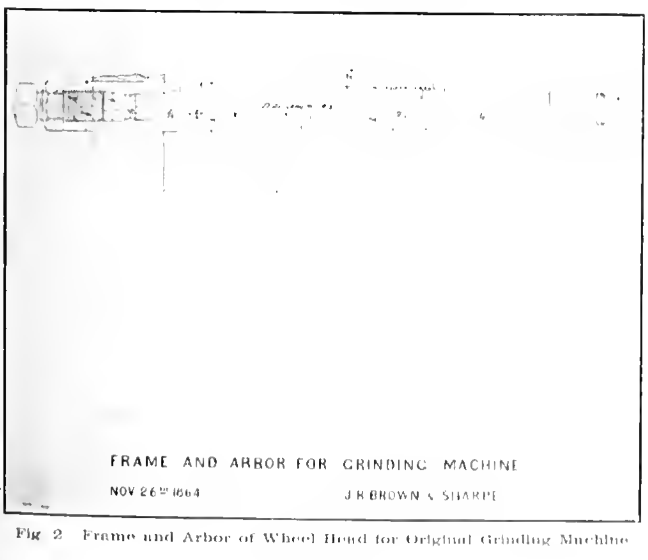

Fig. 2 Frame and Arbor of Wheel Head for Original Grinding Machine

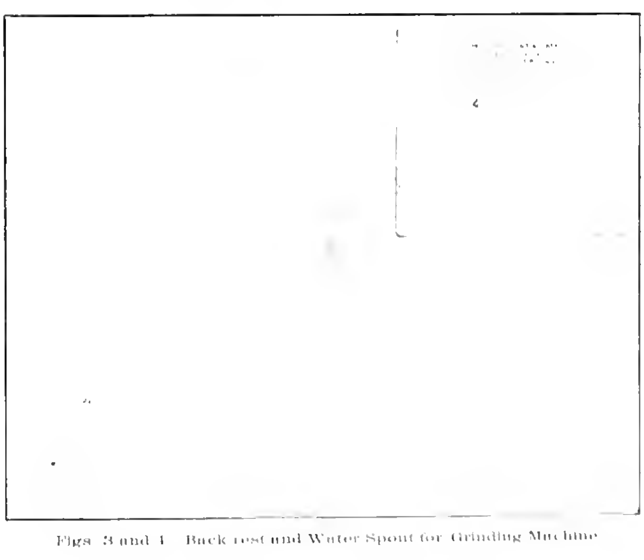

Figs. 3 and 4 Back rest and Water Spout for Grinding Machine

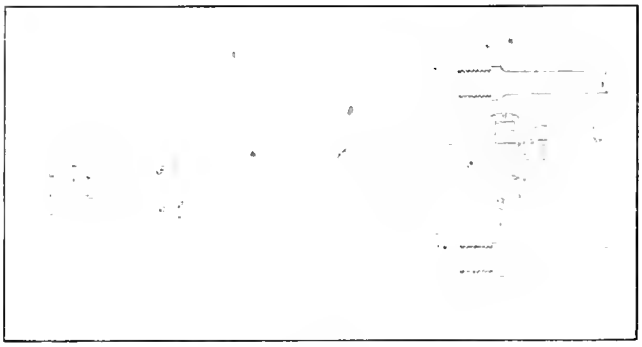

Fig 5. Dead Center Pulley for Grinding Machine

That cylindrical grinding was done in the Brown & Sharpe works at an earlier date than that of these drawings is indicated by the drawing of a back-rest dated September 22, 1862, which contains the essential features of a solid back-rest of to-day. This is shown in Fig. 3. A spring back-rest was also used for finishing and was applied by having a spring rod extending from the footstock, this rod carrying leather washers which pressed against the work. Skill in adjusting this back-rest was required to prevent chattering. A dead center pulley, an important step in the development of the grinding art, is shown in Fig. 5, reproduced from a drawing made in 1864. Wet grinding was done on these early machines by using a wet sponge held by hand against the work. The sparks were quenched in a dish of water placed below the work. Later a supply of water was provided through a nozzle shown in a drawing dated December 22, 1866, Fig. 4.

During the next few years about thirty of these machines were built and sold, the same plan being followed of using Putnam lathes, partly dismantled. These were bought ready to apply the parts which were built and applied at the Brown & Sharpe works. The first machine was sold to the Leavitt Sewing Machine Co. of Boston, Mass., in July, 1865; the second one was sold to Charles Callefaut, Paris, France, and included apparatus for grinding bevel cutters. Several of these machines were in constant use in the shops of J. R. Brown & Sharpe on the sewing machine parts, but work kept piling up ahead of them and could not be hurried as a considerable amount of time and a high degree of skill were required to produce work of a sufficiently high standard on such machines. There were also many kinds of work where finishing by grinding would be an advantage, but which could not be done on this machine. During these years Mr. Brown had constantly in mind the need of building a machine designed from the floor up especially for grinding, and he considered the matter to such good purpose, that in 1868 he had a drawing made of such a machine. This drawing shows a machine containing most of the essential elements of the universal grinding machine of to-day. Un-

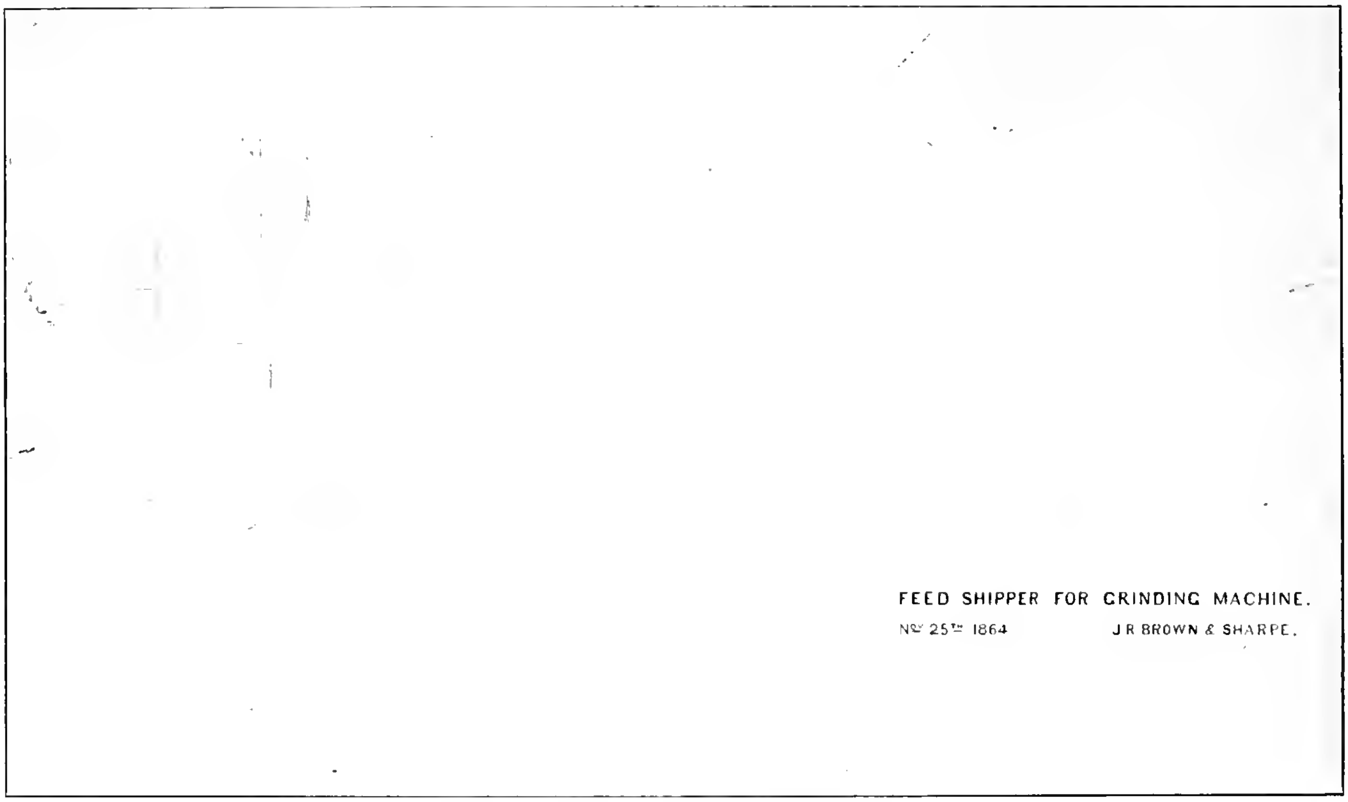

Fig 6 Feed Shipper for Original Grinding Machine

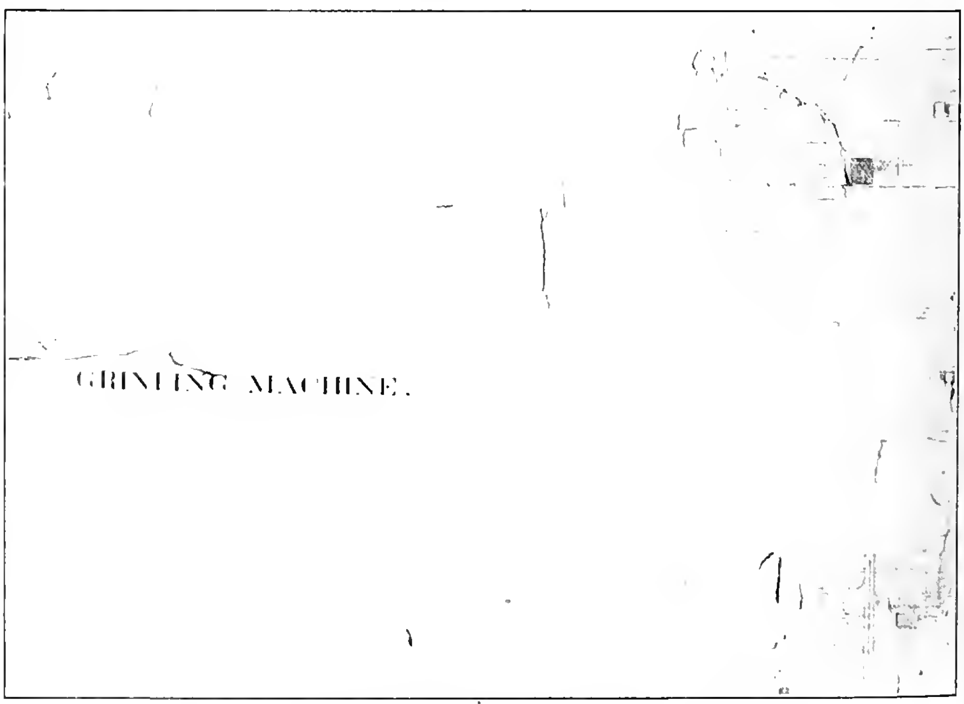

Fig 7 Part of Mutilated Drawing of Grinding Machine made in 1868

fortunately it is made with the fine lines which, in those days, were considered the marks of an expert draftsman, and the drawing is also much the worse for wear. Its historic interest is such, however, that parts of it are here shown in Figs. 7 and 8. This machine has the same wheel stand as that of the earlier grinding lathe shown in Fig. 2, but instead of having the wheel travel, there is a sliding table carrying a swivel table on which are mounted the headstock and footstock, the headstock also being arranged to swivel. This drawing did not, however, show a machine having a swivel wheel stand.

As far as known, none of these machines were built at this time on account of pressure of other matters, but in 1874 working drawings were made for a machine which included a swiveling wheel stand as well as other features of improved construction. One of the drawings of this machine is shown in Fig. 10. This drawing shows stops on the cross-feed handwheel, a feature which had been previously used on the earlier grinding lathe, but of which no record could be found. The machine shown in Fig. 10 also indicates some attempt at providing for carrying off the water used in grinding. An interesting feature of the wheel spindle of this machine shown in Fig. 11 is that its bearings and boxes being of hardened steel and having double tapers would seem to require the use of a universal grinding machine to produce them. It would be an interesting bit of history to know just how the first ones were produced. It is hard for us in these days to appreciate just what our ancestors had to contend with in obtaining results without the machines and tools which we consider essential to-day. One of the machines of this design was sold to E. Cornely, Paris, France, on January 3, 1876. This, however, was not the first machine built, the first machine being reserved to be exhibited at the Centennial Exposition in 1876. It was sold at the close of the exposition to M. M. Heilman-Ducommun & Steinlen, Mulhouse, Alsace, Germany. The first machine sold in America was to the Whitehill Mfg. Co., of New York City, the following year.

The judges at the Centennial Exposition, in commenting on the Brown & Sharpe exhibit, after speaking of the machines in general which they said "are characterized by great neatness of design and excellence of execution," continued: "Their universal grinder is an exceedingly substantial and well studied machine whose working details are exceptionally well managed for facilitating the work it is to perform."

In a history of the Centennial Exposition by Thomas Bentley, published in 1876, is shown a cut of this first universal grinding machine, which is here reproduced in Fig. 12. The comments of the author may be of interest as showing an appreciation of the trend of the times and as something of a prophecy. He says of the Brown & Sharpe exhibit:

"The superior class of tools here represented are of a character fitted to elevate the standard of workmanship in connection with machine shop manipulation. Accurate tools like these produce accurate and interchangeable work, cheapening production and at the same time giving that perfection which is becoming more and more indispensable in the sharp competition attending the manufacture of machinery. The machines themselves illustrate this in their fine workmanship and finish, and in the nice adaptability of their motion and parts to produce the required work."

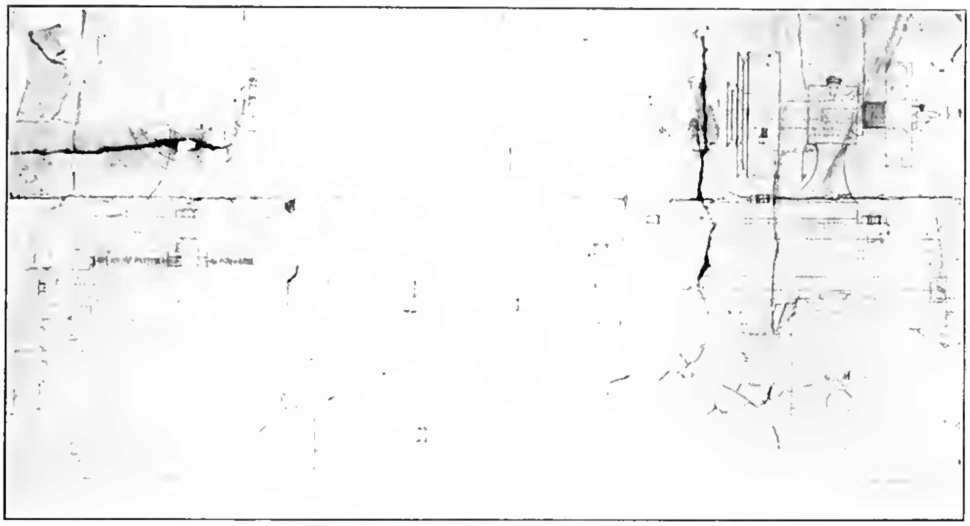

Fig. 8 Another Part of Mutilated Drawing of Grinding Machine made in 1863

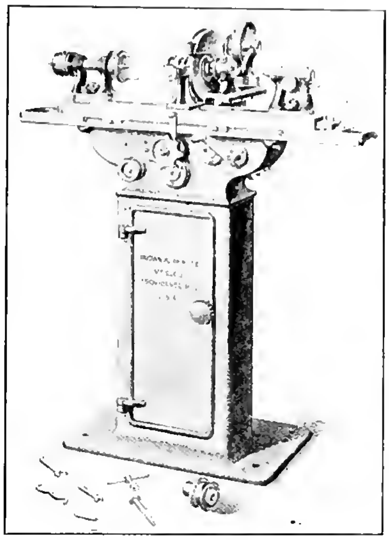

Fig. 9 "The Baby Grinder"

On the death of Mr. Brown in 1876, application was made by his executors for a patent on the universal grinding machine, and it was issued on February 27, 1877. Figs. 1, 3 and 4 of this patent are here reproduced as Figs. 13 and 14, and give a fair idea of the mechanism of the machine as it existed at that date. It will be noticed that these patent office drawings show a machine for form grinding, in addition to the ordinary features of a universal machine. A smaller machine was designed a few years later, which is shown in Fig. 9. This was known for many years in the shop as the "Baby Grinder," a name which still persists among older employes.

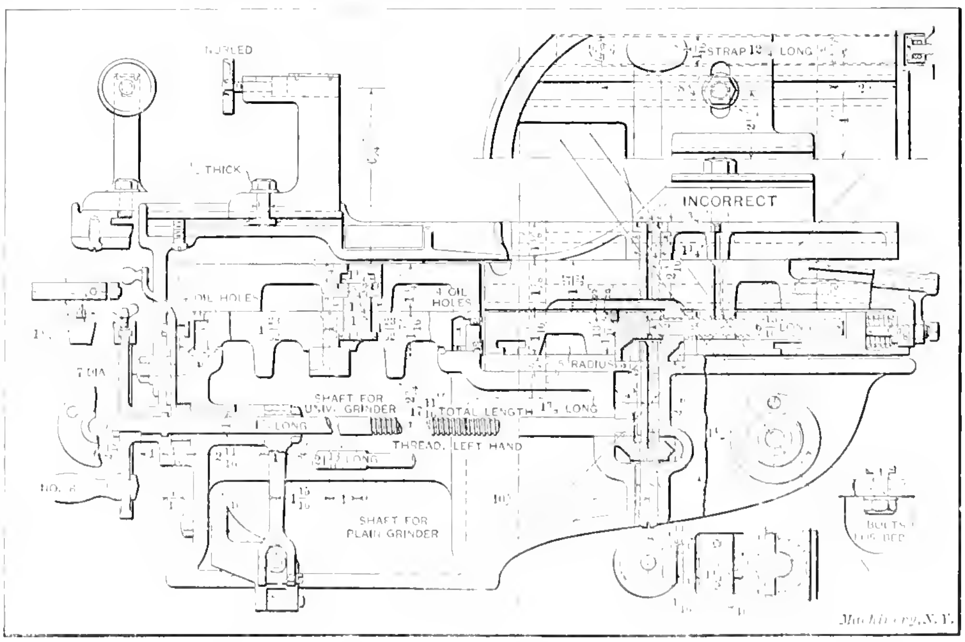

Fig. 10 Part of Drawing made in 1874 of Grinding Machine with Swiveling Wheel Stand

While the development of the grinder art since the Centennial Exposition has brought out many improvements and refinements, the essential principles of the universal grinding machine are found in the machines here described, and are as Mr. Brown left them at the time of his death in 1876.

MACHINE SHOP FLOORS

The question of what kind of floor to put into a new machine shop has become a rather vexing one of late, because the rising cost of lumber has made the wood floor an expensive matter, while the granolithic and other artificial surfaces that have come into use have often proved disappointing in wearing

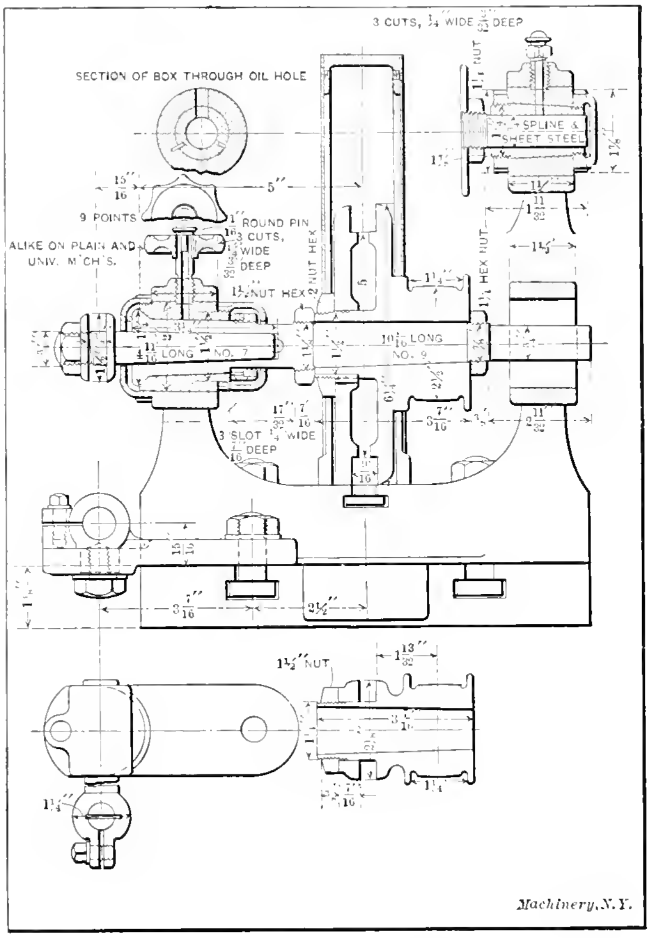

Fig. 11. Details of Wheel Stand of Grinding Machine designed in 1874

qualities, although at the same time they are cheaper than the wood floor. This whole question is thoroughly discussed in a pamphlet called "Wearing Surfaces for Factory Floors," in which the Abertbaw Construction Co., of Boston, reports the results of its investigation into the experience with different

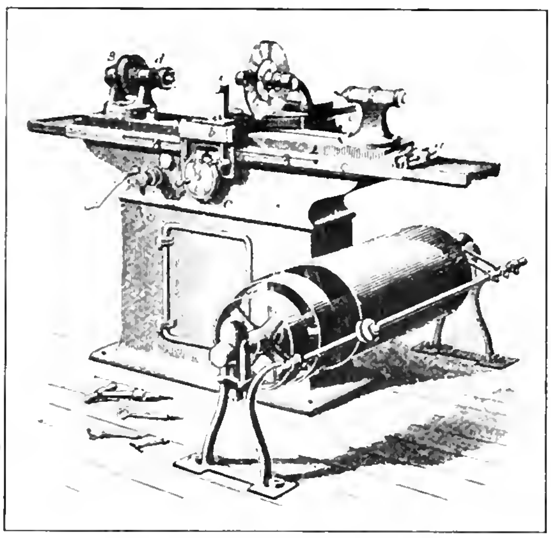

Fig 12 The First Universal Grinding Machine, exhibited at the Centennial Exposition in 1876

floor surfaces of a large number of machine shops and factories.

Discussing the general principles of cost and construction of the two types of floor surface in fireproof buildings, the Aberthaw Co. says that the granolithic finish has the advantage in the points of first cost of the surface itself and in cost of the whole structure. It points out that the wood floor laid on

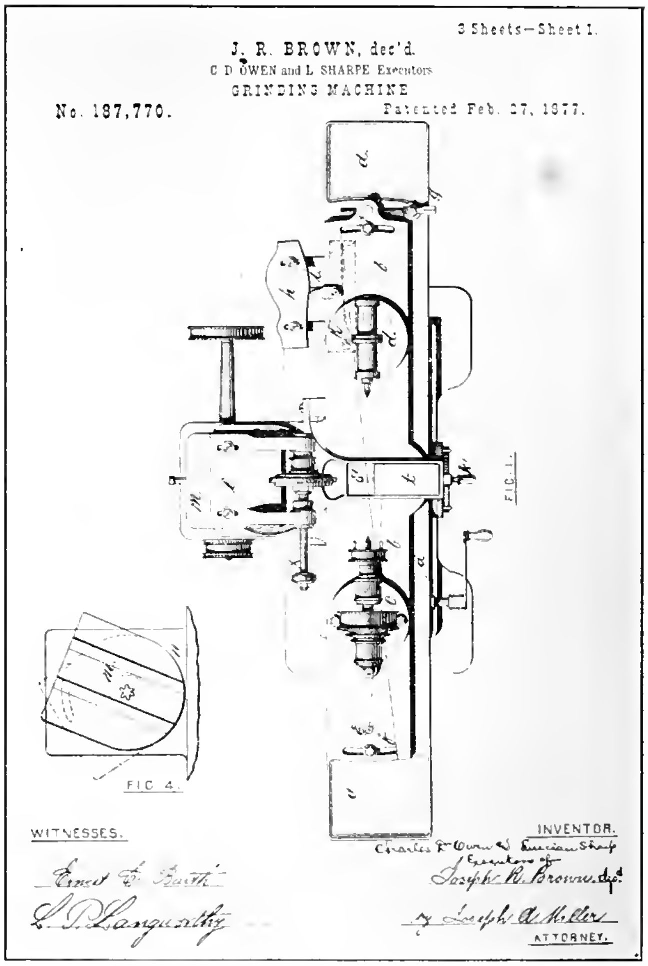

Fig 13. Patent No. 187,770 granted to Estate of J. R. Brown for the Universal Grinding Machine

concrete floor slabs is a dead weight on the supporting structure, and necessitates an increase in thickness of floor slabs,

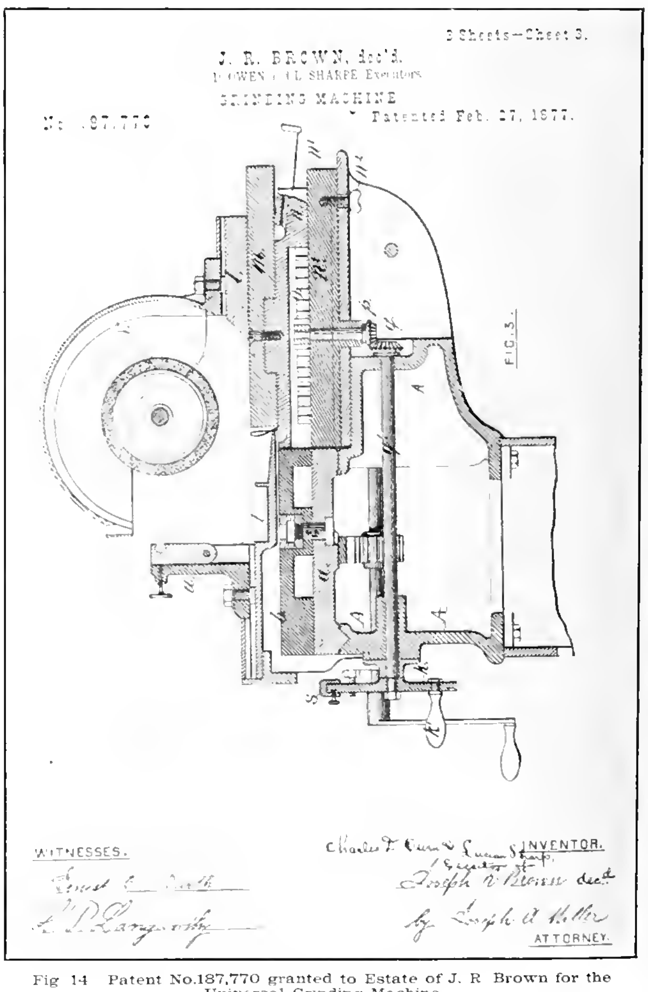

Fig 14 Patent No.187,770 granted to Estate of J. R Brown for the Universal Grinding Machine

size and number of reinforcing members, and also of supporting pillars. In contrast, the granolithic finish, if it is laid as it should be before the concrete of the floor slab has become dry, forms an integral part of the floor slab and takes part of the compression strains. In other words, the granolithic finish laid on the green floor slab is not a dead weight like the wood floor, but is an actual strengthening of the floor slab. This means thinner slabs, lighter supports, and a general lower cost per cubic foot for the whole building.

In making its investigation the company put two questions to a large number of factories of various sorts; machine shops, engineers and architects in the northern and eastern part of the country, these questions being the following:

1. From your experience, do you believe that a granolithic or other masonry surface is actually bad for the operatives, and if so, why?

2. What objections do you know to granolithic finish that would make it advisable to incur greater expense for some other wearing surfaces?

Machine shops returned 68 per cent of the whole number of 118 replies. Of these machine shops, 27 per cent had had no experience with granolithic floors; 25 per cent recommended granolithic floors both in regard to the health of operatives and to the wearing qualities of the surface; 48 per cent offered more or less unfavorable criticism as to the wearing qualities or the effects on operatives from a granolithic surface.

The first question is disposed of in this report by the frank admission that where operatives have to stand still in one place on granolithic floor, they are likely to suffer somewhat from soreness of the feet and lameness of the legs, owing to the fact that concrete is a good conductor of heat and therefore chills the legs of operatives who stand still upon it. The two remedies suggested for this condition are: First, movable gratings of wood or other non-conducting material for workmen who have to stand still, as at a bench or lathe; second, the heating of concrete floors by running through the floor slab hot air ducts or steam pipes so that the floor slab shall be a radiating surface for the warming of the whole building. This system has been tried out with remarkable success in the plant of the Morse Chain Co., at Ithaca, N. Y.

In regard to the wearing qualities of granolithic floors, the company declares that the granolithic surface, if laid according to correct principles and with thoroughgoing, careful workmanship, will be free from dust and will give more and better service for general factory purposes than any other wearing surface. A set of specifications showing its own practice gives the details of what it considers correct theory and good workmanship. The granolithic surface, improperly constructed, the report says, is certain to fail—to be dusty, to crack abundantly, to chip under blows, and to wear away under trucking. A good deal of emphasis is put on the matter of wear by trucking. No masonry surface can long withstand the wear of heavy trucking when trucks are fitted with flat, sharp-edged, iron wheels. For such service a special design of steel plate embedded in the soft concrete, or the use of embedded racks made of small flat bars separated by thick washers and bolted together, are recommended.

The report is not, however, a partisan tract which attempts to give all credit to granolithic surface and none to others. On the contrary, it explicitly states that under many conditions the wood top floor is preferable to granolithic finish. One situation of this sort is that in which the conditions required for the construction of a perfect granolithic surface, cannot be obtained. If the granolithic surface cannot be made properly, it will be unsatisfactory, and it is better to lay a wood floor than to lay a defective granolithic surface. Some special manufacturing conditions also make the wood surface preferable even at higher cost, as for instance, when the manufactured product is very delicate and would be injured or destroyed if dropped upon a masonry surface. Several specifications are given in the report showing the practice of certain prominent engineers in the laying of wood top floors on cement base and on a tar concrete base.

Don't forget, when working around punch presses, that you need all your fingers, and that they will never grow out again; neither are there any more in stock.

THE DESIGN OF FLAT SPIRAL SPRINGS*

By L. J. BUTZOW†

The calculation and design of helical and elliptic springs has recently been treated in MACHINERY; but little has been published on the design of flat spiral springs. The following is an exposition of the principles entering into the calculation of this class of springs, and the most important equations have been deduced so that the reader who has little time for mathematics can obtain an idea of the subject and the use of these equations merely by studying the sample calculation given in the latter part of the article. The discussion on the energy of flat springs is applicable in particular to large springs which dissipate an appreciable portion of the stored energy through friction between consecutive convolutions.

In the following, let

r = radius of case, Fig. 1,
h = radius of hub, Fig. 1,
a = inside radius of unwound spring, Fig. 2,
b = outside radius of wound spring, Fig. 3,
t = thickness,
L = length,
T_u = number of turns in the unwound spring,
T_w = number of turns in the wound spring,
T = number of turns to wind spring,

The number of turns to wind the spring is equal to the difference between the number of turns in the wound spring and the number of turns in the unwound spring.

$$T = T_w - T_u \tag{1}$$

From the figures it is seen that

$$T_w = \frac{b-h}{t} \quad \text{and} \quad T_u = \frac{r-a}{t}$$

Substituting, we have

$$T = \frac{b-h-(r-a)}{t} \tag{2}$$

From the figures it is also seen that

$$\pi r^2 = \pi a^2 + Lt, \text{ or } a = \sqrt{r^2 - \frac{Lt}{\pi}}$$

Also

$$\pi b^2 = \pi h^2 + Lt, \text{ or } b = \sqrt{h^2 + \frac{Lt}{\pi}}$$

Substituting for a and b in equation (2), we have,

$$T = \frac{1}{t}\left(\sqrt{r^2 - \frac{Lt}{\pi}} + \sqrt{h^2 + \frac{Lt}{\pi}} - r - h\right) \tag{3}$$

which gives the number of turns which may be obtained from a spring of given thickness t and length L when placed in a case of radius r and wound on a hub of radius h.

The principal interest in equation (3) relates to the conditions which will give the maximum number of turns. By means of calculus we can find that T becomes a maximum when

$$\sqrt{r^2 - \frac{Lt}{\pi}} = \sqrt{h^2 + \frac{Lt}{\pi}} \tag{4}$$

This equation, however, is simply $a = b$, and hence, the number of turns is greatest when the inside radius of the unwound spring is equal to the outside radius of the wound spring. The spring, in other words, should fill just half of the area provided.

Solving equation (4) for L, we have,

$$L = \frac{1}{2} \times \frac{\pi}{t}(r^2 - h^2) \tag{5}$$

which gives the relation for best proportions.

Substituting for L in equation (3)

* For additional information relating to the design and calculation of springs, see MACHINERY, January, 1910, engineering edition: "The Design of Automobile Springs," and the articles there referred to. See also MACHINERY'S Reference Series No. 58, "Helical and Elliptic Springs."

† Address: 5758 Lowe Ave., Chicago, Ill.

$$T = \frac{1}{t}\left(\sqrt{r^2 - \frac{1}{2}(r^2 - h^2)} + \sqrt{h^2 + \frac{1}{2}(r^2 - h^2)} - (r + h)\right)$$

$$T = \frac{1}{t}\left(\sqrt{2(r^2 + h^2)} - (r + h)\right) \qquad (6)$$

which gives the maximum number of turns available with a given case, hub, and thickness of spring.

The above formula, when correctly applied, gives reasonably accurate results. In the calculations, the thickness of the spring should be assumed to be a little greater than the micrometer measurement, to allow for the small spaces existing between adjacent coils. The radius h should be taken large enough not only for the hub, but also for the spring fastening. The radius r must be taken a little smaller than the radius of the case to make up for the connection of the spring at its outside end.

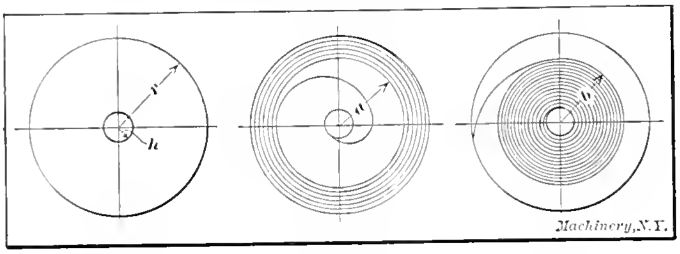

Fig. 1 Fig. 2 Fig. 3

Relation between Torque and Number of Turns

The next step is to obtain the relation between torque and number of turns. A number of springs have been tested by measuring the torque developed at each turn of the hub throughout the process of winding and unwinding the spring. These data were then plotted and a smooth curve drawn through the points. A sample curve is shown in Fig. 4.

Logarithms of the abscissas and ordinates of a number of points were taken from the descending (lower) part of each curve, and plotted out as shown in Fig. 5. Straight lines were then drawn through the points. The inclination or angle of these lines is such that the tangent of the angle with the horizontal base line is 2/3. If this is assumed to be correct, the torque, while unwinding, may be expressed by the product of a constant times the 2/3 power of the number of turns. The lines would probably agree more closely with the points if drawn at a somewhat smaller angle, but the lines as drawn provide for a simple mathematical expression and serve the purpose very well. A greater torque is required when winding the spring, due to the friction. When rapidly unwinding, a spring will not produce as great a torque as indicated by the diagrams, which merely show the torque that might be expected from the spring if it were stopped at any point while unwinding; but the diagrams and the equations in the following are of value for making comparisons.

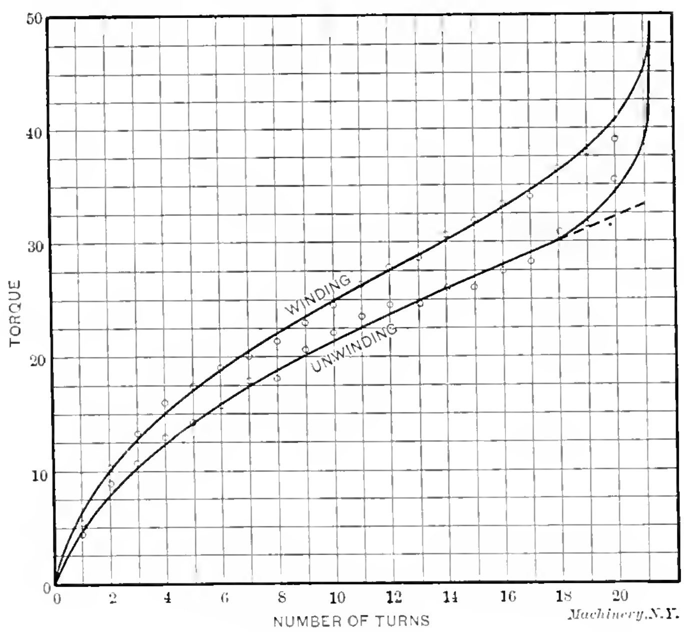

Fig. 4 Diagram showing Plotted Relation of Torque to Number of Turns in a Given Spring

The constant required depends upon the dimensions of the spring and the material and method of treatment. The effect of varying the thickness of the spring is to vary the torque at any given position by approximately the cube of the thickness, and to reduce the number of turns as shown by the formula already given. Varying the diameter of the hub and the length of the spring with small hubs and long springs principally affects the available number of turns. The relation between turns and length for a given hub and case is shown in Fig. 6.

In Merriman's "Mechanics of Materials" the following formula may be found:

$$\frac{S}{C} = \frac{E}{R}$$

where S = maximum fiber stress,
C = distance from neutral axis to remotest fibers,
R = radius of curvature,
E = coefficient of elasticity.

Then, for a spring tempered flat, it is evident that the part next to the hub will be subjected to the greatest stress. The radius of curvature at any given point on the spring very closely approximates its distance d from the center of the hub. Then the above formula may be written

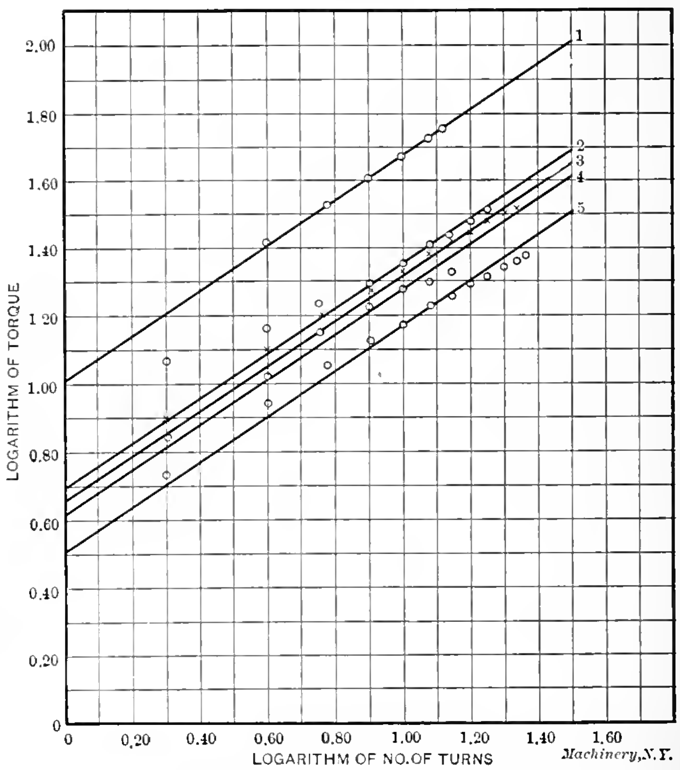

Fig. 5 Diagram showing Method of obtaining Formula giving Relation between Torque and Number of Turns

$$\frac{S}{C} = \frac{E}{d}$$

This gives a method for finding the radius of the hub. This radius should not be so small as to cause the fiber stress to pass beyond the elastic limit except when necessary to meet commercial conditions. In many cases, where the space is limited, it would be advantageous to temper the entire spring, or at least the inside end of it, on a psiral curve, and in that way allow for a small hub and still keep the stress within working limits. If the entire spring is formed to a curve when tempered, it should be so proportioned as to give a constant uniform stress throughout the spring when fully wound. It is evident, however, that this would materially increase the cost of production.

Assume $P = KT^{\frac{2}{3}}$, where P = torque, and K = constant.

Let E = energy in foot-pounds. Then by the methods of calculus

$$E = \frac{6\pi K T^{\frac{5}{3}}}{5}$$

which gives the relation between number of turns and available energy at slow speed for a given spring. This energy is equal to a constant times the cube root of the fifth power of the number of turns.

The amount of energy which may be stored in a given spring is approximately proportional to its weight, and is equal to about 60 foot-pounds per pound of spring. A relatively thick spring of few turns will store no more energy than a thin spring of many turns, provided the weights are equal. On account of this it is also evident that the torque may be increased without changing the number of turns, by merely increasing the width of the spring. If the torque is sufficient, but a greater number of turns is required, the spring should be lengthened. Should it be found that a smaller torque with a given number of turns, or fewer turns with the given torque is sufficient, then material may be saved by reducing the weight of the spring even if the same case is used. When it is found that the capacity of the spring is adequate but that its torque and turns are not correctly proportioned, the difficulty may be adjusted by varying the length and cross-section, keeping the weight constant.

As a practical example suppose that a maximum available torque of 50 pounds is required from a spring having 30 turns. Assume that the spring is tempered flat.

$$\text{Torque} = K T^{\frac{2}{3}}$$

$$50 = K\, 30^{\frac{2}{3}} = K \times \sqrt[3]{30^2} = K \times 9.65$$

$$K = \frac{50}{9.65} = 5.2$$

$$\text{Energy} = \frac{6\pi K T^{\frac{5}{3}}}{5} = \frac{6\pi \times 5.2 \times \sqrt[3]{30^5}}{5} = 5680 \text{ foot-pounds}$$

Assume 60 foot-pounds per pound of spring. Then,

$$\text{Weight} = \frac{5680}{60} = 95 \text{ pounds.}$$

Assume radius of hub $= 3$ inches, maximum stress $= 200{,}000$ pounds, and $E = 30{,}000{,}000$. Then

$$\frac{S}{C} = \frac{E}{R},$$

$$C = \frac{3 \times 200{,}000}{30{,}000{,}000} = 0.02$$

$$t = 0.04$$

Allow 0.042 thickness, for non-uniformity of spring.

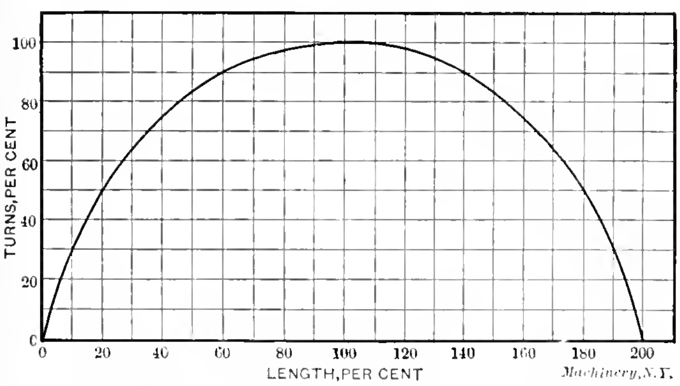

Fig. 6. Diagram of Relation between Number of Turns and Length of Flat Spring

From formula (6) we have, when $T = 30$, and $t = 0.042$:

$$30 = \frac{1}{0.042}\left[\sqrt{2\,(r^2 + 3^2)} - (r + 3)\right]$$

$r = 8.54$ inches, or diameter $= 17.08$, or about $17\frac{1}{8}$ inches.

From formula (5)

$$L = \frac{1}{2} \times \frac{\pi}{0.042}\,(8.54^2 - 3^2) = 2391 \text{ inches, or } 200 \text{ feet,}$$

nearly.

$$\text{Width} = \frac{95}{0.283 \times 2391 \times 0.040} = 3.5 \text{ inches, about.}$$

Hence, size of spring equals 0.04 inch $\times$ $3\frac{1}{2}$ inch $\times$ 200 feet; inside diameter of case inside of spring fastening, $17\frac{1}{8}$ inches; diameter of hub outside of spring fastening, 6 inches.

General Remarks

Springs as large as the one just calculated are used in spring motors. These motors may be built in several ways. When the external diameter is limited, a good method is to make the spring in sections and to place these sections on a shaft so that they may be fastened together. This may be done by providing the inside end of each sectional spring with a clip as shown in Fig. 7, which fits into a notch in the hub of the next case. Then all of the springs may be wound together and all will unwind together. The torque produced equals the torque of one spring, but the number of turns equals the sum of the number of turns of the individual springs. One of the advantages of this method is that if one spring breaks, it can be replaced at a lower cost than could a large spring that took the place of all the individual springs. The calculations previously given may be applied to this construction as well, by assuming that each sectional spring stores its relative portion of the required energy.

SAFETY OF TRAVEL ON THE PENNSYLVANIA SYSTEM

Figures recently compiled by the Pennsylvania Railroad and its subsidiary lines show that in 1908 and 1909 a total of 299,762,658 passengers were carried on its 24,000 miles of track, and only one passenger out of this number was killed as a result of a train wreck. This is an extremely good record, and credit should be given to the management of the railway system to whose efforts in regard to car equipment, signaling systems, discipline and training of employes this result is due. If the same results were duplicated on other American railways there would be only about three passengers (instead of between three and four hundred) killed in train accidents yearly in the whole of the United States. During the same two years 370 passengers were injured in train wrecks. This is also a low figure compared with the total for the railways in the United States. In fact, the number of passengers injured in proportion to the number of passengers carried on the Pennsylvania lines is only about one-eighth of the average number injured on all the railways in the United States. This record of the Pennsylvania Railroad is all the more remarkable as its traffic is heavier than that of any other railroad in the country, which means that it operates more trains than any other railroad and hence would meet with more opportunities for accidents. The number of passenger collisions was two less and the number of freight collisions 15 less in 1909 than in 1908, while the number of freight derailments was 69 less in 1909.

As compared with the records abroad, the Pennsylvania Railroad holds a better record, even, as regards the small number of passengers killed than the German state railroad system, noted for its safety. As regards the number of passengers injured, however, several of the European systems are still ahead of the Pennsylvania Railroad.

SHOP HEATING BY DIRECT RADIATION*

By CHAS. L. HUBBARD†

While it is probably true that a large proportion of the shops and foundries erected at the present time are equipped with hot-blast heating, there are still many cases where for various reasons the older form of heating by direct radiation seems preferable to the owners, and to these a few practical points in regard to the proper methods of installing and operating a system of this kind may be of considerable value. For example, a shop may be heated by a system of direct radiation, which originally gave satisfaction, but which, owing to numerous changes and extensions, fails to operate properly. The owner may feel that it is necessary to install an entirely new system of heating, when perhaps a few changes or additions may make the old one as good as new. Again, an addition to the plant may be in progress and it is

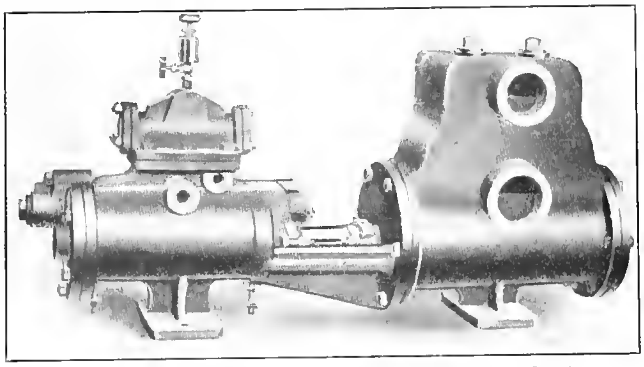

Fig. 1. Special Vacuum Pump for obtaining Necessary Suction in an Overloaded System

desired to extend the present system of direct heating rather than install a hot-blast apparatus in a single building. The object of this article is to give some of the faults of direct heating as commonly found in shops and factories, together with suggestions for overcoming them entirely or in part. Rules to be observed in laying out and installing new work will also be given, as well as a review of correct methods of extending present systems to include new buildings or additions to old ones. Some of the points to be considered in con-

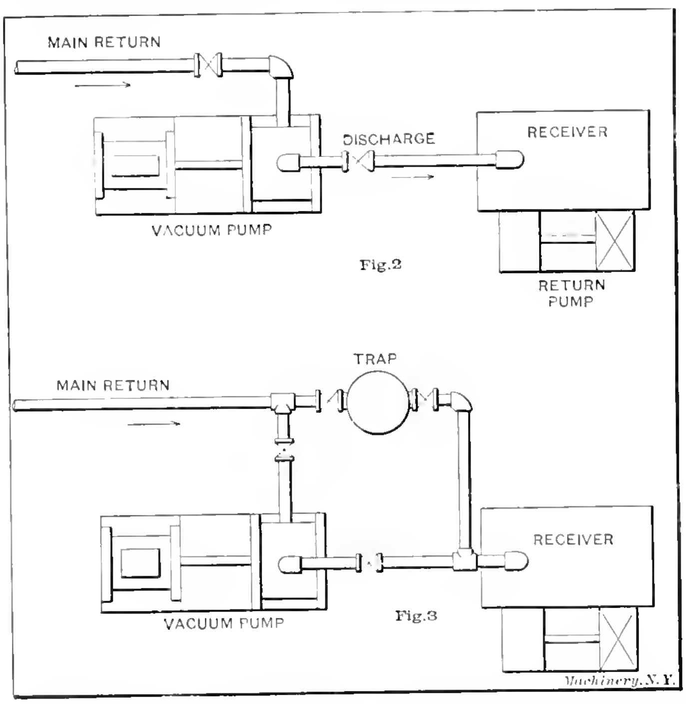

Fig. 2. Method of Connecting Vacuum Pump, used continually, to the Return. Fig. 3. Method of Connecting Vacuum Pump, when used only at intervals, to the Return

necting a heating system with a power plant will also be touched upon.

Faults of Direct Heating Systems

Among the most common causes of trouble in existing plants which have been changed and enlarged from time to time are small pipes, insufficient grading, and air binding. The system may have worked satisfactorily in the beginning, when doing only the work for which it was designed, but numerous additions have so overloaded the supply mains and branches that the pressure is considerably reduced in the

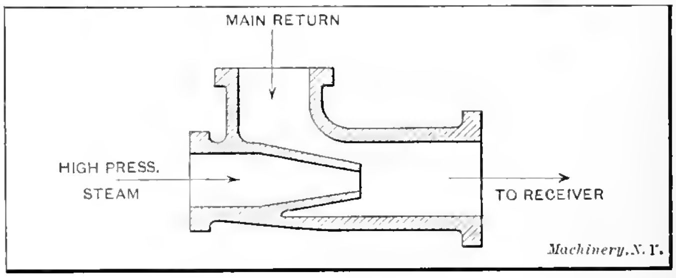

Fig. 4. Steam Ejector used for Cleaning the Pipes and Starting up the Circulation

more remote parts of the system. In addition to this, the returns are flooded by the increased amount of condensation, and the result is poor circulation of steam, cold pipes, and water-hammer.

Matters are made worse from the fact that there are usually no basements in which to carry sealed or wet returns; hence it is necessary to rely on drainage through dry returns, which are much more likely to give trouble than when the mains are sealed. Both supply pipes and overhead returns in extended systems are likely in time to sag and form pockets for the accumulation of condensation. This results in the

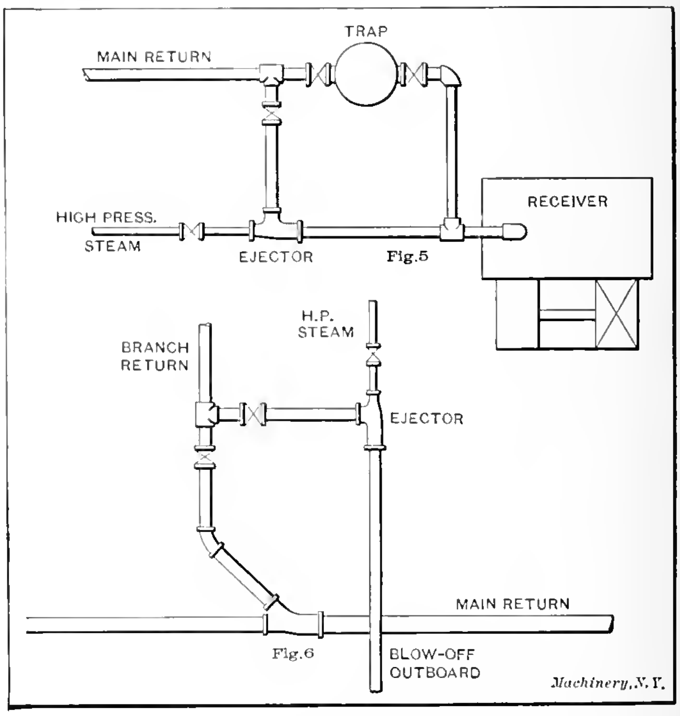

Fig. 5. Method of Connecting the Ejector with the Return Main. Fig. 6. Ejector connected with a Branch having Defective Circulation

holding back of air in certain parts of the piping and coils, and causes poor circulation and water-hammer.

About the only way to deal with a situation of this kind is to first re-grade the piping wherever it is found necessary to give the required pitch in the right direction, and then attach some form of suction to the end of the main return. If the system of piping is quite extensive and in bad condition, it may be best to place the matter in the hands of some engineering concern making a specialty of vacuum systems for the return of condensation. There are many cases, however, where the necessary results can be secured by home-made methods, or by means within the reach of any good steam fitter.

The necessary suction is best obtained by attaching a special vacuum pump to the main return. Pumps for this particular purpose can be obtained from the best manufacturers, and one of well-known make is shown in Fig. 1. The condensation from heating systems of this kind is usually trapped

* For further information on this and kindred subjects, see MACHINERY, November, 1909: "Heating and Ventilating Offices in Shops and Factories," and previous articles there referred to.
† Address: 283 Central St., Auburndale, Mass.

into a vented receiver, from which it is automatically pumped back to the boilers. In attaching a vacuum pump to the return, the connections may be made as shown in Fig. 2, when it is intended to use the pump all the time, or as shown in Fig. 3, when it is desired to retain the trap and use the pump simply for clearing the system of air in the morning when first warming up, or at intervals during the day when the circulation becomes sluggish. There are many cases where the system will work satisfactorily after the pipes and coils are once cleared of air, and steam circulation established. Operating the vacuum pump for a short time in the morning is often all that is necessary.

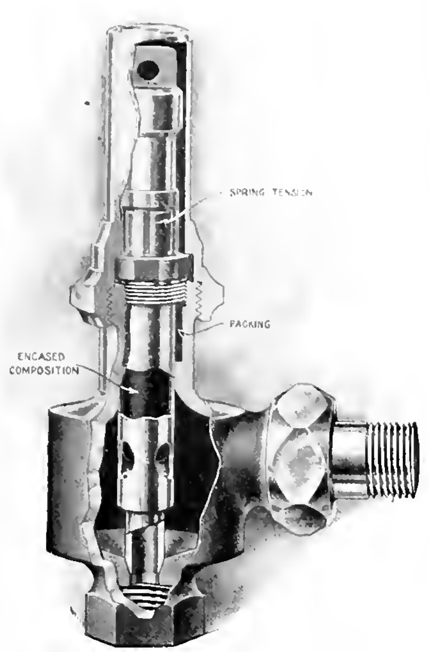

Fig. 7. Thermostatic Valve used in Connection with a Vacuum Pump

Sometimes an ordinary steam ejector connected into the return is all that is necessary to clear the pipes and start up the circulation. Such a device is shown in Fig 4, and the method of connecting it into the return main, in Fig. 5. Sometimes defective circulation may be confined to one particular building or section of the heating plant. In this case all that is necessary may be to connect an ejector into this particular branch, and exhaust the air and water once or twice a day as may be required. If this branch connects with the main return at some distance from the receiving tank, the exhaust may be blown outboard, as it will be operated only for a short time and the waste will be small. Connections for the arrangement above described are shown in Fig. 6. Whenever ejectors are used in this way it is necessary to have steam at a higher pressure for operating them.

The principal feature in the patented vacuum systems is the automatic valve placed at the return end of the coil or radiator which opens only to allow the passage of air and water, and closes in the presence of steam. If the ordinary radiator valve is used and left wide open, there will be short-circuiting through the nearer coils and radiators, while very little, if any, vacuum will be formed in the returns and coils more remote from the pump.

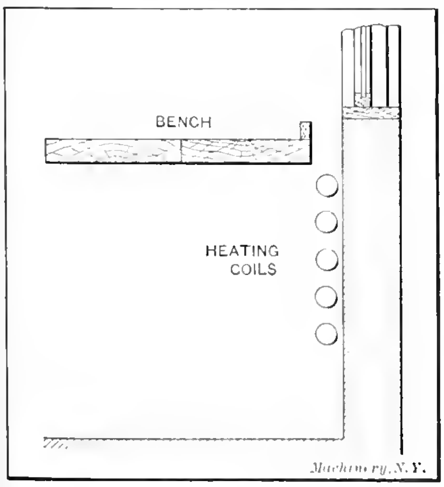

Fig. 8. A Good Method of Placing the Heating Coils

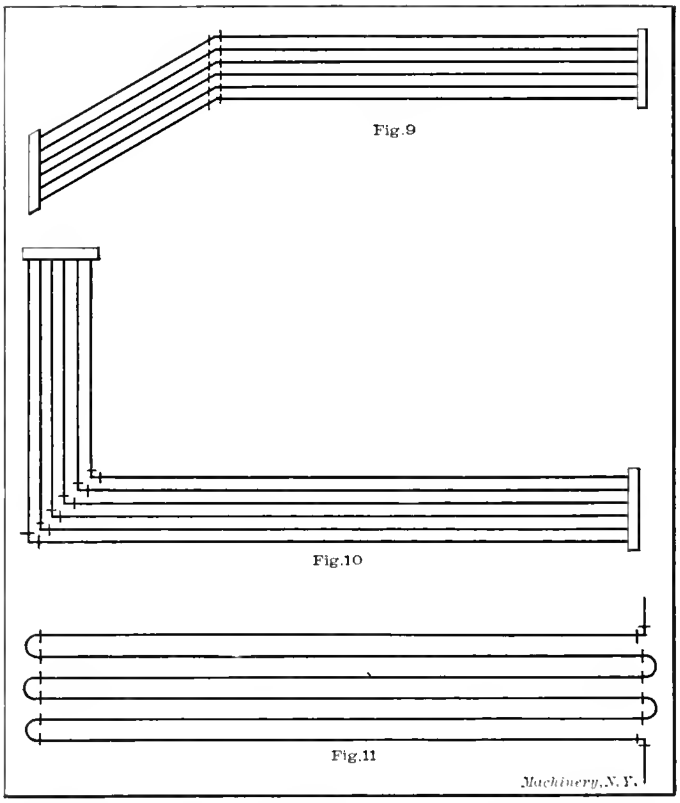
When the plant is not too large very good results may be obtained by throttling the return valves, leaving an opening just sufficient to care for the condensation under the slight vacuum formed in the returns. When this is done, the radiators and coils should be inspected at frequent intervals to make sure that the throttled valves do not become clogged. If this occurs, they should be opened wide and the steam and water allowed to blow through for a short time, which will usually serve to clear them. Sometimes it is not necessary to throttle the valve on each coil and radiator, but they can be grouped together and a throttle valve placed in the branch return from each group. Special thermostatic traps or valves are now on the market which can be used on the return end of the radiators and coils in connection with a vacuum pump if so desired, such a trap being shown in Fig. 7. These open automatically to allow the passage of air and water from the coil.

Throttling and automatic return valves must only be used when the vacuum pump is to be operated continuously, as otherwise the coils would not drain properly when returning by gravity without a vacuum.

There are several types of patented vacuum systems in use, some operating by exhausting the air from the radiators through special air-valves, while the condensation flows to the receiving tank by gravity in the usual manner. In others the vacuum is attached to the return main in a manner similar to the method already described, no air valves being used. The latter arrangement is preferable for the class of buildings under consideration, as it overcomes the effect of improper grading of the return pipes to a considerable extent, and also makes it possible to work with less distance between the heating coils and the return mains.

Design of a New System

Let us next take up some of the points to be considered in the design of a new system. We will assume that it is to



Figs 9, 10 and 11. Branch Coil, Miter Coil and Return Bend or Trombone Coil

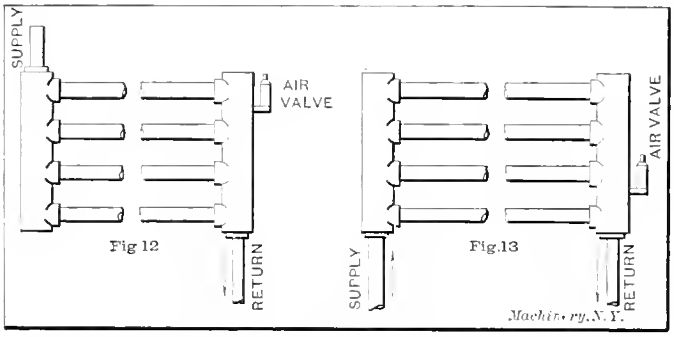
operate by gravity without the use of a vacuum pump, it being a simple matter to add this accessory should the plant outgrow the gravity method for the return of condensation. The first step in the design of a new system is to compute the amount of heating surface. For ordinary conditions, with low-pressure steam, there should be about one square foot of heating surface for each 10 square feet of wall surface, and the same amount for each 4 square feet of glass surface. If the building is in an especially exposed location or not especially well built, use the constants 8 and 3 in place of 10 and 4. For one-story buildings and upper floors having an exposed roof surface without attic space beneath it, count the roof the same as wall. The square feet of heating surface can be reduced to linear feet of pipe by the following:

TABLE I

Square feet of surface multiplied by	Linear feet of
3	1-inch pipe
2.3	1 1/4 inch pipe
2	1 1/2-inch pipe

The next point to be considered is the form and location of the radiating surface. For shops and similar rooms, circulation coils of 1¼-inch pipe are most commonly used. These are best placed along the walls beneath the windows, but if for any reason this cannot be done, they may be suspended on the side at a height of 8 or 9 feet above the floor. This height, again, is governed to some extent by the position of shafting, cranes, etc., and must be located to suit the actual conditions in each particular case. An ideal way to place the coils, from a heating standpoint, is shown in Fig. 8. By setting the bench out about 3 inches from the wall the warm air from the coil rises in front of the windows where it is most needed.

If there is no basement in which to carry the return pipes, there is sometimes difficulty in using this arrangement, for if they are carried above the floor it is likely to bring them too close to the bottom of the coils. If the supply pipes are of good size so as to keep up the pressure, the return may run within 18 inches of the lowest pipe of the coil; but for ordinary conditions 24 inches is better. If the vacuum system is used, the return may be carried much closer to the coil. Sometimes sufficient space may be obtained by carrying the return in a trench. In other cases there may be enough room to carry the returns beneath the floor; but in case this is done, they should be thoroughly protected against freezing.



Figs. 12 and 13. Supply and Return Ends of Branch Coil with Different Methods of Steam Supply, and Corresponding Positions of Air Valve

Common forms of heating coils are shown in Figs. 9, 10, and 11. The coil in Fig. 9, called a branch coil, is shown in perspective and is used wherever there is a chance to carry it around a corner in order to secure flexibility. The miter coil shown in Fig. 10 is used in places where a doorway or other obstruction prevents the use of a branch coil, and where there is space on the wall for carrying up a vertical portion to care for expansion. Overhead coils are usually of the miter form, laid on the side and supported by means of pipe-rolls and hangers. The wall coils are supported on hook-plates made especially for the purpose. Fig. 11 shows a "return bend" or "trombone" coil, which is used where there is no opportunity for breaking the coil around a corner or carrying it up the wall as in Fig. 10.

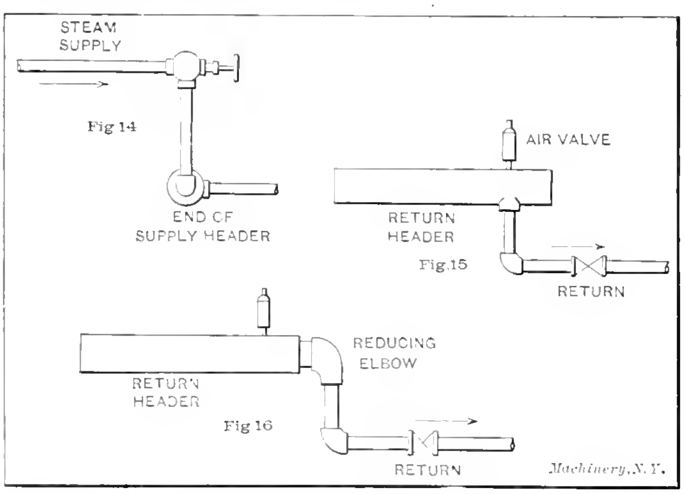


Fig. 14. Method of Making Connection with an Overhead Coil. Fig. 15. Method of Connecting Return Main to Coils. Fig. 16. Using an End Connection between Return Header and Return Main

In making the steam and return connections to coils, care should be taken to arrange them in such a way as to obtain the necessary air venting and drainage. Figs. 12 and 13 show the supply and return ends of a branch coil with different methods of steam supply and the corresponding position of the air valve. Fig. 12 shows the more common way of supplying steam to the top of the header. In this case the steam has a tendency to be driven past the upper pipes of the coil and to flow through the lower ones first. This forces the air to the upper part of the return header, at which point the air valve should be located as indicated in the illustration. Sometimes, on the upper floors, it is more convenient to connect the supply into the bottom of the header as in Fig. 13. In this case the conditions are reversed and the air valve should be placed near the bottom of the return header instead of at the top.

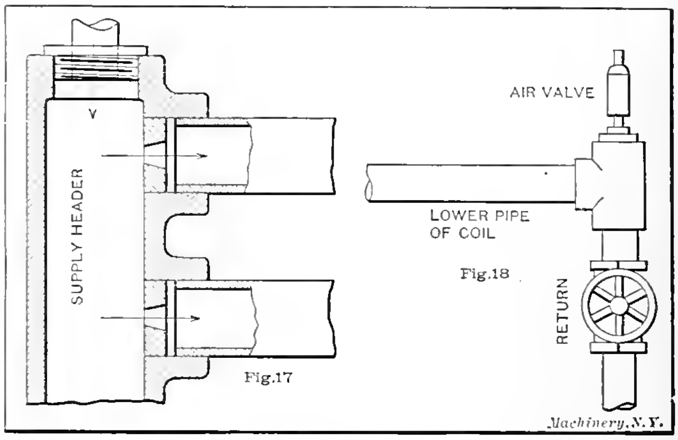

Fig. 17. Method of Equalizing the Flow of Steam from the Header to the Different Pipes in the Coil. Fig. 18. Method of Attaching Air Valve to Trombone Coil

Fig. 14 shows the method of making the connections with an overhead coil. When possible, it is best to use what is known as a "side-outlet" branch-T for the return header, as this, when in position, makes it possible to connect the return pipe into the bottom of the header, thus securing better drainage. The return mains and branches should always be carried at a lower level than the coils, as shown in Fig. 15. Sometimes it is not possible to obtain the side-outlet headers when wanted. In this case an end connection may be used, provided a reducing elbow is employed, taking in the full size of the opening at the end of the header as shown in Fig. 16. The opening in the return header should never be bushed when used in this way. In placing the air valve, it is better to tap into the top of the header, as shown in Fig. 12, rather than to connect it into the plug in the end of the header as is sometimes done. With the former connection there is less liability of its becoming filled with water and dripping.

TABLE II

Square Feet of Radiation	Size of Steam Pipe	Size of Dry Return	Size of Sealed Return
60	1	¾	¾
100	1¼	1	¾
130	1½	1	1
350	2	1¼	1
650	2½	1¼	1
1000	3	1½	1¼
1600	3½	2	1½
2200	4	2½	2
4000	5	3	2
6000	6	3	2½

One difficulty commonly experienced with circulation coils is that the steam, when first turned on, is quite likely to flow through certain pipes first, filling the return header, and then entering the remaining pipes at the return end, thus pocketing a considerable quantity of air in the center of the coil and causing it to remain cold. This condition can be avoided to a considerable extent by inserting a bushing with a small opening, about ¼ inch in diameter, in each pipe opening at the supply end as shown in Fig. 17. This equalizes the

flow of steam to the different pipes and causes the whole coil to fill evenly from the supply end. Fig. 18 shows a good way of attaching the air valve and making the return connection for a trombone coil. In this case the steam flows through each pipe of the coil in series, so there is no danger of air pocketing unless steam enters the return end from some other coil.

The sizes of supply and return pipes may be taken from Table II, which may be used for lengths of run up to 200 or 250 feet; for greater lengths the pipes should be increased a size or more according to conditions.

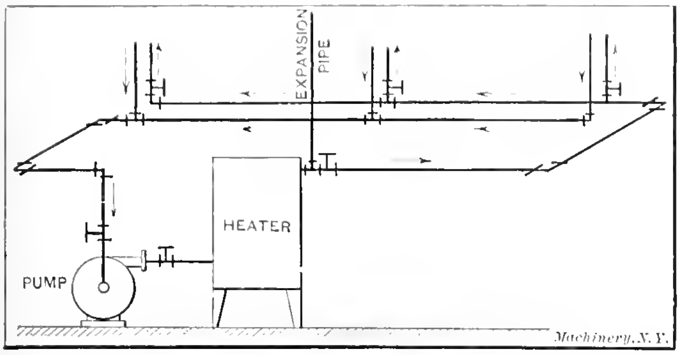

Fig. 19. Two-pipe System for Forced-circulation Hot-water Heating

Thus far only steam heating has been considered. When there is plenty of exhaust from the engines so that the matter of steam economy does not have to be considered, this method of heating is very satisfactory and has its strong points. The principal fault with direct steam is the difficulty in regulating the temperature of the rooms, and this usually results in a considerable waste of heat through open windows in mild weather. It is true that the temperature can be regulated by shutting off and turning on the heating coils, but the chances are that the workmen will resort to the easier method of opening windows. This has its advantage in providing a certain amount of fresh air, but ventilation by means of open windows in cold weather is not always desirable. If a vacuum system is used, a considerable range in temperature can be obtained by using a vacuum reducing valve which allows steam pressures below the atmosphere to be carried in the heating system.

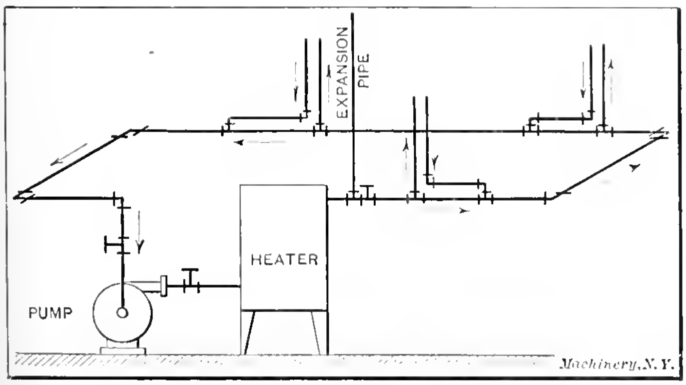

Fig. 20. Single Pipe or Circuit System for Forced-circulation Hot water Heating

When considerable live steam is necessary for heating, and it is desired to economize in its use, very satisfactory results may be obtained by the use of hot water under forced circulation. In this way the entire heating system is under the control of the engineer who can vary the temperature of the water to suit the requirements at all times. Under these conditions of warming very little heat will be lost through open windows. The piping need be no more complicated nor the heating surface more extended than in the case of low-pressure steam heating. By placing the expansion tank at a sufficiently high elevation, and using a small amount of live steam, the temperature of the water may be made to equal that of low-pressure steam in the coldest weather.

The mains for forced circulation are usually carried in one of two ways. In the two-pipe system shown in Fig. 19 the supply and return are carried side by side, the former reducing in size and the latter increasing as the branches are taken off. The flow through the coils is produced by the difference in pressure in the supply and return mains. As this is greatest nearest the pump, it is necessary to place throttle valves in the branches to equalize the flow to the different parts of the system.

The single pipe or circuit system is shown in Fig. 20. In this case a single main is carried entirely around the building, the ends being connected with the suction and discharge of the pump, as shown.

The supply risers are taken from the top of the main and the returns connected into the side, a short distance along the line. Circulation through the risers and coils is due partly to gravity (the hotter water rising from the top of the main to the coil and the cooler return-water falling through the return pipe) and partly to the drop in pressure in the main between the points at which the supply and return pipes are connected. When there is a basement in which the circuit main may be carried, this system of piping is the simpler, but the two-pipe system has the advantage of a decided drop in pressure between the supply and return mains, so there is much greater flexibility in running the pipes, which makes it much better adapted to the conditions found in shop heating. Both supply and return mains may, for example, be carried at the ceiling, or both at the floor, or one at the ceiling and the other at the floor. A good arrangement for a two-story building is to carry both mains at the ceiling of the first story, and connect with the first floor coils by drops and with the second floor by risers. In a one-story building both mains are usually carried overhead, as they are less in the way of machinery and other equipment.

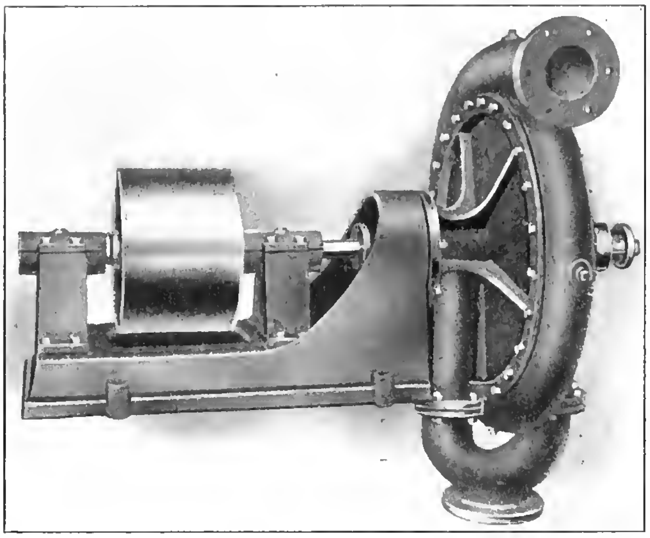

Fig. 21 Belt-driven Centrifugal Pump for Heating Service

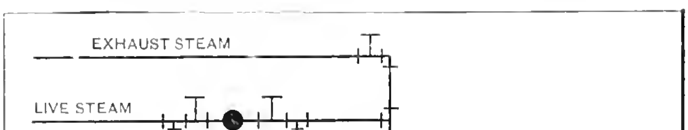

Fig. 22. Diagram of Connections between Pump and Heater when Live and Exhaust Steam are used in the same Heater

In the circuit system it is customary to count on a drop in pressure of about 20 degrees between the pump suction and discharge, and in the two-pipe system to allow a drop of

about 40 degrees. In the circuit system the return water from the radiators flows back into the main, so the supply to the radiators along the line becomes cooler and cooler as the distance from the pump increases. For this reason, a larger volume of water must be circulated at a less drop in temperature, or the size of the heating coils and radiators must be increased along the line to make up for an excessive drop in temperature of the circulating water. Hence, it is a choice between a larger pump and main, or more radiating surface. In the two-pipe system all of the radiation is supplied with water at practically the same temperature, except for the slight cooling which results from radiation from the main

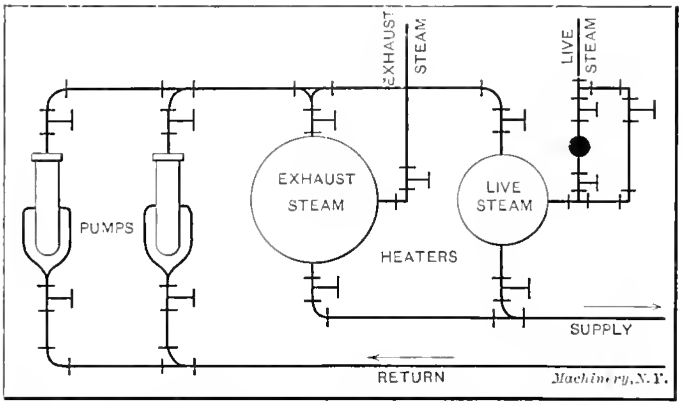

Fig. 23. Diagram of Connections between Pump and Heater when Separate Heaters, in Parallel, are used for Live and Exhaust Steam

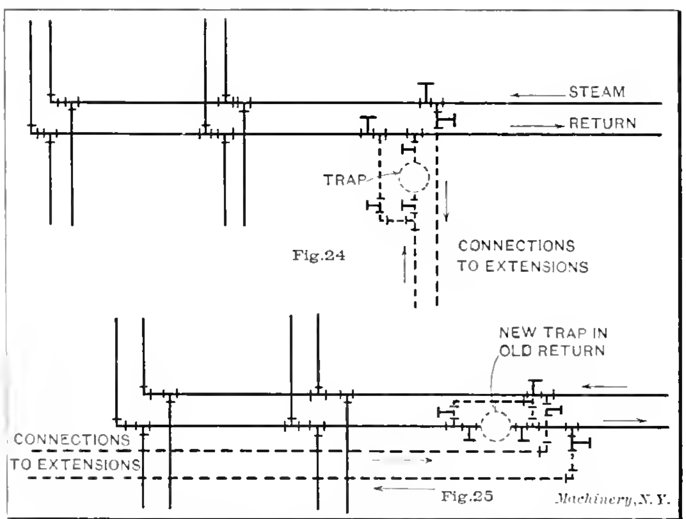
itself. The size of mains and capacity of pump depends upon the volume of water circulated, and this, in turn, upon the amount of radiating surface and the drop in temperature of the circulating water.

Example of Calculations

Taking the case of a circuit main, and allowing a drop in temperature of 20 degrees, there will be $8.3 \times 20 = 166$ heat units given up to the heating system by each gallon of water circulated. If the water is pumped into the system at a temperature of 200 degrees and cooled to 180, the heating coils will have an efficiency of about 220 heat units per square foot of surface per hour. Hence there should be $220 \div 166 = 1.33$ gallons of water circulated per hour for each square foot of radiation, or $\frac{1.33 \times 100}{60} = 2.2$ gallons per minute for each 100 square feet of radiation. Assuming approximate velocities of flow of 3.4 feet per second for pipes 3 inches in diam-



Figs 24 and 25. Methods of Making Connections for Additions located near the Boiler-room and at the Extreme End of the Line

eter and under, 5.0 feet for 4-inch pipes, 5.7 feet for 5- and 6-inch pipes, and 8.0 feet for 7- and 8-inch pipes, we have in Table III the pipe sizes for various amounts of radiating surface. These sizes are suitable for mains up to 1500 feet in length, or even 2000 feet in special cases, if necessary.

The mains in the two-pipe system may be made somewhat smaller, owing to the greater drop in temperature allowed. On the other hand, the radiation will be slightly less efficient, owing to the lower average temperature of the water. Proceeding as before, and allowing a drop in temperature from 200 to 160 degrees, we have $8.3 \times 40 = 332$ heat units given up by each gallon of water circulated. Assuming in this case

TABLE III

Size of Circuit Main, Inches	Square feet of Direct Radiation Supplied

3	7,000
4	18,000
5	32,000
6	44,000

an efficiency of 210 heat units for the radiation, we have

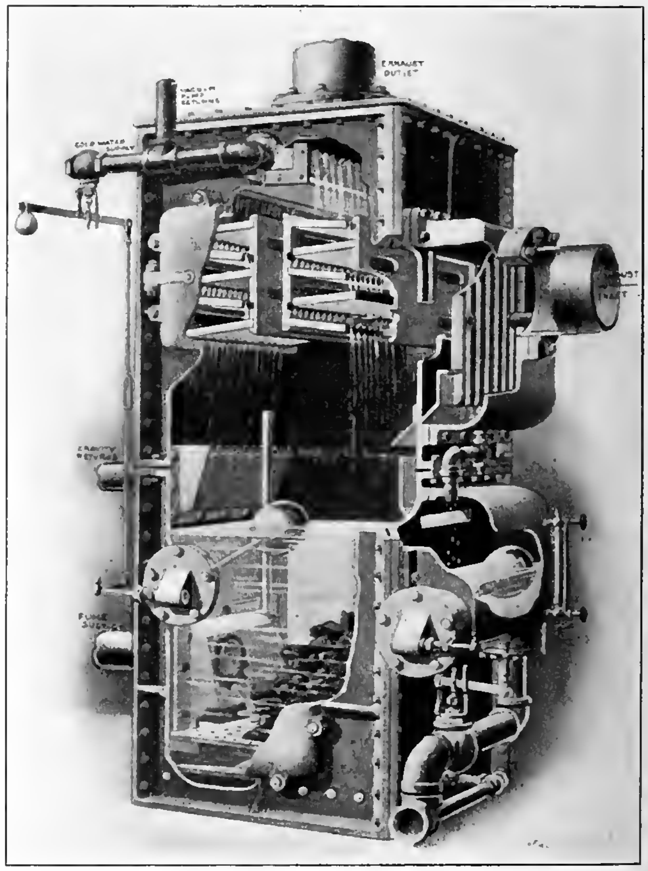

Fig. 26. Open Heater Combining Oil Separator, Feed Water Heater, Purifier, Return Tank and Filter

$210 \div 332 = 0.63$ gallon of water required per hour for each square foot of radiation, or $\frac{0.63 \times 100}{60} = 1.05$ gallon per minute for each 100 square feet of radiation. Using the same velocities as before we have in Table IV the sizes of pipe mains for the two-pipe system. These sizes are also for circuits up to 1500 to 2000 feet in length. Should it be decided to use a drop in temperature of 30 degrees instead of 40, the amount of surface supplied by any given size of pipe would be the mean of the quantities given in Tables III and IV.

The branches and risers to the coils are made considerably larger than the mains in proportion to the volume of water

2	500
2 1/2	600

which they carry. The pipe sizes in Tables V and VI may be used for the circuit and two-pipe systems, respectively.

Pumps

Pumps of the centrifugal type are best adapted to this class of work on account of their simplicity and the low-pressure heads required. For the sizes of pipe given in Tables III and IV the required pressure head for overcoming the friction in the mains will not exceed 40 feet for straight lengths of pipe up to 1500 feet. Each long-turn L and T adds 4 and 9

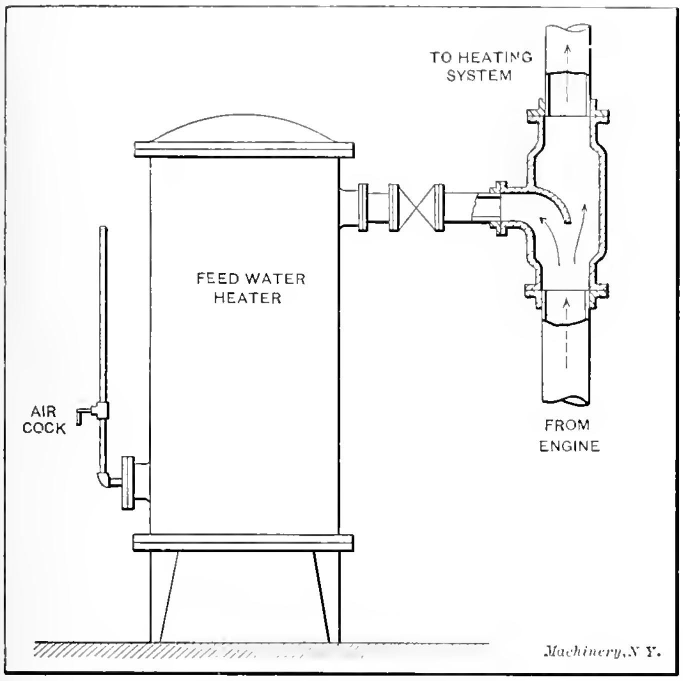

Fig. 27. Induction Method of Connecting the Heater with the Exhaust Main

feet, respectively, to the length of the main. Centrifugal pumps may be driven by direct-connected steam engines, turbines, electric motors, or may be belted to a convenient line of shafting. Fig. 21 shows a belt-driven pump of this type.

The horsepower required for driving a centrifugal pump is given by the equation:

$$\text{H. P.} = \frac{H \times V \times 8.3}{33{,}000 \times E}$$

in which H = friction head in feet,

V = gallons of water moved per minute,

E = efficiency of pump, which may be taken as 0.50 for average conditions.

In heating work the pumps are commonly run under a head

TABLE VII

Size of Delivery, Inches	Rated Capacity in Gallons Per Minute	Revolutions per Minute for Different Pressure Heads				H. P. for each Foot Pressure Head
		20-foot Head	30-foot Head	40-foot Head	50-foot Head	
2	100	780	945	1090	1210	0.063
3	210	710	850	970	1080	0.136
4	430	640	765	870	960	0.217
5	730	530	635	720	800	0.309
6	1050	480	570	650	715	0.446
7	1440	405	485	550	605	0.606
8	1880	355	420	480	530	0.791

of 20 to 50 feet. Table VII gives the capacity and power required for driving medium lift pumps at medium speeds.

Table VII is for the type of pump which would probably be used if belt-driven. If a direct-connected steam engine driven pump were employed, a larger impeller at a lower speed would be used, and for a motor or turbine-driven pump a small impeller at a high speed is required.

Heater

The water is usually heated in a closed feed-water heater with the connections reversed; that is, with the steam on the

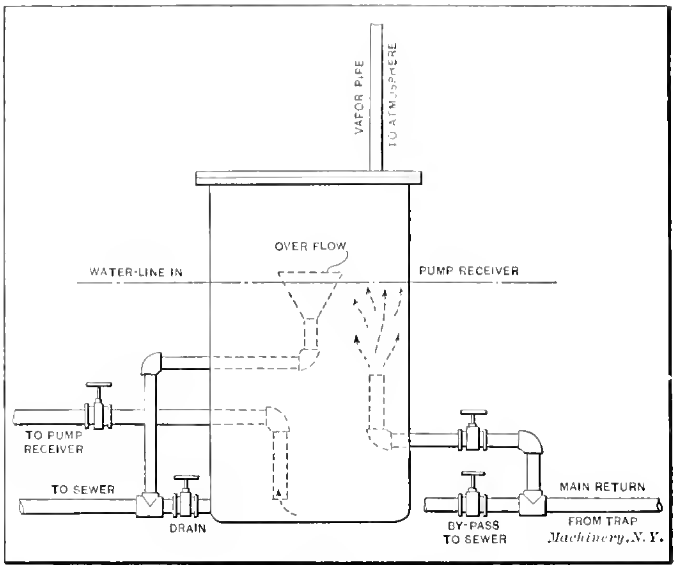

Fig. 28. Arrangement for passing the Return, a Settling Chamber or Tank

inside of the tubes and the water on the outside. Any good form of heater can be used for this purpose by providing it with steam connections of sufficient size. In the ordinary form of heater, the feed water flows through the tubes, and the connections are therefore small, making it necessary to substitute special nozzles of large size when used in the manner described. When computing the required amount of heating surface in the tubes of a heater, it is customary to assume an efficiency of about 200 heat units per square foot of surface per hour per degree difference in temperature between the water and steam.

Taking the case of a two-pipe system where the water is delivered at 200 degrees and returned at 160, the average temperature of the water passing through the heater will be, approximately, 180 degrees. If exhaust steam is supplied to the heater at atmospheric pressure, there will be a difference of 212 − 180 = 32 degrees between the steam and water, thus giving an efficiency of 200 × 32 = 6400 heat units per square foot of heating surface. Hence 6400 : 210 = 30 square feet of direct heating surface that may be supplied from each square foot of tube surface in the heater. Commercial heaters are commonly built on a basis of 1/3 of a square foot of tube surface per horsepower, from which it is seen

that $\dfrac{6400}{3 \times 210} = 10$ square feet of radiating surface supplied by each horsepower of the heater, or in other words, one commercial horsepower of heater is required for each 10 square feet of direct radiation.

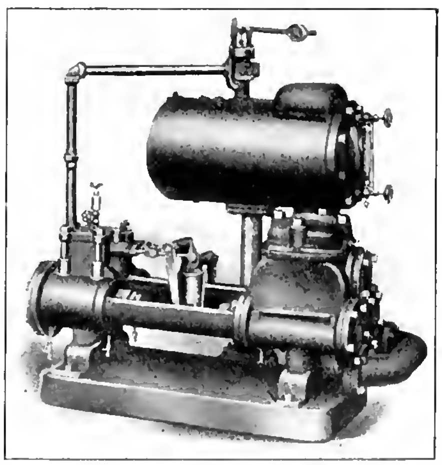

Fig. 29. Combined Pump and Receiver used for returning the Condensation to the Boilers

When there is not sufficient exhaust steam for heating requirements, live steam may be admitted to the heater through a pressure-reducing valve, provided the exhaust is purified of

oil so the condensation may be returned to the boilers. If the exhaust is not purified, and the condensation is allowed to waste, it is better to use a separate heater for the live

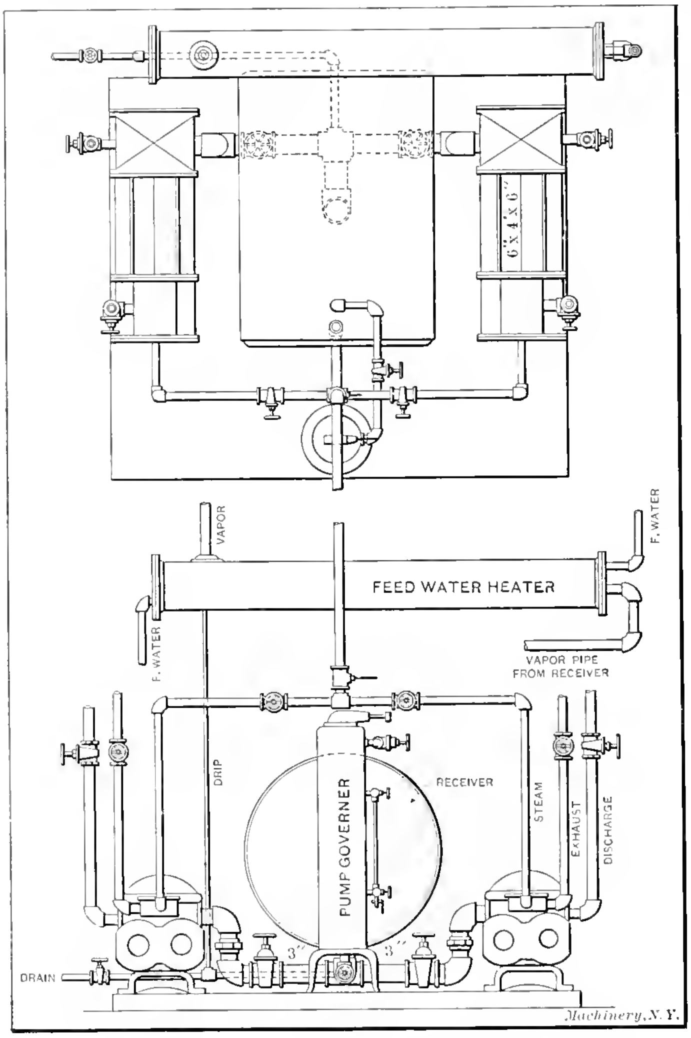

Fig. 30. Arrangement of Duplex Pump and Receiver for Large Plant

steam on the ground of economy. In the Evans-Almiral patented system of hot-water heating, the two heaters are placed in series, with the exhaust heater next to the pumps. Good results may be obtained by placing them in parallel if the water connections are so throttled as to supply the proper proportion of water to each heater. The efficiency of a live steam heater is, of course, greater than one using exhaust, owing to the higher temperature of the steam. The efficiency for any given pressure can be easily determined by the methods already given.

The general methods of making the connections between the pumps and heaters are shown by the diagrams in Figs. 22 and 23. In the first case the live steam is used in the same heater with the exhaust, and in the second, separate heaters are used, connected in parallel. It is best to provide two pumps, each capable of doing the entire work, for if the pump gives out, there is no way of warming the building until it is repaired. In making the connections, the arrangement should be such that any part of the apparatus can be cut out without interfering with the operation of the remainder. All fittings about the pumps and heaters should be of the long-turn pattern, and sweep bends of wrought-iron pipe should be used in the mains for making right-angled turns, when possible.

Extensions to Existing Plants

In making extensions to a plant already in use, the first step is to determine if there is sufficient boiler power in reserve to provide steam for the additional heating surface. If the present boilers are loaded up to their full capacity, new boilers should be installed, allowing one horsepower for each 100 square feet of direct heating surface. Next see if the supply and return mains are large enough to carry the additional radiation, using Table II for this purpose. If not, separate mains should be run from the boilers and receiving tank. Sometimes it is necessary to go back only part way to the boiler room to find a point where the mains are large enough to do the entire work without too great a drop in pressure.

If the addition is of considerable magnitude—a new building, for example—it is usually best to place an independent trap on the return, especially if it is nearer the boilers than the rest of the system. Where several buildings or wings are drained through a single return main it is often of advantage to place a trap in the return from each building and vent the receiving tank to the atmosphere. When the addition is at the extreme end of the line and the main is not of sufficient size to care for the extra load, it is usually much cheaper to run a separate supply and return, parallel to the old lines, than to enlarge them, owing to the work of discon-

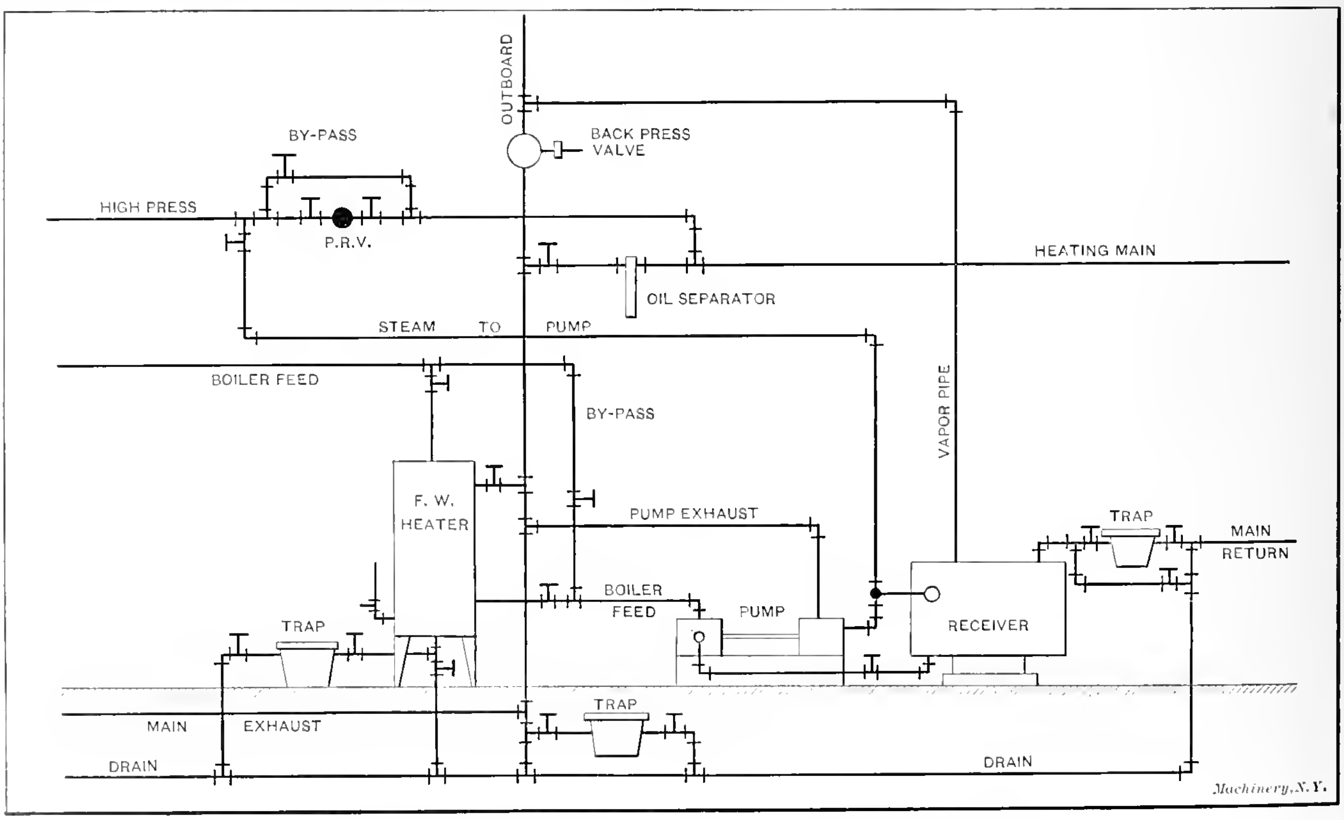

Fig 31. General Method of Making Pipe Connections for Combined Power and Heating Plant

necting and connecting the various branch pipes along the line. Figs. 24 and 25 show methods of making connections for additions located near the boiler-room and also at the extreme end of the line. The full lines represent the old system of piping and the dotted lines the new.

Connecting Heating System to Power Plant

In connecting a heating system with a power plant, it is nearly always advisable to plan for using as much of the exhaust steam as may be necessary for heating the feed water, as this effects a constant saving in summer as well as in winter. With non-condensing engines of average economy, from 1/6 to 1/5 of the exhaust may be used for this purpose. Both open and closed heaters are adapted for use in connection with the heating systems. The former is often made to combine the oil separator, feed-water heater and purifier, return tank, and filter, as shown in Fig. 26. Either type of heater will produce satisfactory results if properly proportioned and connected. The induction method of connecting the heater with the exhaust main makes a good arrangement for a heating system. This is shown in Fig. 27, and when used, the steam for the heating system does not pass through the heater at all. This prevents any possibility of spray from the trays in the open heater being carried over into the heating system, and secures rather dryer steam than in the case of the closed heater with two connections, because the passage of the steam over the cold tubes tends to form a certain amount of moisture in the surplus steam when the whole volume is passed through the heater. The arrangement also makes it easy to cut out the heater in case of repairs.

If the condensation is to be returned to the boilers, the exhaust steam must be passed through an efficient oil separator before entering the heating system, and if there is still any tendency to priming, the return should be passed through some form of filter or settling chamber before entering the boilers. This is provided for in most types of open heaters, but if a closed heater is used, some special device must be used. A good arrangement for this purpose is shown in Fig. 28. This consists of a cast-iron settling tank so arranged that the oil on the surface can be made to overflow into the funnel by closing the valve in the pipe leading to the pump receiver. This can be done at intervals as the oil collects. The best results are generally obtained by venting the receiving tank and trapping the main return into it. If the system is fairly compact a simple trap may be used, placing it near the tank, but if two or more buildings are included, it is best to place a trap in the return from each.

In small plants a combined pump and receiver of the type shown in Fig. 29 is commonly used for returning the condensation to the boilers, but in the case of large and important heating systems it is best to use two pumps, each of sufficient capacity to do the whole work. When two pumps are used they should be run alternately to keep them in good condition. Fig. 30 shows a good arrangement for duplicate pumps and receiver. The pumps are operated automatically by means of a governor or regulator located in front of the tank, as shown. This admits steam to the pumps by means of a float valve when the water in the tank rises above a given point.

The diagram, Fig. 31, shows the general method of making the pipe connections for a combined power and heating plant. This diagram will be found useful in planning the boiler room equipment of a new plant and in remodeling an old one.

* * *

The Navy Department has recently instituted competitive rewards for low fuel and oil consumption records on naval vessels. The economies in power plant operation, which can be secured by proper instruction and encouragement of firemen and attendants, are shown by the fact that according to results thus far obtained, a saving of almost $1,000,000 a year will be effected in fuel and oil alone.

* * *

A monument was unveiled at Spencer, Mass., May 19, erected to the memory of three famous inventors, brothers, namely: Elias Howe, Jr., inventor of the sewing machine; William Howe, inventor of the truss bridge known as the "Howe truss;" and Tyler Howe, inventor of the spring bed.

PUNCH AND DIE FOR ELLIPTIC GEARS

By W. J. McDEVITT*

In the half-tone illustration, Fig. 1, are shown two elliptical gears which are punched out. The method of calculating, laying out and making the punch and die for this work may be of interest to mechanics in general. The known dimensions of the gears to be made were the major axis of the pitch line ellipses which equals the distance between the centers of rotation and the approximate eccentricity. The two gears are, of course, alike. To find the minor axis the number of teeth of a suitable pitch had to be determined. The least allowable eccentricity in this case was 0.437, and the distance between centers was fixed at $1\frac{3}{4}$ inch. According to a formula given in the text-books of the International Correspondence Schools, the perimeter of an ellipse equals

Major axis × 1.82 + minor axis × 1.315.

By assuming 18 pitch for the teeth and $1\frac{1}{2}$ inch for the minor axis, we find that the number of teeth would equal

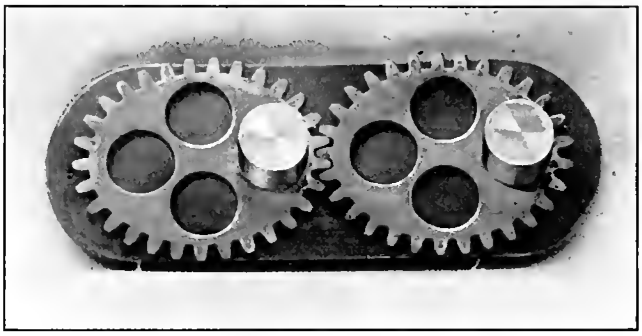

Fig. 1. Elliptic Gears Produced by Punching

29.55. Let us settle upon 29 teeth. It is evident that the number of teeth must be an odd number, inasmuch as when the gears are in the position shown in Fig. 1, the center line passing through the studs on which the gears are mounted must intersect a tooth space in one gear and a tooth in the other at the point where the teeth mesh. In other words, in each of the gears there must be a tooth at one end of the major axis and a tooth space at the other end, and this, of course, necessitates an odd number of teeth. Taking 29 teeth, as mentioned, and 18 pitch, we have

$$\text{Circular pitch} = \frac{3.1416}{18} = 0.1745 \text{ inch, and}$$

Perimeter = 29 × 0.1745 = 5.0605. From the formula

Perimeter = major axis × 1.82 + minor axis × 1.315, we have

$$\text{Minor axis} = \frac{\text{perimeter} - \text{major axis} \times 1.82}{1.315}$$

$$= \frac{5.0605 - 1.75 \times 1.82}{1.315} = 1.426$$

Hence, major pitch diameter = 1.750 inch, and minor pitch diameter = 1.426 inch.

[The formula here given for finding the perimeter of an ellipse is only approximate. More accurate formulas are ordinarily given in the standard hand-books, but these formulas require a table of constants for different eccentricity of the ellipse. The formula above, while less accurate, has the advantage that it requires but two constants which can be retained by memory. For practical work of the character described in this article the accuracy obtained was apparently sufficient.—EDITOR.]

The next step in the making of the tools for these gears was to lay out the ellipse on the drawing board and the construction used was taken from a book on mechanical drawing by Prof. Faunce of the Massachusetts Institute of Technology. This method is as follows:

Having given the axes, to draw a curve of tangential arcs of circles approximate to the ellipse. Referring to Fig. 2 AO

* Address: 182 Lakeview Ave., Cambridge, Mass.

is the semi-major axis and OB the semi-minor axis. Draw a rectangle with the axes as sides. $AOBC$ is one-quarter of the rectangle. Draw AB. From C draw CMP perpendicular to AB and meeting BO produced at P. Make OE equal to OB. With AE as a diameter draw a semicircle AKE. Produce OB to K. Make $OL = BK$. With center P and radius PL draw the arc LN. Make AD equal to OK, and with center M and radius MD draw the arc DN, meeting LN in N. Draw NMR and PNS. With center M and radius MA draw AR; with center N and radius NR draw RS; with center P and radius PS draw an arc through B from S. Repeat this in each of the quadrants.

By laying out the ellipse as carefully as possible at four

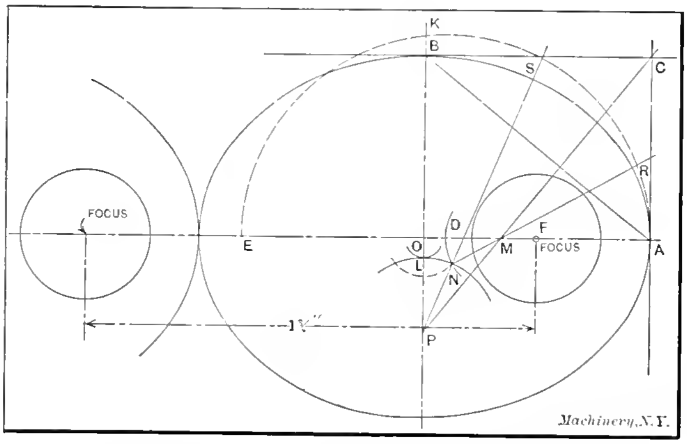

Fig. 2. Method of Laying out an Ellipse by Eight Circular Arcs

times the size and then measuring to the nearest hundredth inch, gives the following distances for pitch line:

$$PS = PB = 4.300 \text{ inch, or } \frac{4.300}{4} = 1.075 \text{ inch.}$$

$$NR = NS = 3.160 \text{ inch, or } \frac{3.160}{4} = 0.790 \text{ inch.}$$

$$MA = MR = 2.320 \text{ inch, or } \frac{2.320}{4} = 5.580 \text{ inch.}$$

As there were nine different centers required on the face of the punch, and it was convenient to lay them out from the center O, the following distances were used:

$$OM = 0.875 - 0.580 = 0.295 \text{ inch.}$$

$$OP = 1.075 - 0.713 = 0.362 \text{ inch.}$$

$$ON = \frac{0.590}{4} = 0.147 \text{ inch.}$$

$$MN = 0.790 - 0.580 = 0.210 \text{ inch.}$$

$$PN = 1.075 - 0.790 = 0.285 \text{ inch.}$$

$$\text{Addendum} = \frac{1}{18} = 0.0555 \text{ inch.}$$

Then major diameter of blank $= 1.75 + 0.111 = 1.861$ inch.
Minor diameter of blank $= 1.426 + 0.111 = 1.537$ inch.
To find distance OF, the center of rotation, we have:

$$OF = \sqrt{OA^2 - OB^2} = \sqrt{0.875^2 - 0.713^2}$$
$$= \sqrt{0.2572} = 0.5072 \text{ inch.}$$

According to the properties of the ellipse, the eccentricity

$$e = \frac{OF}{OA} = \frac{0.5072}{0.875} = 0.579.$$

It will be found that three cutters are required to cut the teeth.

To find the cutters to use for different circles, we have

$1.075 \times 2 = 2.150$, and $2.150 \times 18 = 38.7$ teeth.
$0.790 \times 2 = 1.580$, and $1.580 \times 18 = 28.44$ teeth.
$0.580 \times 2 = 1.160$, and $1.160 \times 18 = 20.88$ teeth.

The center of a tooth or center of a space should be at A. As there were several shifts to be made and changing of cutters the work required considerable care, but the job was done by an exceptionally good workman. After the punch was cut and hardened it was used to broach out the die which was worked out as near as possible. These tools were made at Cummings Machine Works, Boston, Mass.

The punch and die were of the simple push-through style. The hole in the elliptic gear for the shaft as well as the other three holes through it were drilled in a jig. As the gears have an odd number of teeth, they must be placed in the jig in the same position each time, this position being determined by a pilot in the jig which fitted into the tooth space on the line of the major axis. In this way the hole of which the focus is the center would be always either at the tooth end or at the space end of the gear. The original idea was to have a roughing and a shaving punch and die, but only one set was made and the result proved satisfactory.

CONCISE AND DEFINITE INFORMATION

We sometimes wonder if the readers of MACHINERY fully appreciate the concise and definite information that is spread before them. The substance of long articles is often given in notes of a few lines. As an example of the type of articles which tell little or nothing and use a good many words to tell it, we present the following clipped from a Sunday newspaper:

Urauium and Tellurium Solder

Science has at last discovered a perfectly solid solder for metal joints. Just what this will mean in future decades to railroads and in other metallic features, where a solid jointure is so desirable, only experience and actual wear and tear in active use can disclose. However, the fact that is claimed for the new uranium and tellurium solder mixture will practically compose a solid joint between two metals is of vast interest.

In modern electric street railway systems the absence of a solid joint causes millions to be spent annually in connecting rails by wires. Numerons attempts have been made with other solders to form a continuous rail out of the ordinary steel rail.

All these attempts have proved failures. Now comes the assertion that uranium and tellurium in certain proportions will form an absolutely perfect union from a metallic standpoint when put between two steel rails.

The rarity and costliness of the two metals involved in the new composition robs the discovery of much of its present utility, but it can still be used at many points where, in delicate machinery, a solid joint is highly to be desired. This is especially true as regards delicate apparatus used in the scientific laboratories where the solidarity of the metallic jointure frequently would mean success where at present this is unattainable.

Just what the exact proportions of uranium and tellurium are that must be employed in the new solid metallic jointure is not publicly known. It is the claim fonnded on alleged actual achievement that is most interesting to scientists and to the men actively engaged in the varied branches of commercial chemistry and engineering.

An analysis of the statements in the above discloses first that the solder is suggested for uniting rail joints of electric railways—a most brilliant idea! An uninformed reader might infer that engineers were vainly seeking for some solder or other means of efficiently joining street railway rails. As a matter of fact, we have the electric welded joint, the cast-iron joint, the thermit joint and the fish-plate joint with cast zinc filling, all of which are efficient and satisfactory although more or less expensive. The best copper bonds also are fairly efficient and satisfactory. In the second place, the note proposes an impractical solder—impractical because the materials are rare and costly, so costly that it would be totally out of the question to use them for commercial purposes. Moreover, there is no experience quoted indicating that the solder would work efficiently in the situation suggested. Thirdly, the precise constituents of the solder are unknown! The analysis, therefore, discloses that the entire proposition is tenuous and without substantial foundation for commercial purposes. Granted that the fact of a uranium and tellurium solder having been discovered is of some popular interest, the substance of the foregoing lengthy and misleading statement could have been expressed about as follows:

"A new solder composed of uranium and tellurium has been discovered, the exact proportions of which have not been made public. It is believed that this solder will be of considerable value for uniting parts of scientific instruments where it is essential that a perfect union be secured and the cost is not prohibitive. The rarity and high cost of the components probably will limit the use of the new solder to experimental and special purposes."

INTERESTING TOOLS AND METHODS OF CINCINNATI SHOPS—4

THE CINCINNATI SHAPER CO.

By ETHAN VIALL*

The special and original devices and shop kinks in use in the shop of the Cincinnati Shaper Co., are almost unlimited and only a small number of them can be noticed in this article. Of course a good many of them are applicable only to shaper construction, though they may contain, in themselves, a suggestion or idea which may be used on other work. In fact, the principal value of a description or illustration of a "shop kink" to the average toolmaker or designer, is its suggestiveness; that is, it may contain just the idea for which the reader has been searching, and thereby assist him to overcome a difficulty in a line which is, perhaps, radically different from the one in which the "kink" was originally used. It is for this reason that a pictorial panorama of the interesting shop devices in use not only in Cincinnati, but in other cities, is run in these pages each month.

Tool Turret for a Shaper

Toolpost turrets of various shapes and sizes are in common use on lathes, but one seldom sees a revolving tool-holder on a shaper, though it is extremely useful wherever several tools are to be used on a number of pieces of the same kind. Such a tool-holder with four tools in place, is illustrated in Fig. 1.

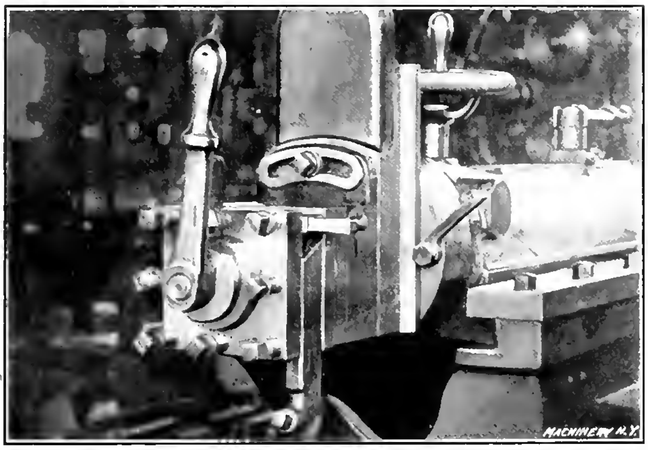

Fig. 1. Shaper with Turret Toolpost

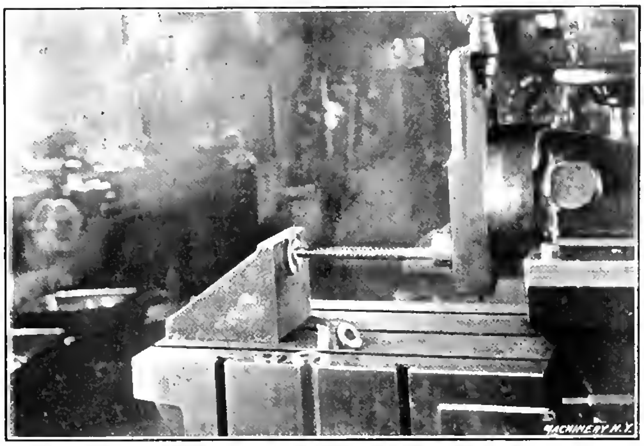

Fig. 2. Broaching D-Washers in the Shaper

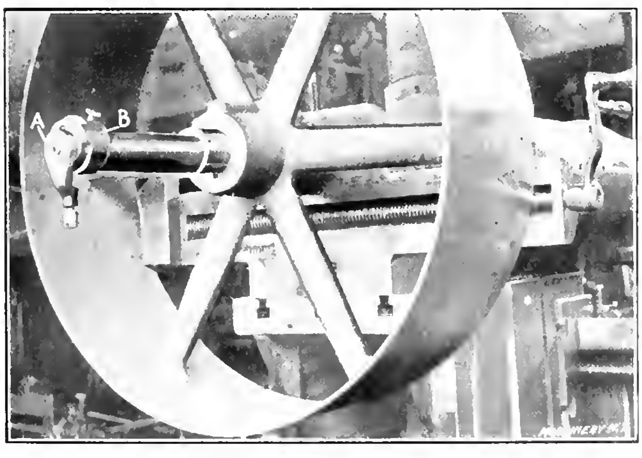

Fig. 3. Keyseating a Large Pulley—Front View

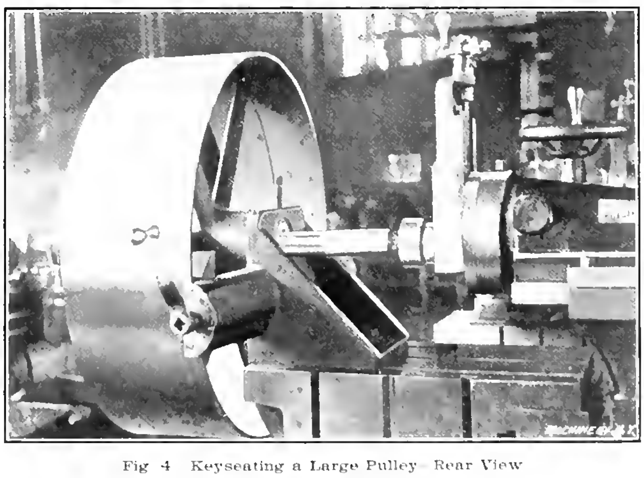

Fig. 4. Keyseating a Large Pulley—Rear View

Broaching D-Washers—Keyseating on a Shaper

Many small parts such as D-washers may be broached out to advantage in a shaper, as shown in Fig. 2. For this work, the clapper-block is, of course, either removed or locked, and the shank of the broach is held, preferably, in a split block or socket, so as to be easily removed. In the example shown, the drilled washer is placed in a U-shaped socket in the face of a foot-plate, which allows the operator to put a washer in place at every stroke of the ram, only stopping the machine when the shank of the broach is full.

Cutting keyways in pulleys is a job often done on a shaper, but in the shop under discussion, a regular keyseating attachment is made which practically makes a keyseating machine out of an ordinary shaper. A front view of this attachment at work on a big pulley, is shown in Fig. 3. The feeding of the keyway cutter is done by turning the handle *A*. Fig. 4 shows a rear view of the same job, while Fig. 7 shows the construction of the attachment in detail. The ball-and-socket connection of the cutter bar to the shaper head, is to be noted in this illustration, as well as the method of feeding the cutting tool. The adjustable stop-ring and set-screw *B*, Fig. 3, show plainly the way the depth of the cut is gaged. Fig. 5 shows a large cone pulley being keyseated. This last illustration is included because it shows the vise jaws set on the outside of the pulley, while the large single pulley was chucked from the inside of the rim. The vise jaws, however, do but little more than to center and steady the pulley. As the tool cuts only on the return stroke of the ram, the entire pull is against the angle-plate body of the vise.

Miscellaneous Shaper Appliances

Bushings with solid keys are cut in an automatic feeding fixture, Fig. 6, in which the feed worm is worked by the rod *A*, which is attached to the head of the shaper ram. The bushings, a finished one of which is shown at *B*, are placed on a shouldered mandrel and held between the centers of the fixture. The tail of the dog is held between the drivers *D* and *E*, in such a way as to avoid any unnecessary play. If, in setting, it is required to revolve the mandrel, it may be done by turning the small crank *F*. The worm-wheel is also an indexing disk and may be set or locked, at various points, by using the arm and pin *G*, which makes the fixture suitable for other work not requiring the automatic feeding device.

Figs. 8 and 9 show two shaper jigs for holding special parts, which need no explanation, and in Fig. 10 is shown a special motor-driven mill used to machine the surface of the shaper base on which the bottom of the table support rests. As this milling device travels on the horizontal table ways, the surface milled must necessarily be parallel to them, which is what is required in order that the support may properly do its duty.

*Associate Editor of MACHINERY.

The semi-circular spots on clamp-bolts are accurately reamed to the correct radius by using the special left-hand spiral reamer *A*, Fig. 11. *B* and *C* are guide bushings, fitting the hole in the casting *D*; *E* is the clamping bolt, and *F* is a size-testing bar. By using reamer *A* to finish the recess in the bolt, a

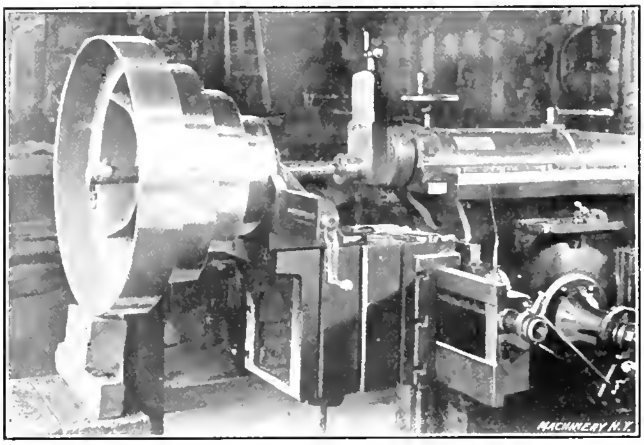

Fig. 5 Keyseating a Large Cone Pulley

perfect fit is obtained and, in consequence, only a slight tension is needed to lock the parts securely.

Graduating and Numbering Swivel Heads—Testing Vise Jaws

Shaper swiveling heads are graduated on a machine built along lines similar to several other Cincinnati graduating machines, though it differs in several points from them. Fig. 12 is a front view of the device. It may be run either by hand or by means of the motor attached. This motor is an old fan motor and the method of belting, as shown in this illustration and in Fig. 13, is interesting. These two engravings show the cam motion for obtaining the one long and the four short graduating strokes, as well as the various adjustments, so plainly that no explanation is needed. After graduating the swiveling heads, the degree numbers are rolled in on the machine shown in Fig. 14, an enlarged view of which is shown in Fig. 15. An inspection of the last engraving will show that

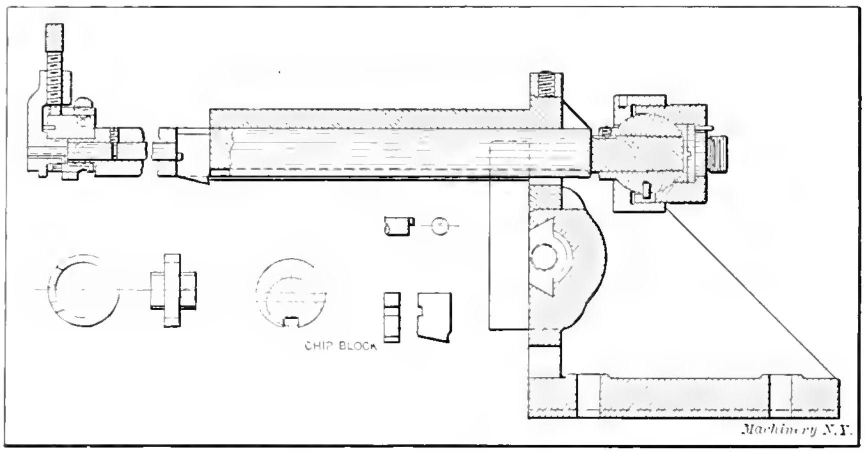

Fig. 7. Details of the Shaper Keyseating Attachment

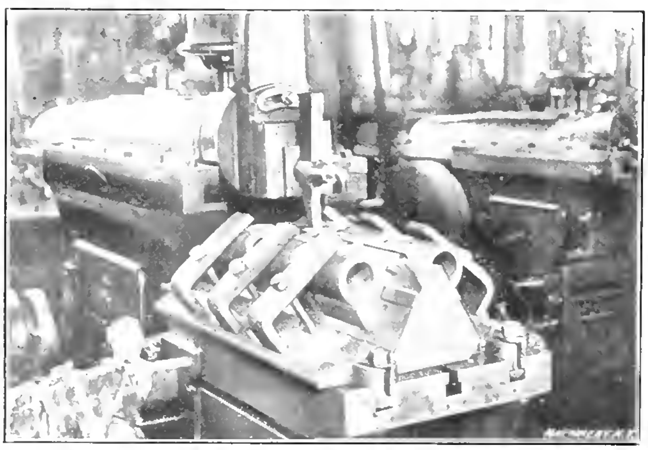

Fig. 8. Shaper Fixture for Machining Dovetails

two sets of figures and two sets of "half gears" are used, so that the figures may be pressed into two different sizes of swivel heads on the same machine.

Shaper vise jaws are tested for parallelism and the correct position of the pointer relative to the graduations on the base, on the machine shown in Fig. 16. A Brown & Sharpe dial indicator is carried on the end of a small ram, similar to that of a shaper, and it is fed out or in by means of a handwheel. The tops of the vise ways are tested by turning the vise one-quarter around and setting the indicator as shown in Fig. 17.

In Fig. 18 are illustrated three adjustable scraping blocks,

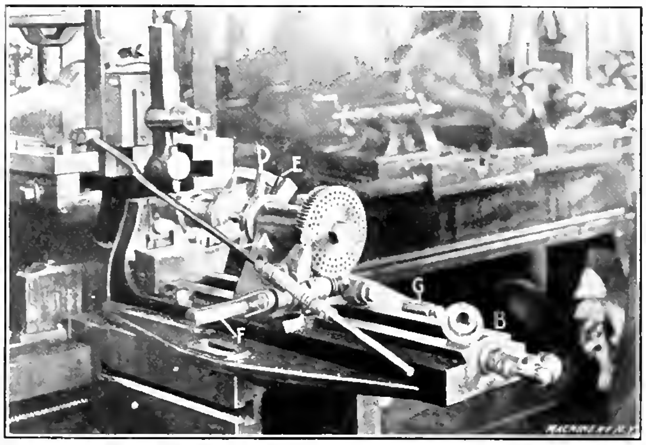

Fig. 6 Shaper Attachment for Cutting Bushings with Solid Keys

the variation in size being obtained by taper gibs which may be firmly locked wherever set. *A* is a block used for marking and gaging while scraping for stroke nuts; *B*, for slides and *C*, for column V's. In using these scraping blocks, the procedure is much the same as in using ordinary flat scraping surface plates, the surface being smeared with lead, the block worked back and forth, and the metal touched up with a hand scraper according to the marking. For scraping in ram slides and ram clamps, as they are too large and heavy to be worked back and forth by hand, the machine shown in Fig. 19 has been especially designed. This scraping machine is portable and may be attached to any shaper under construction. Bolted to the ram head is a bracket which fits into the fork of the rocking arm of the machine in such a way as to be easily lifted out, when it is necessary to lift the ram clear of its bearings, with the chain hoist. Fig. 20 is another view of the machine showing the arm and crank motion, the position of

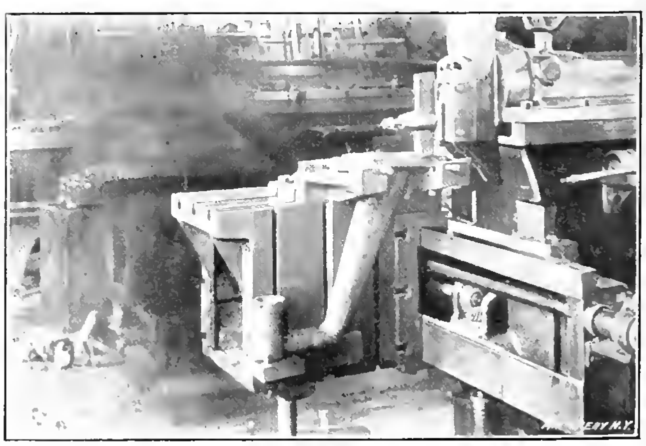

Fig. 9. Special Shaper Fixture

the motor, rheostat and switch, and the gearing.

Turning Gear Blanks and Disks for Setting Cutters—Grooving Solid Journal Boxes

Change gear blanks are first bored out, the hub faced and the keyway cut; then they are placed on a keyed mandrel and

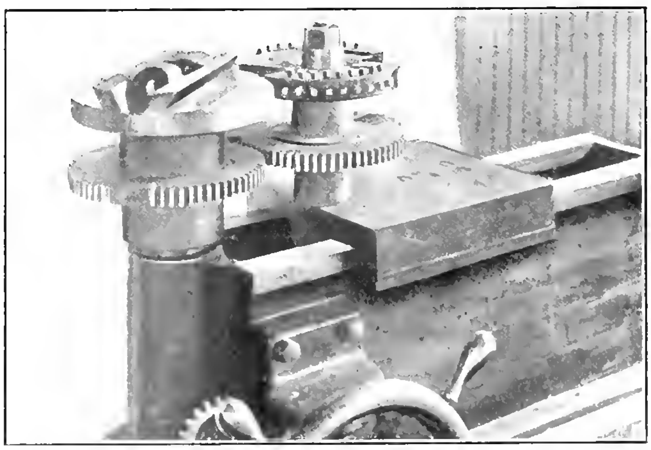

Fig. 15. Enlarged View of Numbering Machine Head

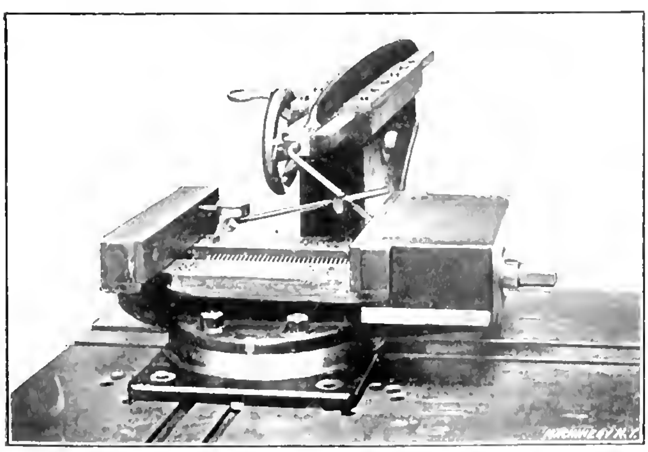

Fig. 16. Shaper Vise-testing Machine—Testing Jaw Faces

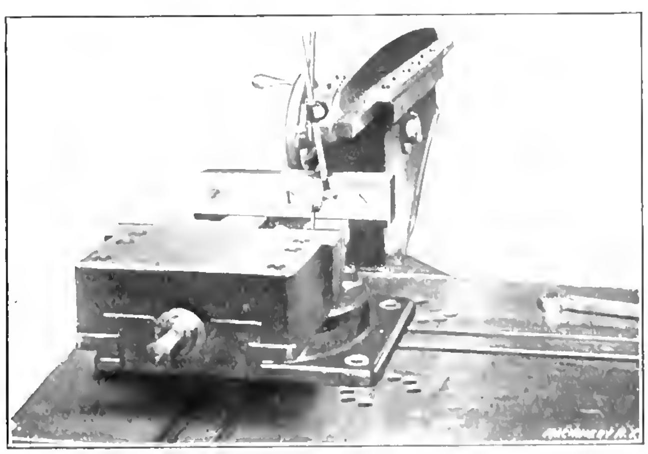

Fig. 17. Testing the Ways of a Shaper Vise

finished in a lathe fitted with a special tool carriage having two sets of tools, a roughing and finishing set, shown in Fig. 23. At *A*, Fig. 21, is a blank in position for roughing and at *B* are a number of mandrels and gear blanks. A gear is pressed on a mandrel while the cut is being taken on the one in the lathe, so as not to lose time. An arbor press which is used for this purpose is conveniently located at *C*.

In cutting gear teeth, it is common practice to set the cutter with the outside diameter of the blank and then raise the table or lower the cutter a certain number of thousandths to secure the right depth of the teeth, but to do away with the errors that are bound to creep in through setting by an off-size blank or miscalculation in the setting, a series of setting blanks, Fig. 24, is used, which are exactly the diameter that the gear for which they are marked should be at the bottom of its teeth, so that if one of these setting blanks is put on a mandrel and placed between the centers, the gear cutter may be set so that it just barely clears the rim and the operator is absolutely certain of its correctness without having to check up his table height or measure the outside of a gear blank when setting.

The principle of the solid journal box oil-grooving device, shown in Fig. 25, which is used on a drill press, has been described before, but it will stand describing again for the benefit of those who haven't seen one. The grooving cutter *A* is set into the holder *B*, which fits into the drill press spindle.

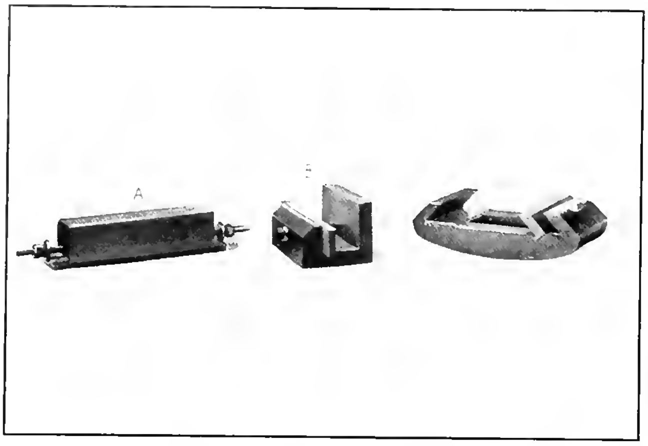

Fig. 18. Test Blocks used in Connection with Scraping

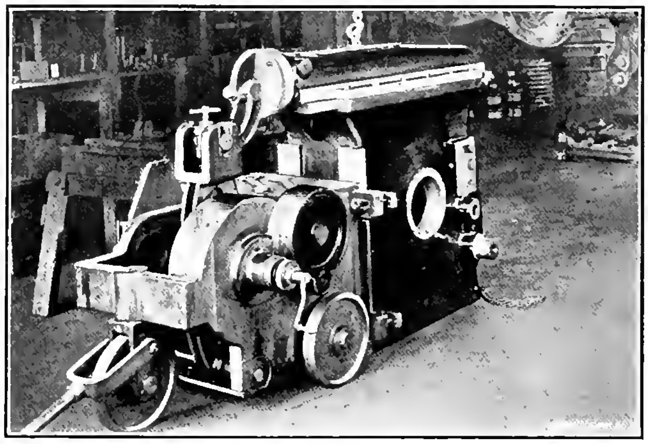

Fig. 19. Portable Machine for Moving the Ram when scraping it

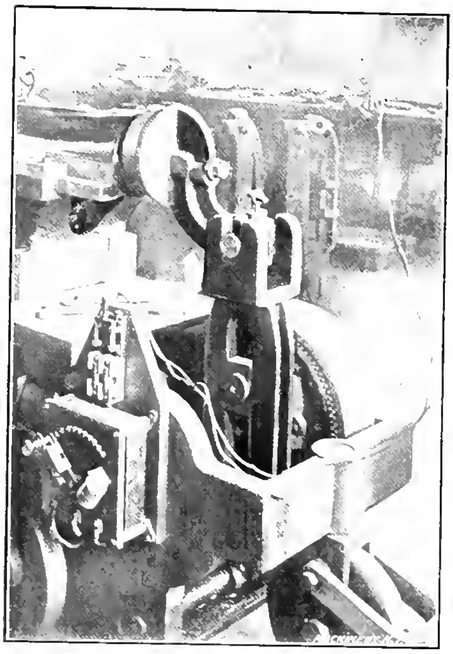

Fig. 20. Enlarged View of the Scraping Machine, showing Starting Box, Slotted Cross-head, etc.

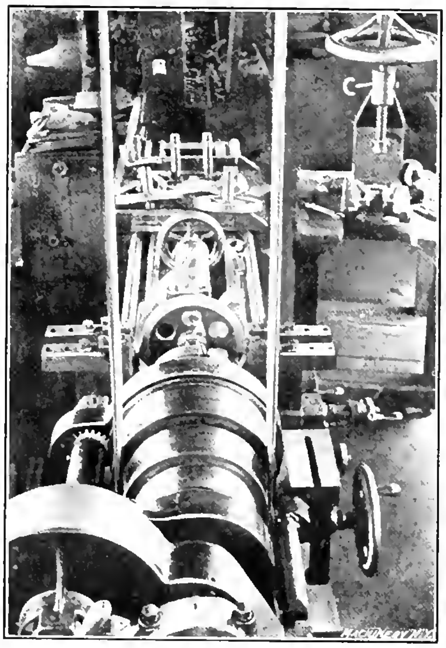

Fig. 21. View of Lathe especially fitted for Turning Gear Blanks

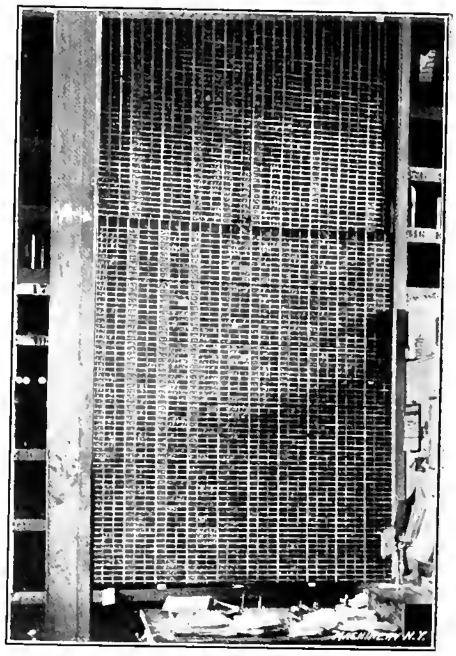

Fig. 22. Counterbalanced Stock Report Boards

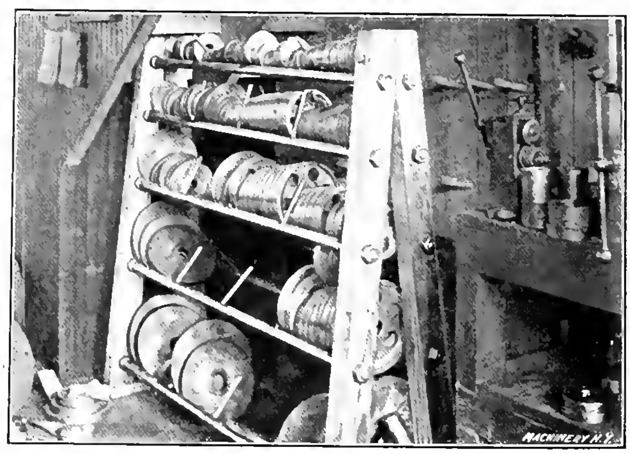

Fig. 24. Disks of Various Sizes for Setting Gear Cutters to Depth

When in use, this holder fits down over the guide *C* which has a long piece *D* in it, something like a key, but which may be forced outward by a taper wedge back of it, operated by pushing in the member *E*; this forces the wedge upward

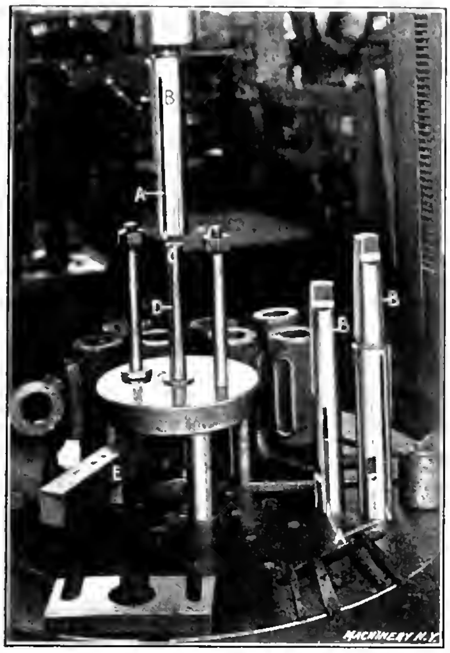

Fig. 25. Fixture for Cutting Oil Grooves in Solid Journal Boxes

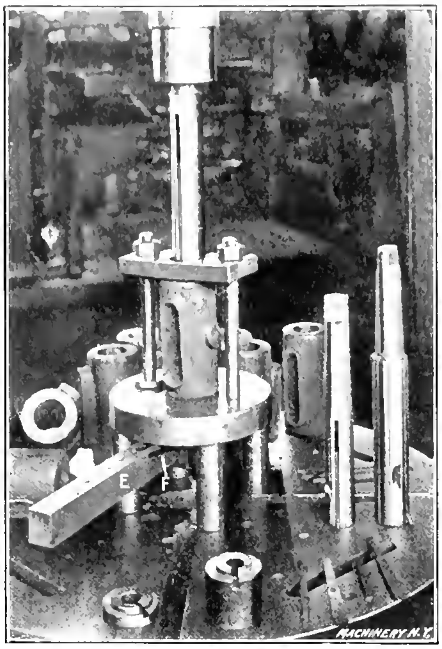

Fig. 26. Oil Groove being cut in Solid Journal Box

and pushes the piece *D* out against the cutter *B*. By working the drill press spindle up and down and gradually pushing in the member *E*, the oil groove is easily cut. Fig. 26 shows a journal box in place, and also shows the slanting slot *F* in the end of part *E* by which the taper wedge is forced upward.

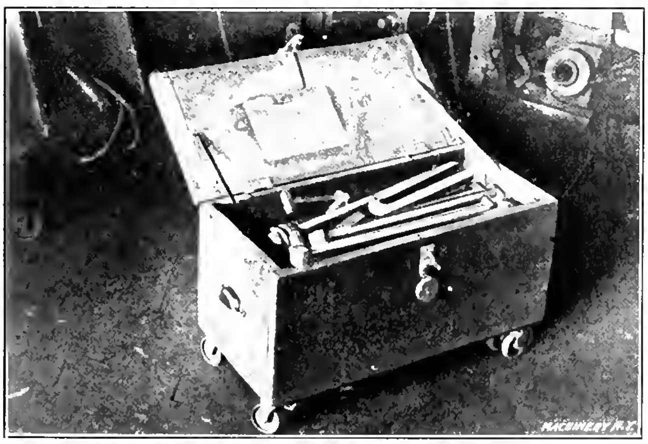

Fig. 28. Type of Chest in which Bolts and Clamps for Each Job are kept

Miscellaneous Devices

The big ruled blackboards which are used to keep track of the number of pieces in stock or orders for the various machine parts, are shown in Fig. 22. These big boards are counterbalanced, like a window, and when one is down where it can be easily read, or chalked in, the others are up out of the way. The first column shows the number of the parts; the second column the number of pieces in stock and the third column the number on order. In the engraving, one full board is shown and, above *A*, a part of another.

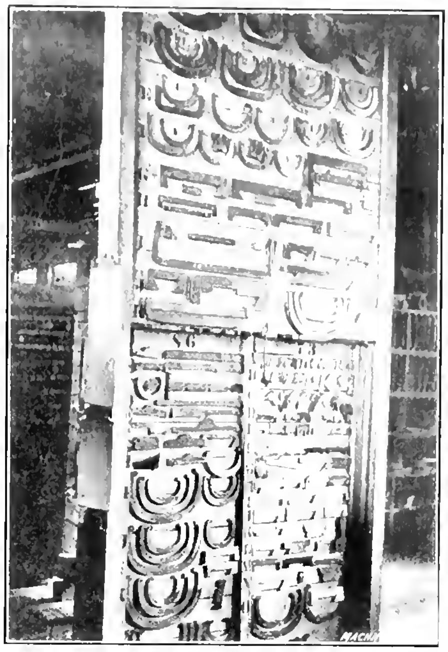

Fig. 27. Counterbalanced Gage Boards

Fig. 27 shows a set of counterbalanced gage boards, which are neat and save a great deal of space as well as trouble, for the boards are easily pulled down and no step ladder is needed to reach the upper ones.

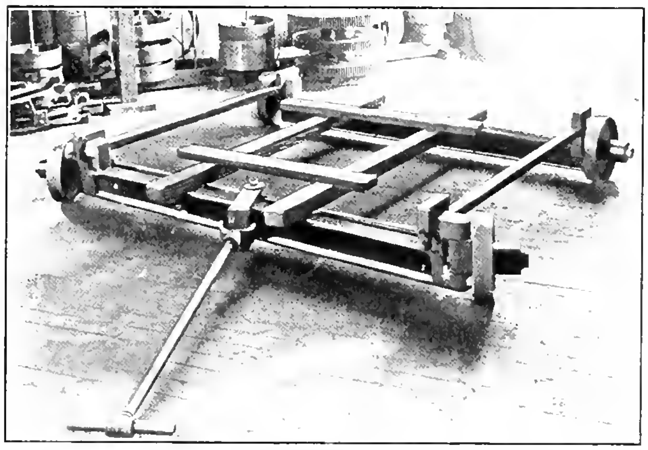

Fig. 29. Heavy Machine Moving Truck

A splendid time- trouble- and temper-saving plan carried out here, is to keep all the bolts, blocks, clamps or wedges, needed to set up any regular job, in a chest (Fig. 28), the key of which is accessible only to those who have a right to it.

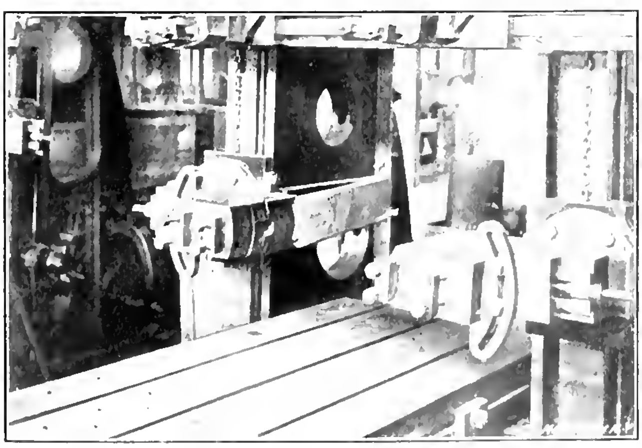

Fig. 30. Planer equipped with Reinforced Side-heads

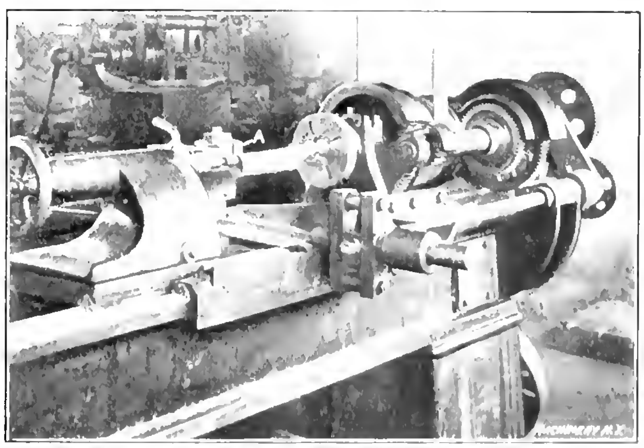

Fig. 31. Lathe with Special Eccentric Turning Attachment and Tool

Each chest is numbered to correspond to the parts to be machined, and as it is on large casters, it is easily rolled from the tool storage room to the machine on which the work is to be done. By this system a man doesn't have to keep a whole junk pile near his machine, from which to dig out his bolts or clamps, with the chance that he won't find what is needed after a half hour's wasted search, and will have to make something or rob his neighbor.

Heavy machines may be easily moved to places not accessible to a crane, by using the truck shown in Fig. 29, which is very low and strong. Special note should be taken of the steering knuckles, the long hubs of the wheels and the method of connecting the two axles.

Fig. 32. Shaper Rams with Brass Caps attached to the Finished Ends for Protection

Fig. 30 shows a planer fitted with special cross-slides and braces for its side heads, in order to secure the proper rigidity for high, narrow work.

In handling shaper rams after the heads have been finished, it has been found impossible to prevent damage to them unless the finished head is protected in some way; for this purpose easily applied brass caps have been made which are put on as shown in Fig. 32.

Instead of using two centers for eccentric work, a lathe has been fitted up as shown in Fig. 31. The mechanism is plainly shown, but the point I wish to bring out is that a single pointed cutting tool will not turn a true eccentric, as the motion of the piece being turned and its relation to the cutting point varies considerably, so that a tool like the one shown at *A* must be used to obtain the desired result.

* * *

PENSION FUND OF THE U. S. STEEL CORPORATION

The United States Steel Corporation announced early in May that it has established a pension fund for its employes. The sum of $8,000,000 has been set aside for this purpose which will be consolidated with a $4,000,000 fund given some years ago by Mr. Andrew Carnegie for the same object. The aggregate amount will be known as the United States Steel and Carnegie Pension Fund, and the net proceeds will be administered by a board of twelve trustees for the benefit of the employes of all subsidiary companies of the United States Steel Corporation. It is understood that under the tentative arrangement for the distribution of the proceeds from the fund, injured employes will receive part of their wages during the time of their disability. Single men are to receive 35 per cent of their wages, and married men 50 per cent, with an extra 5 per cent for each child under 16, and 2 per cent for each year of service over five. For permanent injuries lump sums are provided, based on the extent of the disability. In cases of death, the widow and children will receive 1½ years' wages with an additional 10 per cent for each child under 16, and 3 per cent of each year of service over five.

* * *

Don't let your work fall below inspection par by sacrificing quality for quantity.

DETERMINING DIMENSIONS OF GEARS FROM SAMPLES*

By E. WINSLOW BAXTER†

Many articles have been published in the engineering press on the subject of gearing, and formulas have been given for the solving of the different problems which arise in designing gear transmissions. There is another phase of the subject, however, which is seldom mentioned. This is the duplication of worn out or broken gears sent to the gear cutting shop by the customer who wants a new gear "just like the sample." Often these samples are accompanied by instructions, sketches, or blueprints which render the work of duplication simple, but a large number are sent in by customers to whom all gears are "cog-wheels," and the information needed to reproduce the old gear must be obtained from the sample.

The writer intends to give in the following a few of the methods by which problems of this kind may be solved, although these methods are by no means original. For testing the pitch of gears a prominent firm sells a set of three spur-gear gages having teeth cut on their periphery for all the principal diametral pitches. Such a set of gages is very handy for measuring the pitch of gear samples. However, all gears are not cut with standard diametral pitches. Sometimes they are cut with an odd circular pitch which must be determined by calculation. In the engraving accompanying the table of spur gear formulas is given the nomenclature used for regular involute teeth. All the formulas given in the following are based on the proportions given in the table.

Spur Gears

Assume that we are to reproduce a spur gear, the teeth of which are not worn more than to make it possible to measure the outside diameter with reasonable accuracy. From the known outside diameter and the number of teeth we can find the circular pitch required for selecting the proper cutter for cutting the gear. The formula used is as follows:

$$P' = \frac{3.1416 \times O}{N + 2}$$

Assume, for example, that the sample gear has 18 teeth and that the average of a number of different measurements for the outside diameter taken at different points is 4⅜ inches. Substituting these values in the formula gives:

$$P' = \frac{3.1416 \times 4.375}{18 + 2} = 0.687, \text{ or practically } 11/16 \text{ inch.}$$

When the circular pitch is found it can be approximately converted into standard diametral pitch by tables published in nearly all gear catalogues, and also in MACHINERY'S Reference Series No. 15, "Spur Gearing." The proper cutter to use can then easily be selected.

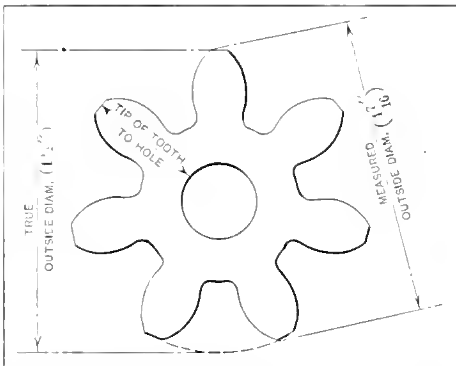

Fig. 1. Method of Measuring the Outside Diameter of a Gear with an Odd Number of Teeth

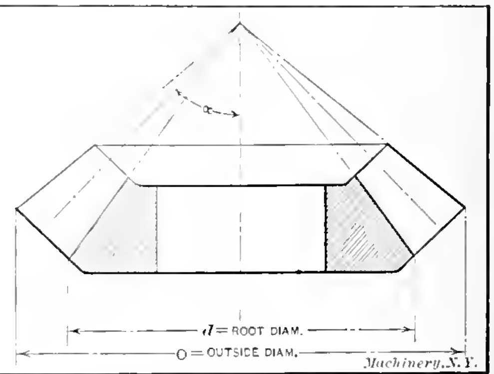

Fig. 2. Nomenclature for Bevel Gears

If the sample gear is worn so that the outside diameter cannot be accurately measured, measure the bottom diameter and substitute in the formula below:

$$P' = \frac{3.1416 \times d}{N - 2.3142}$$

* For additional information relating to gearing, see MACHINERY'S Reference Series, No. 1, "Worm Gearing," No. 15, "Spur Gearing," No. 20, "Spiral Gearing," and No. 37, "Bevel Gearing."

† Address: 33 Flynt St., Norfolk Downs, Quincy, Mass.

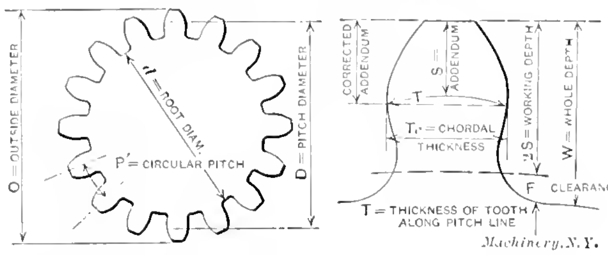
As an example assume that the sample gear has 50 teeth and that the root diameter is 3.97 inches. Then:

$$P' = \frac{3.1416 \times 3.97}{50 - 2.3142} = 0.262 \text{ inch.}$$

This circular pitch corresponds almost exactly to 12 diametral pitch.

If the sample gear has an odd number of teeth and the pitch is coarse, the outside or root diameters cannot be obtained with sufficient accuracy by direct measurement, as plainly shown in Fig. 1. In this case, however, we can measure from the hole to the tip of one tooth, multiply this dimension by 2, and add the diameter of the hole, the total sum then being the true outside diameter.

TABLE OF SPUR GEAR FORMULAS



Name	Symbol	In Terms of No. of Teeth, Diametral Pitch or Pitch Diameter	In Terms of Circular Pitch	In Terms of Diametral Pitch	In Terms of Addendum	In Terms of Thickness

Bevel Gears

In duplicating bevel gears it is necessary to know the number of teeth in the mating gear and the angle of the shafts on which the two gears run. The center or pitch cone angle α (Fig. 2) of the gear must first be found.

Let N_1 = number of teeth in sample,
N_2 = number of teeth in mating gear,
α = pitch cone angle of sample,
γ = shaft angle.

Then for 90-degree shaft angles:

$$\tan \alpha = \frac{N_1}{N_2}$$

For shaft angles of more than 90 degrees:

$$\tan \alpha = \frac{\sin (180^\circ - \gamma)}{\frac{N_2}{N_1} - \cos (180^\circ - \gamma)}$$

For shaft angles of less than 90 degrees:

$$\tan \alpha = \frac{\sin \gamma}{\frac{N_2}{N_1} + \cos \gamma}$$

Having measured the outside diameter and found the center angle, we substitute these in the following formula:

$$P' = \frac{3.1416 \times O}{N + 2 \cos \alpha}$$

If the outside is so worn that we have to work from the root diameter, the following formula is used:

$$P' = \frac{3.1416 \times d}{N - 2.3142 \cos \alpha}$$

If necessary we can caliper to the hole, double the dimension and add the diameter of the hole for finding either the outside or the root diameters as already explained for the spur gears.

Worms and Wormwheels

In the case of a worm and wormwheel it is a simple matter to find the circular pitch, as it equals the distance from one worm thread to another in a line parallel with the axis of the worm. The lead equals the advance of one thread in one revolution. When the circular pitch and the outside diameter are known, then:

Pitch diam. of worm = outside diam — $0.6366\ P'$

$$\text{Tangent of thread angle} = \frac{\text{lead} \times 0.3183}{\text{pitch diameter of worm}}$$

In the case of a wormwheel, we should always determine the dimensions of the worm before starting to replace the gear, and should always know the center distance between the worm- and wheel-shafts, as the throat diameter of the wormwheel is seldom correct. The gear, therefore, should not be hobbed so as to get the same throat diameter as the sample worm-gear, but it should be hobbed with the hob corresponding to the mating worm at the correct center distance at which worm and wheel will run.

Spiral Gears

The following formulas may be used for finding the pitch diameter of spiral gears, when the outside or root diameter, the angle of the teeth with the axis of the gear, and the number of teeth are known. Let:

D = pitch diameter,
N = number of teeth,
α = angle of teeth with axis of gear,
O = measured outside diameter,
d = measured root diameter.

Then:

$$D = \frac{N \times O}{N + 2 \cos \alpha} = \frac{N \times d}{N - 2.3142 \cos \alpha}$$

The formulas given above are in all cases, of course, derived from the regular formulas for standard gears.

* * *

The following receipt for a non-shrinking alloy was recently published in the *Metal Industry*: Tin, 50 pounds, and zinc 50 pounds, gives a tough, hard metal that runs well. It is improved by the addition of 2 pounds of bismuth. By the use of heavy sprues, and by pouring cold, the slight shrinkage may be largely overcome.

PRIMITIVE BORING MACHINES

By JOSEPH G. HORNER*

In the French encyclopedia of D'Alembert and Diderot (1777) a drawing is shown of a machine for boring a cannon. (See Plate I.) A building with stone walls, supporting a single span ridge timber roof is provided with a central tower extending to a considerable height above the ridge. From horizontal beams *L* in this tower, pulley blocks *K* are hung, the lower blocks being attached to a sliding timber framing carrying the gun *H* to be bored, and sliding between vertical timber guides *Ff*, reaching from the floor up into the tower. These guides keep the gun to be bored in a fixed position in its framing throughout its vertical movements. It is suspended, mouth downwards over the boring tool, which is simply rotated. The feed is imparted to the gun as follows: The falls of the two ropes which come from the two upper blocks *K* of the suspended tackle are wound round a small drum

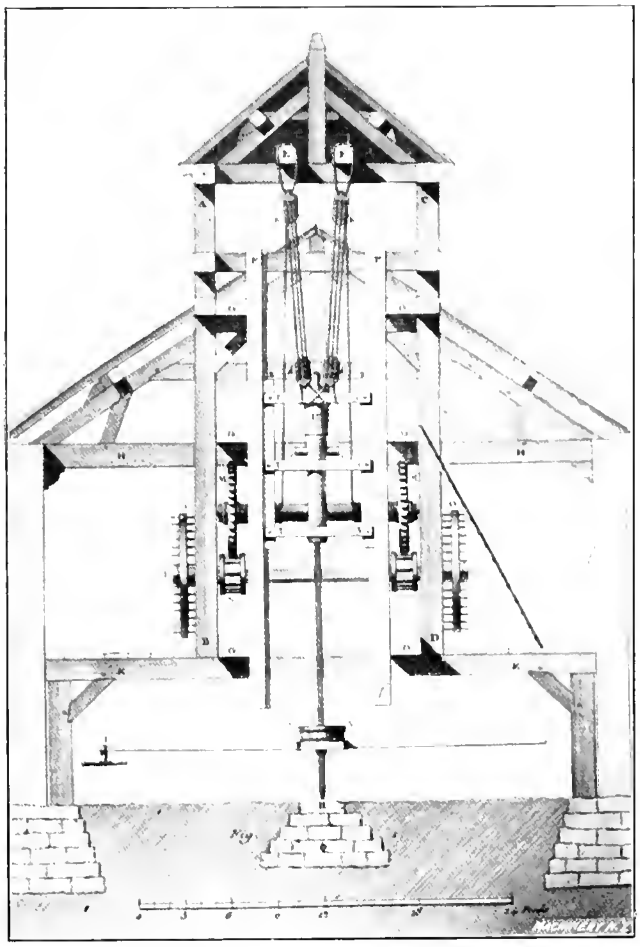

Plate I. A Gun Boring Machine of Large Proportions—Model of 1760

of several feet in length, the journals of which are carried in bearings on the uprights which carry the tower. The drum is rotated very slowly through two pairs of gears *M* and *N*, consisting of trundle pinions on a first motion shaft, and wooden cog-wheels on the drum shaft. The pinion shaft is turned by large wheels *O* on the shaft *P* with projecting pins arranged all around their peripheries. The down-feed of the gun in its sliding frame is thus controlled while boring.

The boring appliances are shown in detail in Plate II. Fig. 2 in this plate shows the vertical stem of the boring arbor broken off and carried up at *B*, and stepped into a bearing *R* below, which rests on masonry. It is rotated by a long lever with a loose handle seen at the right-hand end in Plate II, and at the left-hand end at *T* in Plate I, by which a workman or a horse pulls it around in a circle.

The remainder of the illustrations in Plate II show the boring tools, which are mostly reamers with inserted blades or milling cutters in embryo. Fig. 3 shows the boring tool *A*, having a four-sided tapered recess at *D* to fit over the end *b* of the arbor *B*. The end *A* is hemispherical, and is channeled. At the lower part of the plate the numbers 1, 4, 8, 12, 16 and 24 represent different bodies of copper which carry steel cutters to fit on the arbor *B*, the largest ones being used for finishing the bores. The tool No. 1 is used first, followed by the boring tool *A*, Fig. 3, after which the larger tools are used

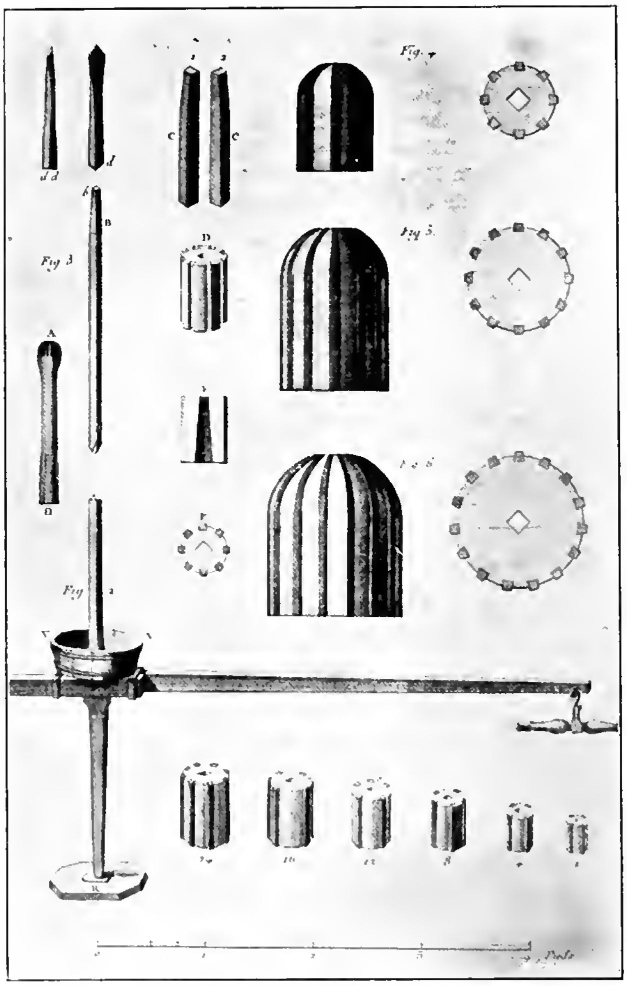

Plate II. Tools used for Boring Guns in France a Century and a Half ago

by which the diameter of the bore is gradually augmented until the boring is terminated. The details of tool 24 are shown above it; *F* is its plan, *E* its axial section, and *D* the

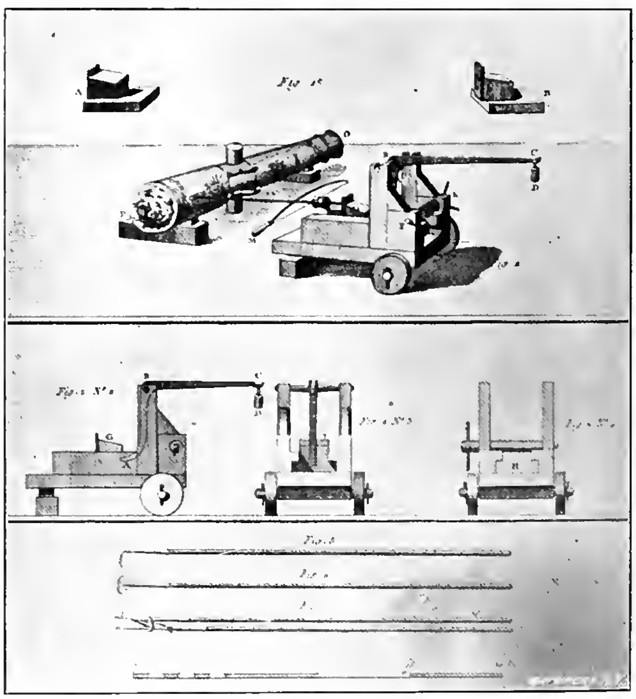

Plate III. A Portable Drilling and Boring Machine with Automatic Feed—Early French Type

body without its cutters. At *C* are seen two of the eight cutters drawn to a twice enlarged scale. The ends are bent, it is stated, for giving to the tool an opportunity to enter the bore.

Figs. 4, 5 and 6 illustrate boring tools for mortars of differ-

* Address: 45 Sydney Buildings, Bath, England.—See biographical note, MACHINERY, May, 1908.

ent calibers. The plan end views, showing the dovetailed setting of the cutters, are seen to the right.

The illustration at the top in Plate III shows the drilling of the touch holes in the cannon, and is an example of an early form of portable drill. The cannon which is being bored is supported on timber blocking, with wedge pieces, and the hole is being made with a fiddle drill, the bow being seen at *M*. The pressure against the drill is imparted by the lever *BC*, weighted at *D* as required. The block *G* takes the pressure of the pointed rear end of the drill. The shape of this block is seen at *A* and *B* above, giving front and rear views, the iron plate with its holes being shown at *B*. The axle *EF*, with a cross handle has a cord wound round it, the function of which is to withdraw the drill from the hole. In the middle view, Plate III, are shown side, front, and back views of the portable drilling frame.

NEW DESIGN OF HYDRAULIC CYLINDER GLANDS

By BENJAMIN BROWNSTEIN

The repacking of cylinders of large hydraulic presses of the type shown in Fig. 1 is not an easy and convenient matter, especially when the stroke is short and the cylinders large. The pressure on the rams of these presses ranges from 2000 pounds per square inch upward.

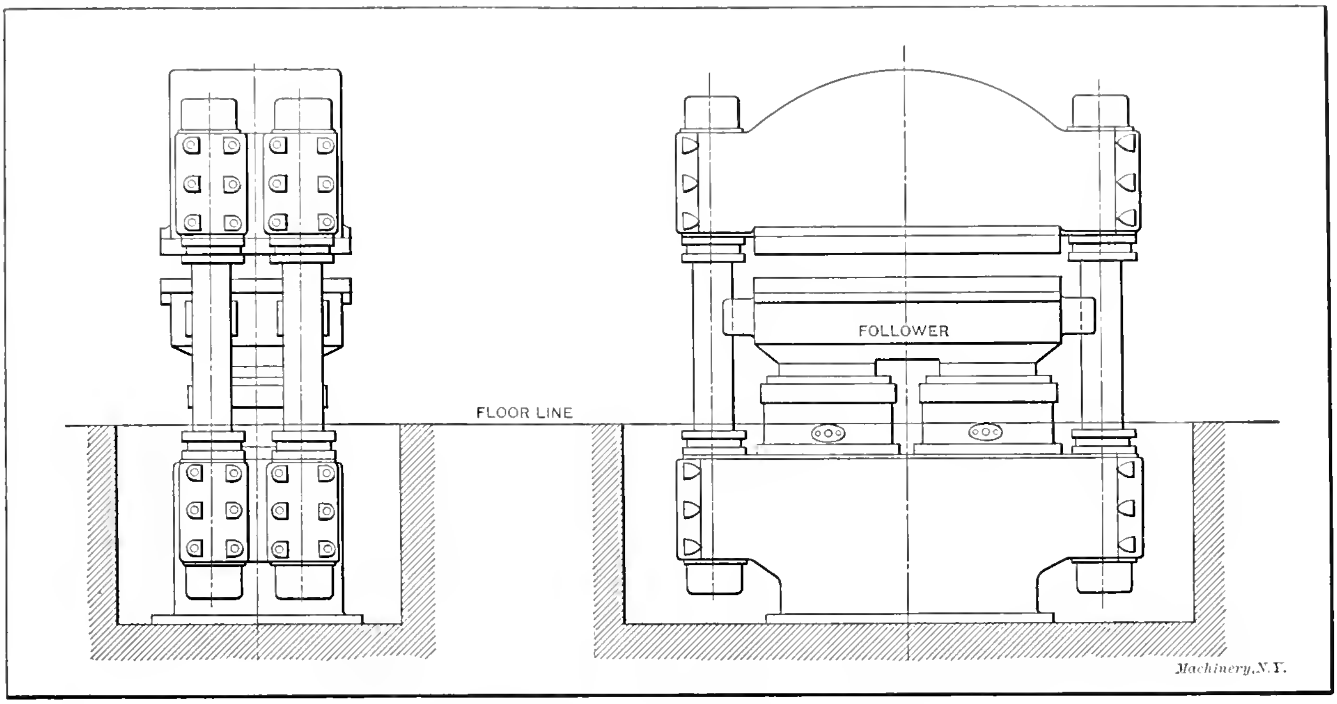

Fig. 1. Large Hydraulic Press of a Type Presenting Difficulties in Repacking the Cylinders

The usual design of the cylinder and gland is shown in Fig. 2. The gland is held down by a considerable number of studs and nuts which resist the upward pressure of the water acting on the packing at the bottom of the gland. When repacking this type of cylinder and gland, the follower is raised up from the rams and the nuts removed. This work is not very easily done, especially when the nuts are rusted

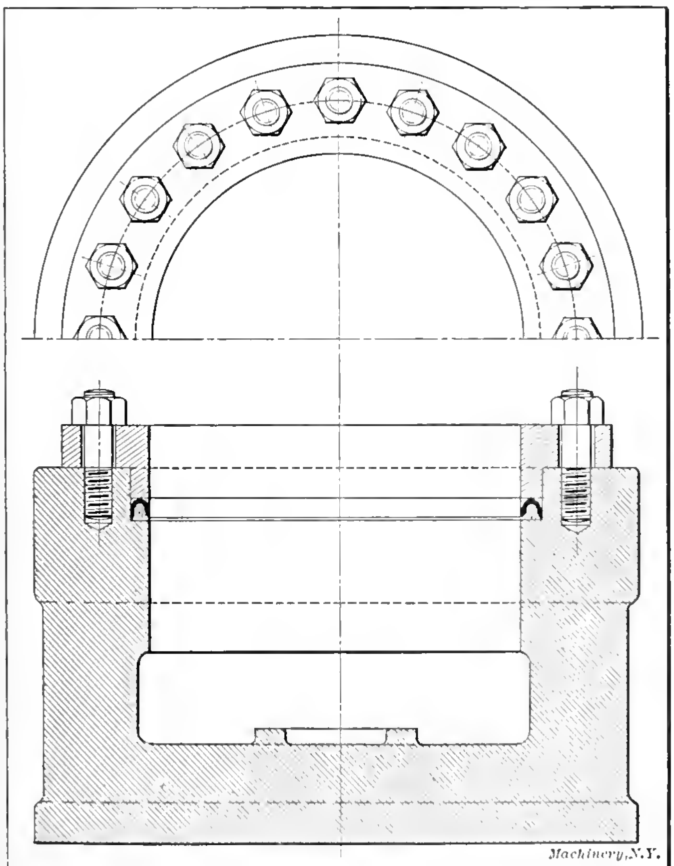

Fig. 2. Usual Design of Cylinder and Gland

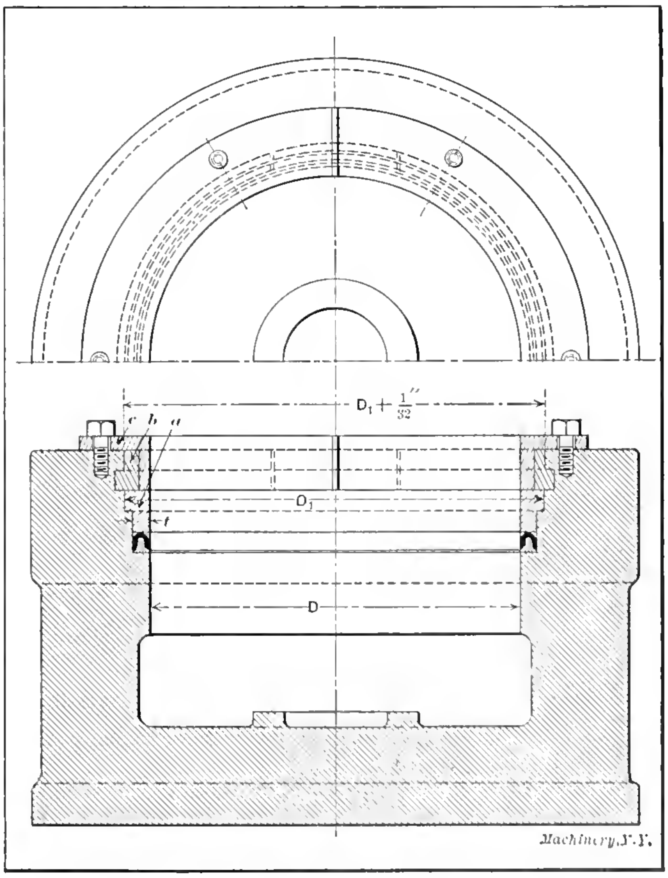

Fig. 3. Improved Design, Facilitating Repacking

in place, and when the space available prevents the use of a good-sized wrench. In many cases it is found more convenient to remove the cylinder with the ram and other parts from the press in order to repack it. Difficulty is also met with when replacing the gland and screwing the nuts home. If the nuts are not screwed down so that the tension on all the studs is equal, the load is thrown entirely upon those studs which are in greater tension.

The design of the hydraulic cylinder glands shown in Figs. 3 and 4 eliminates the troublesome studs and nuts; it allows the cylinder to be repacked without taking the press apart (the follower is simply raised up from the rams); it is stronger than the design with the greater number of studs,

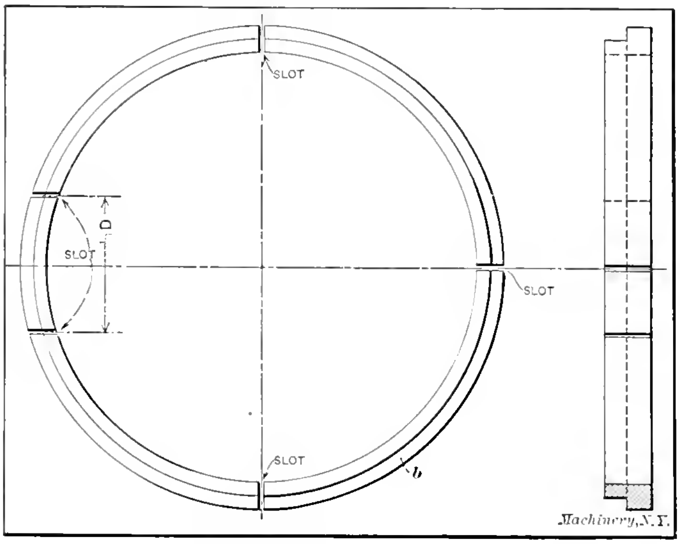

Fig. 4. Detail of Gland Bushing

as can be easily seen from studying the illustration Fig. 3, and is, therefore, capable of carrying a greater pressure and will give less trouble. In Fig. 3 is shown a section of the cylinder and cylinder gland. The gland is divided into three parts, *a* the bottom gland, *b* a gland bushing which is shown in detail in Fig. 4, and *c* the top gland. The bottom gland *a* is made solid and put in after the leather and hemp packing is inserted in its proper place. Then the gland bushing *b* is

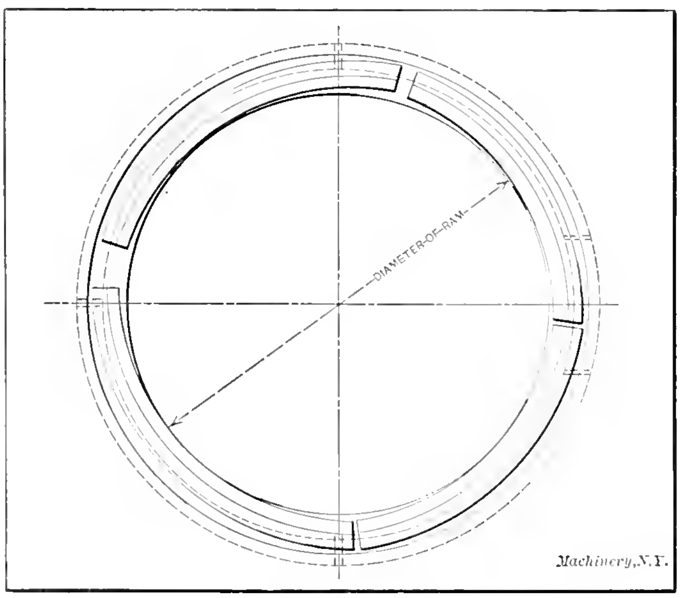

Fig. 5. Diagram showing how Bushing Sections can easily be removed and replaced

put into place. This bushing is made in five or more sections as shown in Fig. 4, according to the diameter of the cylinder and the thickness of the parts making up the gland. By making the bushing in this way the sections can easily be put in or taken out without removing the ram from the cylinder as will be apparent from a little study of the engraving Fig. 5.

The top gland *c* which is shown split but which can be made solid if the design of the press allows it, is then put into place and held down with two, four or six cap-screws or studs and nuts, as desired, the number of screws depending upon the size of the cylinder. It will be seen in Fig. 3 that this design of gland and cylinder eliminates the difficulties common to the general design shown in Fig. 2. This method of packing is superior in every way.

It is not possible to give all the proportions of the gland, as the most important factors, the diameter of the cylinder and the pressure per square inch are variable quantities, but the following may be stated as a general formula for calculating the stress on the gland.

Let P = pressure per square inch on ram,
t = thickness of bottom gland = width of packing,
P_1 = total pressure on gland *a* per inch of mean circumference,
S = safe shearing stress of flange of gland bushing *b*.

Then

$$P_1 = Pt, \text{ and } t = \frac{P_1}{S}.$$

AEROPLANE FLIGHT FROM LONDON TO MANCHESTER

A new record in aviation was established by Louis Paulhan, the French aviator, April 27 and 28, when making a flight from London to Manchester, England, and thereby winning a prize of $50,000 offered by the *Daily Mail*. According to the rules of the prize it was to be paid to the first aviator who traversed this distance of 185 miles, making only two stops and completing the journey in twenty-four hours. This is the greatest feat so far performed in aviation and is rewarded by the largest sum offered as an aviation prize. Mr. Paulhan started from London at 5.31 P. M., April 27, and continued in one uninterrupted flight as far as Litchfield, where he arrived at 8.10 P. M., after having covered 117 miles in two hours and thirty-nine minutes at an average speed of 44 miles per hour. From this point he resumed his journey at 4.9 A. M. the following morning, and arrived at Didsbury, near Manchester, at 5.30, completing the remaining 66 miles of the journey in 81 minutes at an average speed of 48.8 miles per hour. Mr. Paulhan competed with Mr. Grahame White, an Englishman, for this prize. Mr. White's efforts also deserve to be recorded. He started from London at 6.33 P. M. and stopped at Roade, 60 miles away at 7.55 P. M. In an effort to over-reach his rival he resumed his flight in the dark at 2.50 A. M., but had to again descend at 4.30 A. M. Starting again at 5.02 A. M. he found the wind conditions so adverse that he was compelled to descend at Litchfield at 5.20 A. M. for a second time.

Mr. Paulhan now holds both the long-distance record and the altitude record for aeroplanes. The week before his flight from London to Manchester he went a distance of 130 miles "cross-country" in France without alighting. At Los Angeles last January he won the altitude record for the heavier-than-air machines, rising to a height of 5000 feet.

ARTIFICIAL RUBBER

Dr. Carl Harries, professor of chemistry at the University of Kiel, Germany, has discovered a process of making artificial rubber. The product is said to have all the characteristics of natural rubber. The importance of the discovery to the automobile world can hardly be overestimated. The enormous consumption of rubber in the manufacture of tires has jumped to a price of $2.50 or more a pound, for pure Para rubber, from about 75 cents a pound less than two years ago. It is said that the artificial rubber is as tough and elastic as the natural product, and is a light brown to white in color. At present the manufacture is very costly, but it is expected that the process will be so simplified and cheapened as to produce the artificial rubber cheaper than the natural rubber. It is anticipated by some optimistic persons that the natural rubber industry will eventually suffer the same fate as that of the natural indigo industry. To-day artificial indigo, manufactured by German chemists, has virtually ousted the natural article from the market entirely.

THREADING OPERATIONS—2

PRACTICE FOR THE BROWN & SHARPE AUTOMATIC SCREW MACHINE

By DOUGLAS T. HAMILTON*

The producing of a correct lobe on the cam for threading, and a knowledge of the various threading attachments and devices used, is essential, as was explained in the previous installment, but careful consideration should also be exercised in the selection of suitable dies and taps if good results are to be expected. The nature of the material to be threaded, of

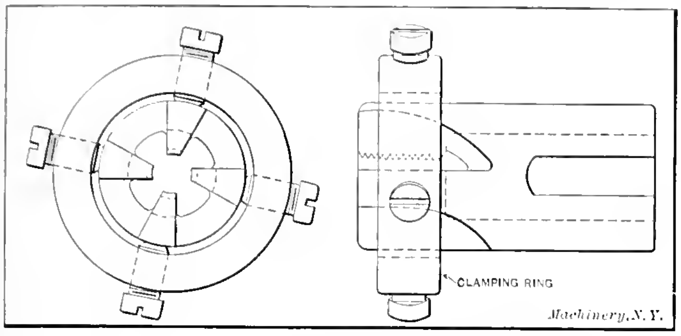

Fig. 11. Spring Screw Threading Die and Adjusting Ring

course, governs to a certain extent the particular design of die or tap to use. The various types of dies and taps, and die and tap holders, will be briefly reviewed.

Spring Screw Threading Dies

In Fig. 11 is shown a common form of spring screw threading die with its adjustable ring. Dies of this type are used to a large extent on the Brown & Sharpe automatics, but the results obtained are not always entirely satisfactory. There are a number of objections to this type of die, some of which are here given. The common method of making these dies is to hob them out with a tap larger in diameter than the basic screw and then close them in by means of the

TABLE VI. ADJUSTABLE ROUND SPLIT SCREW THREAD BUTTON DIE SIZES FOR A. S. M. E. STANDARD SCREWS

0.450 — 14	0.450	0.4036	0.3495

adjusting ring shown. This produces an imperfect thread if a tap much larger in diameter than the basic size of the screw is used. The correct method of tapping out a die of this kind is to use a taper tap which gives clearance at the back of the die, as is necessary. This necessitates the making of taper taps, as can be easily seen, which adds to the expense of the die. This type of die is also difficult to harden without springing the prongs, thus causing chattering and producing a thread which is not spherical in shape. Making a die with three prongs or cutting edges obviates chattering and produces a more nearly perfect thread. When cutting a small screw, the work sometimes breaks off in the die, leaving it practically useless, because in drilling the broken pieces out, the thread in the die is sacrificed in most cases. A type of die which overcomes this latter objection is shown in Fig. 12, the die here shown being split, allowing the broken screw to be easily removed. The location of the cutting edges on spring screw threading dies should be radial for brass, and about 0.1 of the diameter ahead of the center for Norway iron, machine steel, etc.

*Associate Editor of MACHINERY.

Adjustable Round Split Screw Threading Dies

This form of die has an advantage over the spring screw threading die for the following reasons: It can be hardened without springing out of shape, and can be held more rigidly, which produces good results; and although it cannot be ground to advantage, its first cost is so much less that it can be discarded when dull. On account of the rigid manner in which this die can be held, the cutting edges in all cases can be located ahead of the center about 0.1 of the diameter which gives good results. An improved method of laying out button dies was described in the March, 1909, issue of MACHINERY.

In Fig. 13 is shown a type of adjustable round split button die as used by the Northern Electric & Mfg. Co., Ltd., of Montreal. This type of die has been found to give such favorable results that it is used by this firm in preference to all the other types for screw machine work. In Tables VI and VII are given the sizes as used by the above firm in making their

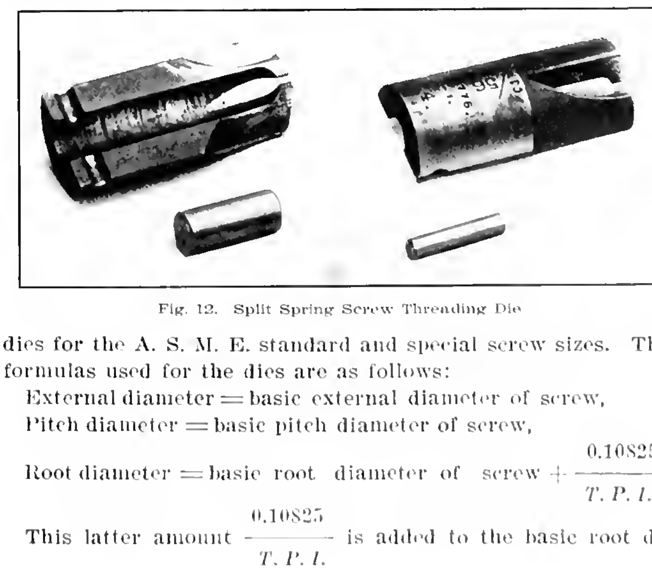

Fig. 12. Split Spring Screw Threading Die

dies for the A. S. M. E. standard and special screw sizes. The formulas used for the dies are as follows:

External diameter = basic external diameter of screw,

Pitch diameter = basic pitch diameter of screw,

$$\text{Root diameter} = \text{basic root diameter of screw} + \frac{0.10825}{T.\,P.\,I.}.$$

This latter amount $\frac{0.10825}{T.\,P.\,I.}$ is added to the basic root di-

ameter to provide for wear. While the sizes as given have been used by the firm mentioned, for a considerable time, theoretically it is not the correct way of making the die, because, to cut a clean thread, a die should have clearance as shown at *a*, Fig. 14, and as a screw is generally cut below the maximum diameter, the sizes as given would not provide any clearance at all; in fact it would be just the reverse, as the die would have to be closed, instead of opened up. The writer would suggest that when good results are desired the die should be tapped out smaller than the basic screw, and then opened up, as this would give a good clearance as shown enlarged for clearness at *a*, Fig. 14. Making the root diameter of the die the same as the minimum screw would give the desired results. This has been experimented with and the results obtained were perfectly satisfactory. The following formulas should be used for obtaining the sizes of adjustable round split button dies:

External diameter = basic external diameter of screw,

Pitch diameter = minimum pitch diameter of screw, or

$$\text{basic pitch diameter of screw} - \frac{0.168}{T.P.I.+40},$$

Root diameter = minimum root diameter of screw or basic

$$\text{root diameter} - \left(\frac{0.10825}{T.P.I.} + \frac{0.168}{T.P.I.+40}\right)$$

Making the external diameter equal to the basic external diameter allows for clearance, which is necessary, as the external diameter of the die should not be used for cutting the screw to size. This should be accomplished either by a finishing box-tool or by the cross-slide forming tools. It is obvious that making the dies to the sizes given in the formulas permits them to be used longer and still cut a clean thread. The work should be turned slightly smaller than the finish diameter required, depending on the material and the pitch of the thread.

Machine Taps

Internal threading is more difficult to accomplish than external threading on the automatic; the reason for this is, of course, that the tap, when it once enters the work, cannot be reversed to relieve the clogging of the chips, as can be done in hand tapping. The spindle also, revolving at a high rate of speed, has a tendency to break the tap—it is at this point that the tap generally breaks, as the chips lodging in the flutes of the tap prevent it from reversing. For this reason the land should be just strong enough to resist the cutting pressure, leaving plenty of chip space without reducing the cross-section of the tap too much. The flutes in the tap are generally cut radially with the center, and slightly deeper than the root of the thread, the amount, of course, varying according to the diameter of the tap and the pitch of the thread. For brass work the ordinary tap is generally used with the teeth cut radially with the center. In Tables VIII and IX are given the manufacturing limits, as adopted by the Northern Electric & Mfg. Co., Ltd., Montreal, for the A. S. M. E. standard and special sizes. The taps are made from Stubbs' imported drill rod. The diameters of shank used are given in the tables, and also the length of the threaded portion and the overall length. All taps 0.100 inch diameter and less have three flutes, and all taps over 0.100 inch diameter have four flutes. The formulas used by the above firm for the manufacturing limits are as follows:

TABLE X. FORMULAS FOR FINDING MANUFACTURING LIMITS FOR TAP AND DIE SIZES

No. of Threads Per Inch	Value of $\frac{0.10825''}{T.P.I.}$	Value of $\frac{0.112''}{T.P.I.+40}$	Value of $\frac{0.224''}{T.P.I.+40}$	Value of $\frac{0.336''}{T.P.I.+40}$	Value of $\frac{0.168''}{T.P.I.+40}$	Value of $\frac{0.6495''}{T.P.I.}$	Value of $\frac{1.2990''}{T.P.I.}$

14	0.0077	0.0021	0.0041	0.0062	0.0031	0.0464	0.0928

External diameter:

$$\text{Maximum} = \text{basic external diameter of screw} + \left(\frac{0.10825}{T.P.I.} + \frac{0.224}{T.P.I.+40}\right)$$

$$\text{Minimum} = \text{basic external diameter of screw} + \left(\frac{0.10825}{T.P.I.} + \frac{0.112}{T.P.I.+40}\right)$$

Pitch diameter:

$$\text{Maximum} = \text{basic pitch diameter of screw} + \frac{0.224}{T.P.I. + 40}$$

$$\text{Minimum} = \text{basic pitch diameter of screw} + \frac{0.168}{T.P.I. + 40}$$

Root diameter:

$$\text{Maximum} = \text{basic root diameter of screw} + \frac{0.336}{T.P.I. + 40}$$

$$\text{Minimum} = \text{basic root diameter of screw} + \frac{0.112}{T.P.I. + 40}$$

The only changes from the A. S. M. E. formulas (see MACHINERY, December, 1907) for the taps are the minimum external diameter, and the minimum pitch diameters. The reason for increasing the minimum external diameters can easily be seen by comparing the results as obtained by the formulas used by the Northern Electric & Mfg. Co. and the A. S. M. E. respectively. For example: Take a tap 0.164—36 pitch. The minimum external diameter given by the A. S. M. E. is 0.1656 inch. Now the maximum or basic screw is 0.164 inch. This leaves 0.0016 inch for wear, when the tap has been made the minimum size. This amount has been found not to be sufficient. The minimum external diameter, as found by the formula used by the Northern Electric & Mfg. Co., is 0.1685 inch, which gives 0.0045 inch over the basic screw. As will also be noted, this decreases the limit between the maximum and minimum external diameters of the tap, allowing only 0.0014 inch. In all cases the limits as derived by these formulas have been found to be sufficient. It will also be noted that the minimum pitch diameter is also increased to extend the life of the tap. In Table X the results as obtained by the various formulas are given, which simplifies the calculations necessary in determining the limits, as the amounts given are added to the basic sizes of the screw. In the last two columns are given the single and double depth of the thread.

As has previously been mentioned, an ordinary machine tap is suitable for cutting brass, but it does not give satisfactory resnlts when tapping Norway iron, machine steel, etc. In Fig. 15 is shown a tap which gives good results in threading Norway iron or machine steel. This tap should be slightly tapered towards the back for clearance, and also to eliminate friction. The end is ground at an angle of about 55 degrees, and slightly cupped at the center, aud backed off as shown. A groove, as shown, is ground the entire length of the threaded portion, after the tap has been hardened. This allows the oil to penetrate to the point in threading, and also provides clearance for the chips to back out. When made from Stubbs' imported drill rod and carefully hardened, this tap can be worked at from 35 to 40 surface feet per minute, which would be impossible with an ordinary tap. Taps for threading copper have their flutes cut spirally and should also have an odd number of flutes. A right-hand spiral about one turn in 12 inches should be used.

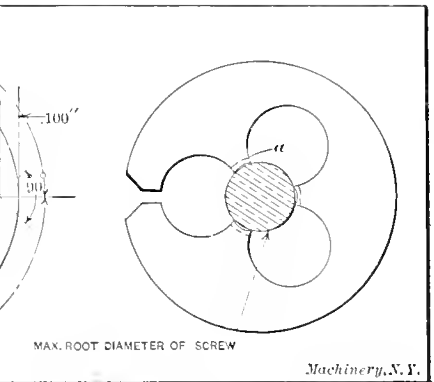

Fig. 14. Illustration showing Clearance for Adjustable Round Split Button Dies

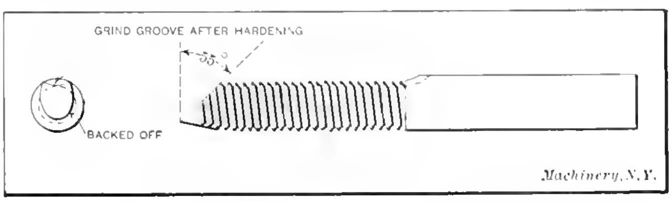

Fig. 15. A Suitable Tap for Norway Iron and Machine Steel

Tapping Drills

The tapping size drills as recommended by the A. S. M. E. are not suitable for general work, as I presume many who have experimented with them have learned to their sorrow. The question of tapping drills cannot be settled by giving a table and saying that the sizes therein contained are the best.

Of course, to a certain extent, the sizes used in various shops do not vary greatly, but nevertheless there is really no standard size. Considering this the writer submits a list of tapping size drills which have been adopted by the Northern Electric & Mfg. Co. for general work. These sizes have given good results in practice. The sizes as given in Table XI are used for all classes of work and material. The amount of thread obtained by these sizes is from ⅝ to ¾ of a full thread.

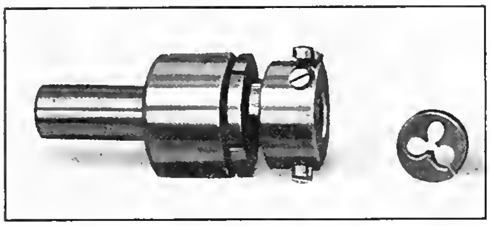

Fig. 16. Button Die Holder of the Draw-out Type

Speeds for Dies and Taps

As a general rule, a die can be operated at a higher rate of speed than a tap, for the following reasons: A die can be left harder than a tap on account of the weak cross-section of the tap, and as the tap is easier to re-sharpen, it can therefore, be left softer. Another reason is that the die can be supplied with oil much easier than can the tap. The following surface speeds have been found suitable for taps and dies made from ordinary carbon steel and used on the materials specified:

Surface Speeds for Dies

Material	Feet per Minute
Brass (ordinary quality)	190-200
Norway iron and machine steel	30-40
Drill rod and tool steel	20-30

Surface Speeds for Taps

Material	Feet per Minute
Brass (ordinary quality)	150-160
Norway iron and machine steel	25-30
Drill rod and tool steel	15-20

When the diameter of the tap and the surface feet per minute are given, the revolutions of the spindle can be found by the following formula:

$$R = \frac{12 \times S}{D \times \pi}$$

where R = revolutions of the spindle,
S = surface feet per minute,
D = external diameter of tap or die.

When the surface speed and diameters are required the formula takes the following forms:

$$S = \frac{\pi \times D \times R}{12} \text{ or } D = \frac{S \times 12}{R \times \pi}$$

Die and Tap Holders

The manner in which a die or tap is held when being applied to the work has a considerable bearing on the results obtained. For this reason careful consideration should be exercised when deciding on the type of die or tap holder to be used. The die or tap holders as supplied by the Brown & Sharpe Mfg. Co. give satisfactory results in most cases, and, therefore, the writer would suggest that for general automatic work these holders should be used. In Fig. 16 is shown a button die holder of the draw-out type, as made by the above firm. This holder gives good results when the work is not required to be threaded up to a shoulder. In Fig. 17 is shown an improved design of releasing button die holder also made by this firm, a section through the holder being shown at *A*. The main feature of this die holder is that it can be reversed without shock; therefore, when threading small screws it has less tendency to break the screw off in the die. At *B* and *C* are shown two views taken from the cross-section *X Y*. At *B* and *C* are also shown two small balls *e* which are used, allowing this die holder to reverse without shock. The operation of this die holder is as follows: When the die holder or spindle *a* draws out from the body *b*, the driving pins *c* are also withdrawn so that the radius on the end of these pins is drawn out flush with the plate *m*. Thus when the machine spindle is reversed the spindle *a* revolves with the work, the centrifugal force throwing the ball *e* out of the deep part of the pocket as shown at *B* into the position as shown at *C*. This locks the holder, allowing it to be backed off the work. This holder can be used either for right- or

left-hand threading simply by inserting the balls *e* in the various pockets, *e. g.*, when ball *e* is placed in pocket *f* it will cut a right-hand thread, and when placed in pocket *g* it will cut a left-hand thread. This holder is used to advantage especially when cutting up to a shoulder. In Fig. 18 is shown a releasing tap holder. The spindle *A* carries a pawl *a*, which is held back against the shoulder *C* by the spring *b*. When the spindle *A* draws out, the bevel portion on the pawl *a* allows it to slide past the block *B*, thus allowing the spindle *A* to make one revolution when the opposite face of pawl *b* comes in contact with the block *B*, thus allowing the tap to back out of the work. A blank bushing *d* is shown in the holder.

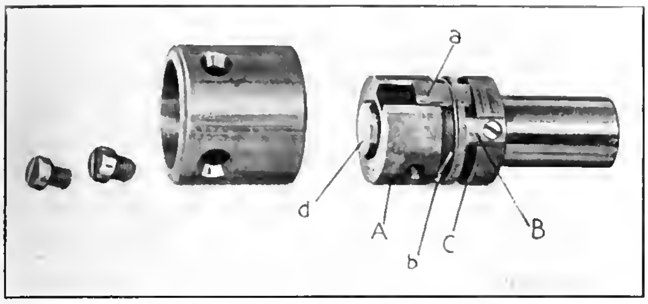

Fig. 18. Releasing Tap Holder

Using Two Taps

When a full thread is desired and the size of the tap will not stand the cutting pressure, it is sometimes found convenient to use two taps. The first tap should be ground tapered somewhat similar to a starting tap which is used for hand tapping. The taper should extend back equal to the distance that the tap is to go into the work so that the first thread left in the work will be to the full diameter. The second tap is left with a full thread. To set the taps, the dogs on the drum should be set so that the spindle will be reversing at about the same point on both the thread lobes. Then the first tap is set and made to travel into the work the desired distance. The second tap is then set in the turret, the distance from the face of the turret being the same as for the first tap. If this procedure is followed, little difficulty will be encountered. A reversing tap holder as shown in Fig. 18 is preferable to the draw-out type for this purpose, as the taps are not required to be set as accurately.

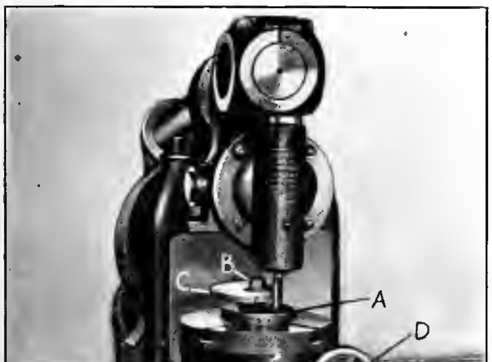

Fig. 19. Cutting Thread Lobe on a Circular Milling Attachment

Cutting the Thread Lobe

In Fig. 19 is shown the circular milling attachment (mentioned in the previous installment of this article) in position on the Brown & Sharpe universal milling machine, which is equipped with the vertical milling attachment. Before cutting the cam the various lobes are laid out in their respective positions as designated on the drawing, and the superfluous metal is removed either by shearing in a punch press or by drilling a series of 3/16-inch holes about 1/16-inch from the outline of the various lobes. The cam is then placed on block *A*, as shown, which has a projecting stud, nut *B* being used to hold the cam down tight against the face of this block. The block is held to the circular milling attachment by two screws not shown in the illustration. To cut the cam, raise the knee until the end mill passes the lower face of the cam *C* as shown and bring the end mill into position at the bottom of the lobe, in other words, at the point where the die would start on the work. Then feed the end mill in the desired distance. The micrometer collars on the shafts carrying the handles *D* and *E* are then set at zero. Referring to Fig. 10, which was given in the previous installment of this article, we find that the lead on the lobe is one thousandth inch for each 3½ minutes of its circumference, but the smallest division on this attachment is five minutes. We will, therefore, revolve the attachment five minutes for each 0.00175 inch that we feed the cam in, continuing in this manner until that side of the lobe is finished. The attachment is then swung around and the other side of the lobe completed in the same manner. Milling the cam in this manner leaves a series of slight flats on the lobe which can be removed by filing, giving the cam lobe an approximately true curve.

REMOVAL OF CHIPS WHEN REAMING

By T. COVEY

Jim, the apprentice boy, started one morning to fasten some angle-plates onto some castings that were to be used as jigs, and it was not desirable to have the screw and dowel-pin holes go through both pieces; in other words they were "blind" holes. He had been instructed to drill the screw holes first, making the holes in the angle-plate a little larger than the screws that went through them so that the plate could be shifted slightly. Then, to set the plates accurately where they are wanted, clamp them fast with their own screws, and then drill and ream dowel-pin holes through the angle-plates into the casting. He was busy reaming these dowel-pin holes, and in order to get the reamer to go clear down to the bottom found it necessary to frequently remove it and clean out the chips, which was very troublesome on account of the necessity of using oil. A toolmaker who was going to finish the jigs, being about ready to start work on one of them, came up to see how he was progressing. "You seem to like to probe around in that hole with that little flattened wire," said he. "What is the object?"

"How do you suppose I can get a reamer into a hole that is half full of chips," said Jim; "if they were dry I could blow them out with this little bent pipe, but oily ones don't blow worth a cent."

"If you were to fill that hole you have just reamed full of oil and force the reamer down into it quickly, what would be the result?"

"Why, the oil would squirt up the sides of the reamer I suppose."

"Exactly! Now if you were to fill one of the holes that you haven't reamed full of oil and were to go ahead and ream it, the result would be the same; that is, the oil underneath the reamer would be forced up along the sides of the reamer just the same only not so fast; still it would be plenty fast enough to carry the chips out as fast as the reamer made them. Try one and see how it works—only after you start the reamer down, keep it going down; if you lift it up the oil will be sucked into the hole and the chips with it where they would soon settle to the bottom."

"Say, that works all right," said Jim.

"Yes, with large holes though, that would not be a very profitable way to use oil; but then with large holes it is easy to get the chips out, so it is not necessary."

* * *

According to an estimate by the *Elektrotechnische Zeitschrift* the actual available water power on the European continent, after deductions have been made for water power which cannot be commercially exploited, is about 36,000,000 horsepower. Of this more than 14,000,000 horsepower is available in Sweden and Norway, 6,000,000 horsepower in Austria-Hungary, and in France and Italy about 5,500,000 horsepower each.

Associate Editors

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on.

JULY, 1910

PAID CIRCULATION FOR JUNE, 1910, 26,617 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 700 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, about 300 pages a year of additional matter and forty-eight 6 x 9 Data Sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. The Railway Edition, $2.00 a year, is a special edition including a variety of matter for railway shop work—same size as Engineering and same number of Data Sheets.

Ralph E. Flanders, for five years an associate editor of MACHINERY, has resigned to return to practical work, a change which he has long desired to make, and which deprives trade journalism of one of its ablest writers. Mr. Flanders is a mechanic of wide practical knowledge, and an all-around fine fellow whom it was a pleasure to have on our staff. As our readers know, he is the author of *Gear Cutting Machinery* and is an authority on gear practice, in which line of work his experience will undoubtedly be of great value to our friends, the Fellows Gear Shaper Company, with whom he will be connected.

Our best wishes for his success go with him. L.

* * *

THE BENEFITS OF COOPERATION

The recent meeting of the National Machine Tool Builders' Association exemplifies some of the benefits that come from hearty, whole-souled cooperation. One hundred and sixteen concerns, many of them competitors, came together to promote the common good, which means not only the good of the members, but also of their customers. The association aims to be the means for interchanging ideas by which manufacturing costs shall be reduced, machine design improved, and knowledge of important matters affecting the trade, generally disseminated. But of more importance, it has proved to be a means of inspiration. No one who heard the address on the Cincinnati Continuation School could help being inspired with the feeling that to help others is to help one's self—that altruism has a commercial value. If the employer raises the standard of intelligence and living for his employes, he will surely raise the standard of his product and increase his own prosperity.

The gospel of cooperation is being preached everywhere, but few fully understand and apply it. Cooperation is the keystone of the arch of civilization. A hundred weak threads twisted together make a rope which the strongest man cannot break—many working together accomplish what is impossible for a few. Cooperation in the machine tool business means better shop management, better shops, better men, better product, and better employers. It is as far removed from the popular idea of the trust method of conducting business as one pole is from the other. The initiative of individuals is not stifled, but stimulated. Secret methods have no place in the proceedings, which are characterized by frankness and liberality throughout.

* * *

NEW FIELDS FOR MECHANICAL ENGINEERS

H. L. Gantt's paper, "The Mechanical Engineer and the Textile Industry," read at the Atlantic City convention of the American Society of Mechanical Engineers outlines a new field for the profession. It shows that one important industry in which many opportunities exist for effecting very large economies of operation and improving the grade of product, has been practically neglected by engineers. As an illustration, Mr. Gantt described the common, crude method of bleaching cloth, which requires operatives to work in unhealthful surroundings and results in an irregular product and much confusion in bringing together the cloth of different mills when the bleaching is completed. The improvement as described was effected by designing simple apparatus which enabled the cloth to pass progressively from one bath to another without break and almost without the aid of human labor.

The changes were of so simple a nature that practically any mechanical engineer would have worked out essentially the same means of accomplishing the desired result, had he been required to improve the existing conditions. But strange as it will seem to the readers of this journal, practically every bleachery in this country or Europe is following the old crude method, illogical in plan and unsatisfactory in product. Parallel conditions, not so readily improved perhaps, exist in the textile industry generally, and doubtless in many others which so far have not received the critical attention of trained minds. The technical colleges have largely devoted themselves to the training of power plant engineers, neglecting fielos of endeavor where vastly greater economies are possible.

* * *

GRINDING GAS ENGINE CYLINDERS

There is an honest difference of opinion, shared by engineers and manufacturers alike, as to the desirability of internally grinding gas engine cylinders. Those opposed to the practice say it is a useless refinement practiced by certain automobile manufacturers more for the purpose of making a good talking point than for anything else. They say that the bored cylinder has exactly the kind of surface required to quickly wear the piston rings to a smooth bearing, and that after lapping it is more likely to be tight than a ground cylinder. The parallel grooves left by the boring tool catch and hold the lubricating oil and check gas leaks, on the principle of action of the so-called water packing grooves sometimes provided in the valve stems and piston rods of hydraulic mechanisms.

The supporters of piston and cylinder grinding make three principal claims for the practice, *viz.*, interchangeability, improved wearing surfaces and the saving of one set of piston rings. By grinding both cylinders and pistons, perfect interchangeability may be secured at low cost, all scraping, filing and fitting being avoided. Anyone acquainted with the economies of a strictly interchangeable system of manufacture will fully appreciate this feature. Fitting, in the common way, is a time-consuming process, especially when done by the use of abrasives. When finished by grinding, the wearing surface is perfect at the start, and the cylinder begins its work with a standard size bore. This latter condition is impossible with the boring and lapping method. Lapping will wear the bore of the common automobile engine cylinder 0.006 inch larger perhaps, and then it may be neither round nor straight. The process wears out a set of piston rings and a new set must be furnished after the finishing operations are completed, which, of course, means double cost for piston rings.

Judging from the experience of users, it appears to an unprejudiced observer that grinding machines, of both the external and internal types, will be among the machine tools most highly prized by gas engine builders when they fully understand and appreciate their possibilities and economies, and have trained workmen to use them efficiently.

FORCE REQUIRED FOR BENDING

It is a curious fact and one not very creditable to the authors, that practically all the text-books on mechanics treat bending stresses and resistance to bending from the view-point that bending is to be resisted. In the design of most machines and structures this view-point is perfectly correct, but if the designer requires to know the force that will actually bend a bar or beam, he will find no direct information on the subject in the great mass of engineering literature. Of course, it does not require profound reasoning to deduce the fact that the ordinary beam formulas apply just the same whether the beam is to bend or resist bending, but doubtless it would comfort the callow engineer to be assured that, for example, $P = \frac{S\,l\,t^2}{6}$ can be used to find the force required to bend a plate held at one edge, if he will but insert a value S equal to or slightly greater than the elastic limit of the material.

* * *

WHERE ARE OUR MARKETS?

The total value of metal working machinery manufactured in the United States amounted to $32,408,766 in 1905, the last year for which census figures are available. The value of the same product in 1900 was $24,737,904, and the same proportionate increase during the past five years would bring the total for 1910 to $42,000,000 or more.

Our exports for each of the years from 1905 to 1909 inclusive, were as follows:

Year	Europe	Canada	West Indies, Central and So. America	Asia	All other Countries	Total
1905	$3,718,824	$150,180	$143,148	$245,066	$ 75,447	$4,332,665
1906	5,825,505	169,206	207,060	114,507	129,334	6,445,612
1907	8,423,471	261,272	329,255	255,551	99,507	9,369,056
1908	6,859,319	551,155	544,435	514,430	226,896	8,696,235
1909	2,853,605	223,650	345,447	88,374	128,958	3,640,034

A comparison of these figures shows that the great market for American machinery is at home; and while due attention should be given to foreign outlets, the home market is the one which best repays cultivation, for this belongs to American manufacturers and cannot be taken away from them unless there is a material change in conditions. There is no doubt that our home market can be substantially increased, even though the process may be a slow one, and one requiring attention to problems other than those purely commercial. The manufacture of machine tools is a basic industry, and a larger home market for its product can be created by an increased development of the resources of the country, for which there are vast opportunities. In proportion to its area and natural wealth, the country is as yet sparsely settled; but the opportunities for development are being monopolized, and natural resources that could be used in various industries are held out of use. Under such conditions the country cannot develop as rapidly as if its resources were open to such enterprise as would make the best immediate use of them.

The proper use of our natural resources is not contrary to the idea of conservation. It is true that the consumption of coal and other mineral wealth gradually exhausts the supply, but no other resources of the country diminish or decrease in value through proper use. Among those which, with proper care, should be virtually inexhaustible, are the water power, a valuable natural asset, the forests, which can and should be replanted, and the land itself, which, for agricultural and other purposes is to a very large extent held out of use. If we really want to create larger home markets, monopoly in these natural resources must be opposed by logical and intelligent methods, and the greatest possible freedom given to competitive enterprise wherever it manifests itself. Thus a much greater home market than the present one can be created, and the United States can become more independent of foreign trade, for which the competition is constantly increasing.

GOULD & EBERHARDT'S APPRENTICESHIP SYSTEM*

By FRED L. EBERHARDT†

With the necessary requisites in mind we select applicants for apprenticeship from our public grammar and high schools by applying to the superintendent of public schools and his principals; also to our Newark Technical School, Municipal Labor Bureau, and by advertising in the daily papers, alternating our advertisements by first appealing to the boys themselves and second to the parents, approaching the latter from the standpoint that they should not overlook their responsibility in considering their sons' future welfare and earning power. Too many parents look only at the present and think, because their boys can earn $6, $7, $8, or $9 per week, that it is helping them more than to put the boys out at lower wages, and no doubt there is a good deal of truth to this contention. But, if the boy is made of the proper mettle and has the natural ability, he would be destined for far greater results in a few years than if he had not started on a trade at all. We would lay great stress on the need of educating parents to allow their boys who have a mechanical inclination to serve an apprenticeship of say, four years, in a well-regulated factory. While not making it obligatory, we strongly advocate our apprentices attending the Newark Evening Technical School, from which a number of our apprentices have been graduated.

At present we have about 65 apprentices, all bound and indentured according to the apprenticeship laws of New Jersey, and have none who are not bound in this manner.

We have practically two forms of apprenticeship, one for young men about seventeen years of age, embracing what we term our regular course and covering a period of four years of 10,800 hours, and another for two years, or 5400 hours, called our "one-branch," and intended for young men 21 years and older. Reckoning a year at 2700 hours, in the case of our four-year course, we have a first period of 2000 hours at 8 cents per hour, a second 2000 hours at 9 cents, a third 2000 hours at 10 cents, a fourth 2000 hours at 11 cents and a fifth 2800 hours at 12 cents. This makes a total of 10,800 hours.

The total hours in each period are required to be completed before the next advance in pay is made. We require that the apprentices' parents shall pay us $1 per week during the first four periods, which amount forms the collateral for a bond which the father or guardian is required to execute. This amount is returned at the expiration of the term, if the said term is completed in a satisfactory manner. However, if for any reason the terms of the papers are violated or the young man runs away, the money paid on account is forfeited. Incidentally, I would say that the amount which we pay the young man, as stated above, is larger than what it was formerly. We made it sufficiently more for the purpose of enabling the parent to pay back the $1 per week to make good the bond. In this way, we feel, we make it more feasible for a worthy young man, so to say, to pay his own way so far as securing a bondsman is concerned, a collateral bond always having been one of our requirements.

The regular apprenticeship course includes work at the vise, lathe and planer. In addition, milling machine and gear cutting machine experience, and also other work, is afforded to those boys who show ability to absorb.

Our experience has taught us that there is so great a variation in capacity that wherever we see a boy who shows ability we do not hesitate to advance him, and when we find a boy who does not possess ability we strongly advise him and his parents to have him take up some other line of work. This we do within the first 4000 hours of service. It does not always take 4000 hours to determine this, but there are times when, before taking summary dismissal measures, we try out a boy at more than one branch, or place him with different foremen, so that, in the final disposition of the case, neither the parent nor the boy can say that he was not given a fair trial. For all these efforts expended on the boy up to this time, should he prove deficient and be dismissed, we require that whatever money has been paid on account of the bond be

* Abstract of paper read before the Convention of the National Machine Tool Builders' Association, in Rochester, N. Y., May 25, 1910.
† President of Gould & Eberhardt, Newark, N. J.

forfeited. This is, in a measure, partly to compensate us for the time spent, work spoiled, etc., in giving the boy a chance to demonstrate, in our opinion or judgment, whether or not he is suited for the trade. The necessity for this measure does not occur often, but we feel that it is absolutely necessary to have some such method of procedure.

Our second form of apprenticeship, called our one-branch, is for young men who, having attained their majority, realize the necessity for learning some trade and regret not having been given the opportunity in earlier years. This apprenticeship, as stated, is for two years, or 5400 hours, divided into periods of 2700 hours each, the first at 12 cents per hour and the second at 14 cents per hour. We require the young men themselves to pay us $1 per week, the same as before explained. This amounts to about $165 in the four-year course and $130 in the two-year course, and in each case is paid back at the expiration of the term when completed in a satisfactory manner. This latter amount is also subject to the same penalties as previously mentioned.

At the present time we have seven in our drafting-room. Our chief draftsman and three journeymen draftsmen were our own apprentices at the machinist's trade. Another is an apprentice at the machinist's trade, and has been given drawing-room privileges and practice. One of the journeymen draftsmen is foreign born and a trained technical graduate. We do not include instruction in the foundry or pattern-shop generally, although all of the apprentices who gain drawing-room experience have access to and come in contact with the work in the pattern-shop and foundry. For the foundry and pattern-shop we have similar but special and separate courses.

All of our apprentices during their apprenticeship are furnished with the necessary tools required in the several branches, and we pass free title to them upon the apprentice completing his term.

CASEHARDENING PRACTICE AT THE JUNIATA SHOPS OF THE PENNSYLVANIA R. R.

We are now able to give more detailed information on casehardening practice at the Juniata Shops of the Pennsylvania Railroad, as described in the June, 1910, number of MACHINERY, on page 824 of the engineering and railway editions. This information relates particularly to the method of packing the work, and to the use of test pieces to determine the quality and depth of the hardening. The following formula is used as a packing mixture:

11 pounds prussiate of potash.
30 pounds sal soda.
20 pounds coarse salt.
6 bushels powdered charcoal (hickory preferred).

The whole is mixed thoroughly, using about 30 quarts of water in the mixing; the above quantity is sufficient to harden three boxes of material containing the following parts:

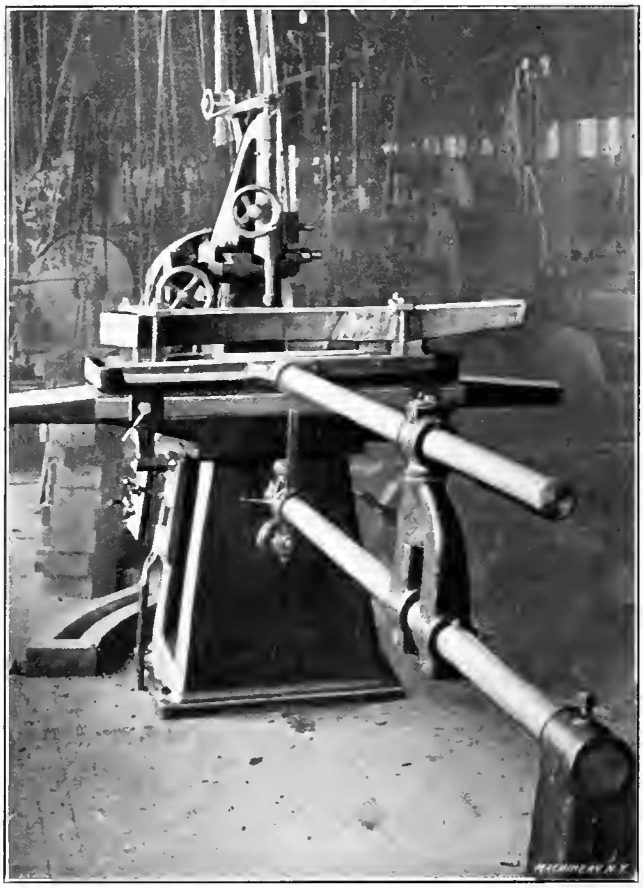
2 links, 2 link blocks, 2 link-block pins, 2 valve-rod pins, 4 knuckle-joint pins, and 24 gibs for spring rigging.

The box required to hold these parts measures 40 inches long, 16 inches wide, and 12 inches deep; the time required to harden them properly is fourteen hours. Smaller parts, like link die plates, eccentric-rod jaw pins, and nuts below 1 inch, are usually packed in smaller boxes, or pipe 8 inches in diameter, which require between four and five hours heating. Link motion bushings and similar light parts are also packed in small boxes or pipe and require from two and a half to three hours.

The following method is pursued in packing the material: The bottom of the box is covered to a depth of 2 inches with the compound; the parts to be hardened are placed solidly, so that the compound is in contact with the bottom surface of the work; care is taken, however, that the work does not touch the sides of the box or other pieces in the box. After the first layer of the material is placed, it is covered on all sides and on the top with the compound, and is solidly packed with a suitable implement—a bolt with a large head will do. After the first layer is packed the same process is repeated, being sure to have sufficient compound between the two layers to prevent contact. There should not be less than 2 inches of compound on top of the last layer. The lid which fits inside the box is then thoroughly sealed with a luting of fire clay.

When in the furnace, the box rests on rollers to allow the flames to pass under it. The furnace is kept at a bright red heat, but not hot enough to scale or blister the work; when the material has soaked in the fire a sufficient length of time, the box is withdrawn to a trestle which is flush with the floor of the furnace, and stands parallel with and close to the water tank. The lid is then removed from the box and, if links are being hardened the link is turned on edge and a bar passed through the slot in the link and lifted by two men, being plunged into the water endwise; the bar is then withdrawn and the link is allowed to remain in the tank until cold.

The best results are obtained when the contents of the box can be emptied into the water at once. The tank used has a line of $1\frac{1}{2}$-inch iron pipe connected with the service pipe, running around the four sides and close to the bottom, with $\frac{1}{4}$-inch holes drilled about $1\frac{1}{2}$ inch apart. This supplies cold



Hammett Grinding Machine for Finishing the Slots of Locomotive Links

water to the work and drives the hot water to the top, where it is carried to the sewer by means of an overflow pipe.

With each box of material to be hardened a test piece is used, the same as described in the article last month. In the case of links, the test piece is $1\frac{1}{4}$ inch thick by 3 inches wide, and 12 inches long; this test piece is stenciled with figures giving the class of engine, the construction number and the date of hardening. After the links are taken out, the test piece is broken under hydraulic pressure and examined for depth of hardening, after which it is also subjected to a file test. Smaller parts are similarly tested. These test pieces are kept for two years or more for reference. It is possible to put from 1/16 inch to 5/32 inch depth of case on the link work in fourteen hours' time, and 1/16 inch on bushings and other small parts in from two and a half to three hours' time. All parts to be casehardened must be thoroughly cleaned.

It was stated that the slots of the valve gear links are ground accurately to fit the radius templet shown in Fig. 24 of the article in the June number. The accompanying illustration shows the machine on which this grinding is done. It is a vertical spindle machine, as may be seen, the work being clamped to the top of a flat table. This work table is free to swivel, and to move in and out on top of the longitudinal slide which carries it. It is guided by a long radius rod, as shown, which is attached to a pivot adjustable to any required radius.

AUTOMOBILE FACTORY PRACTICE

THE OLDS MOTOR WORKS, LANSING, MICH.

By ETHAN VIALL.*

To the man traveling through Michigan for the first time, it almost seems as if the sole product of the state were auto

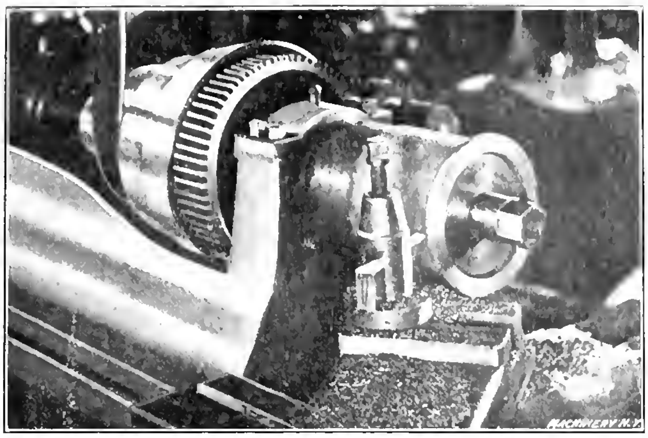


Fig. 1. Turning the Chucking Flange on Piston Ring Casting

mobiles, furniture and breakfast foods, and a fair-sized town that doesn't boast of a factory for the production of at least

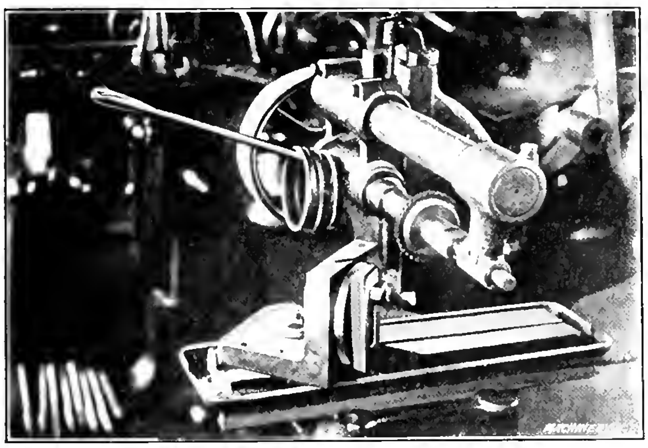

Fig. 3 Machine in which Piston Rings are split

one of these, is apparently out of the running and should at once shake up its chamber of commerce or its commercial

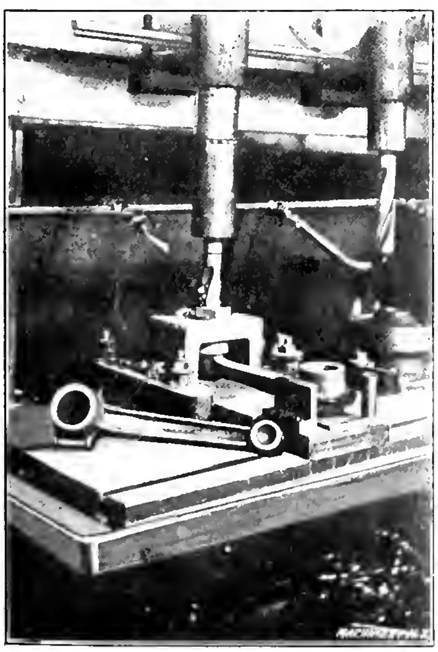

Fig. 5 Drilling Wrist pin End of Connecting rod Forging

club or whatever it happens to possess for the stimulation of its growth. The production of furniture or breakfast foods does not concern us, mechanically speaking, to the same ex-tent as do automobiles, though if we sit in a good comfortable chair while eating our breakfast we are in better condition to enjoy our automobile ride later.

The first automobiles the writer ever saw of any one make, in respectable numbers, were those little curved-dash Oldsmobile runabouts, so familiar a few years ago, which were made

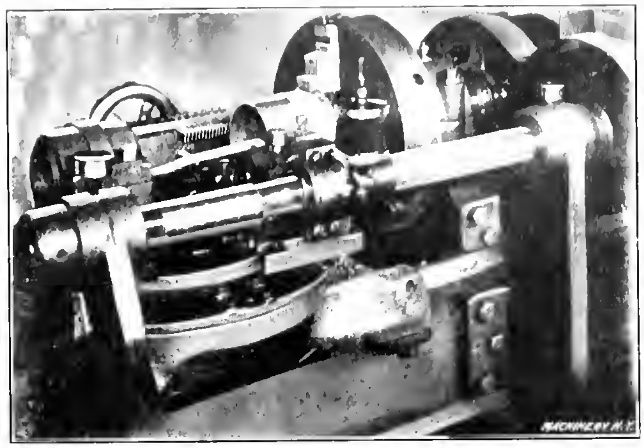

Fig. 2 Turning the Outside and Cutting off Piston Rings

at Detroit. To-day the Olds Motor Works has large factories at Lansing, Mich., where they are producing thousands of

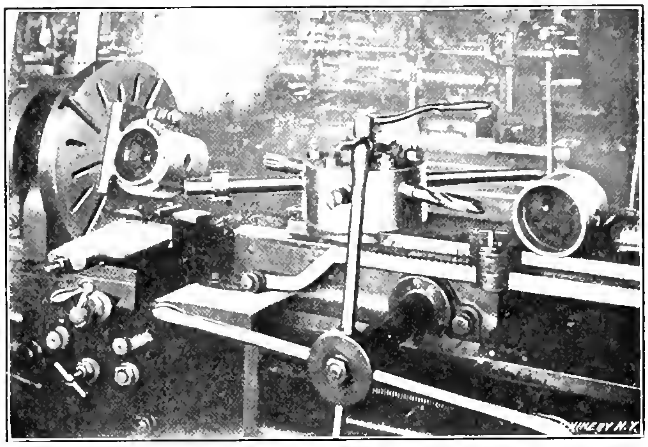

Fig. 4 Turret Lathe set up for Drilling, Boring and Reaming Wrist-pin Bosses

Oldsmobiles, some of them sixty horsepower six-cylinder cars. The shop practice, while not radically different from that of

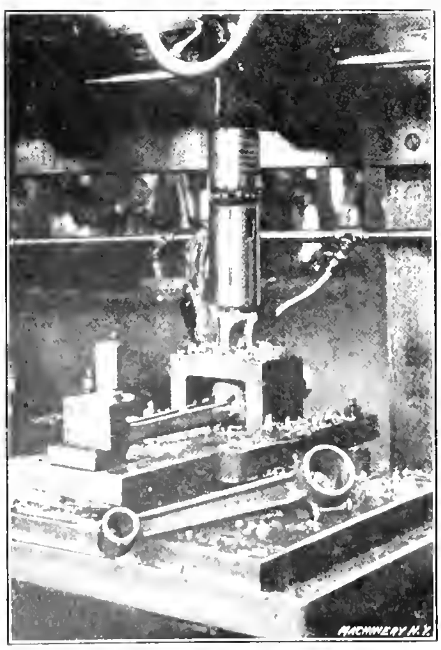

Fig. 6 Drilling Crank end of Connecting rod

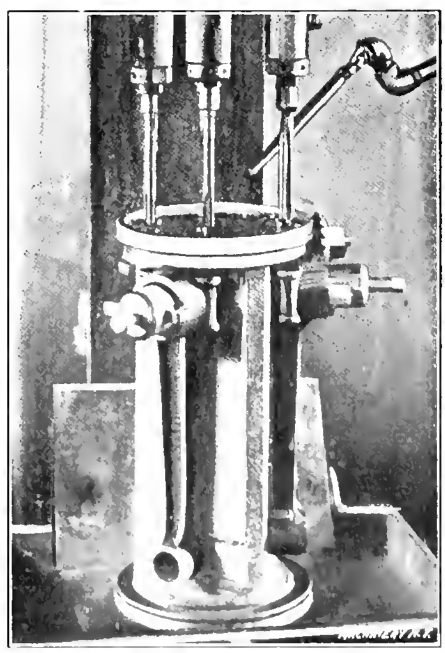

Fig. 7 Drilling, Reaming and Finish Reaming Cap-screw Holes

other similar factories, is nevertheless interesting and well repays the student of practical mechanics who is fortunate enough to have an opportunity to inspect the factory and its methods. Mr. Robert Pierpont is the factory manager

*Associate Editor of MACHINERY.

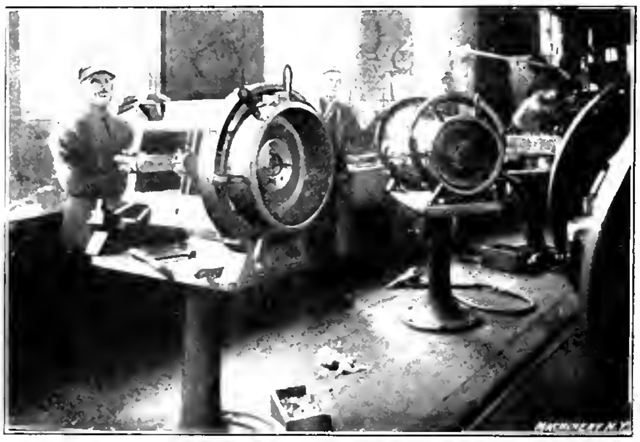

Fig. 13. Another View of the Revolving Assembling Stands

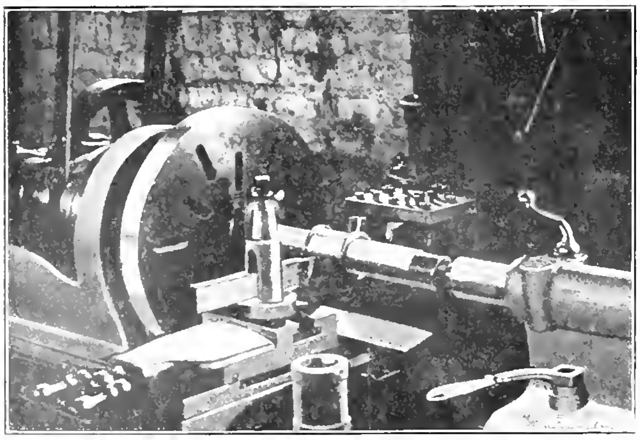

Fig. 14. Turning the Outside of Connecting-rod Bushings

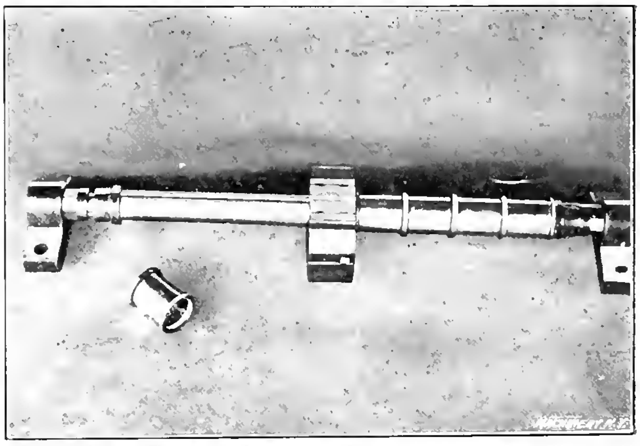

Fig. 15. Mandrel used when splitting Connecting-rod Bushings

Packing Rings and Pistons

The cast-iron sleeve from which the piston rings are made is first placed on an expanding mandrel and the flanged end turned, as shown in Fig. 1; it is then caught in the grooved jaws of a universal chuck, Fig. 2. The machine shown in

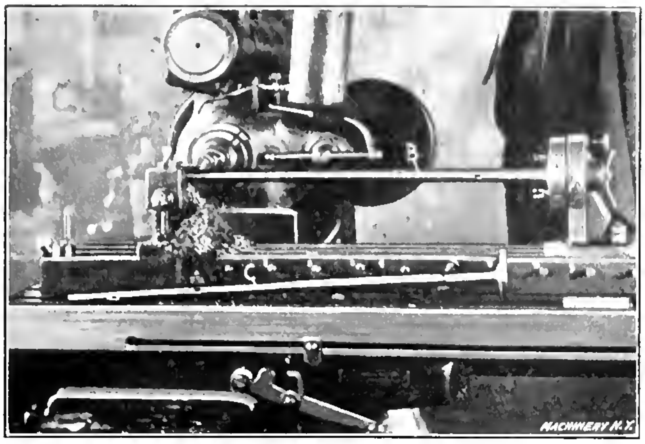

Fig. 16. Fixture for Holding Cam-shafts while Milling for Woodruff Keys

this engraving is a lathe to which has been added the turning attachment shown, which turns the outside of the rings eccentric and cuts them off; the inside of the ring not being bored out as is the practice in many shops. Just why so many shops spend time and trouble boring out the inside of the

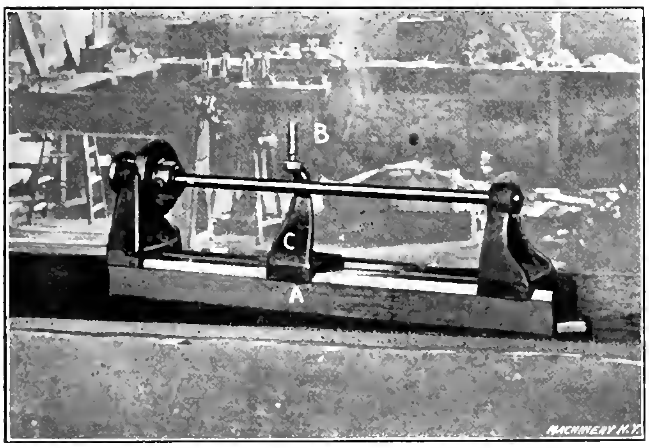

Fig. 17. Inspector's Fixture for Testing Cam-shaft Keyways

ring is not clear, as it not only takes so much more time, which, of course, increases the cost, but also decreases the value and life of the ring by the removal of the hard surface. After being turned and cut off, the rings are placed in a jig and split by using two milling saws properly spaced,

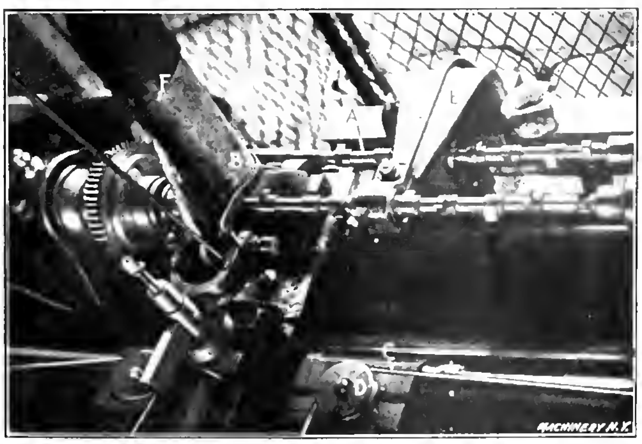

Fig. 18 Top View of Lathe equipped with Cam-grinding Attachment

as shown in Fig. 3; they are then compressed in sleeves, clamped on a flanged mandrel and ground as usual.

Wrist-pin holes in the pistons are drilled and reamed, after which the inside ends of the bosses are faced with a double-end mill in a turret lathe fitted as shown in Fig. 4.

Steps in Connecting-rod Production

The first machine shop operation on a connecting-rod consists in surfacing the ends of the bearings on a milling machine, there being 3/32 of an inch difference in the width of the bearings; the rod is then placed in the jig shown in Fig. 5 and the small bearing drilled out, after which it is placed in another jig and the large end drilled, the proper spacing being obtained by using a plug in the small end as shown in Fig. 6. Next both ends of the connecting-rod are finish-reamed in the jig, Fig. 8. The ends are then faced to the exact thickness, by using a butt mill with a pilot which fits the holes in the bearing posts of the jig, Fig. 9. From here the connecting-rod goes to the triple drilling jig, Fig. 7, where the clearance holes for the cap-screws are rough drilled and finish reamed; all three operations are performed simultaneously, so that a finished rod is taken out and a new one put in every time the jig is indexed. The next operation consists of milling a slot

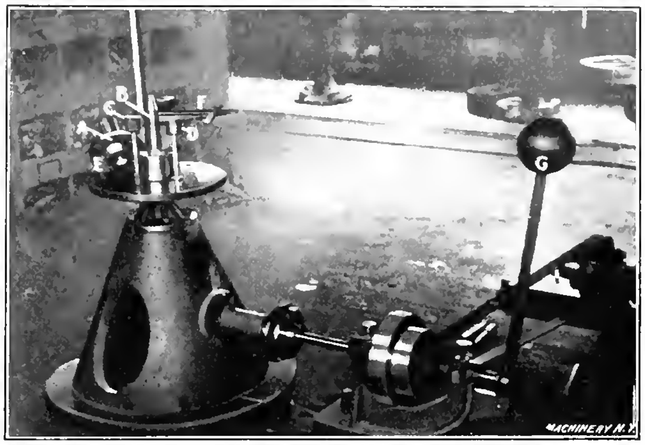

Fig. 19. Machine used for Balancing Flywheels

in the small end for the oil hole, as shown in Fig. 10. The rods are then placed, ten at a time, in the milling jig, Fig. 11, where the caps are cut off and the inner ends, or bosses of the cap bolt-holes, faced in two operations; one cut is taken, the connecting-rods are turned over on the clamping mandrel and the final cut made. After the Parsons' white bronze bushings

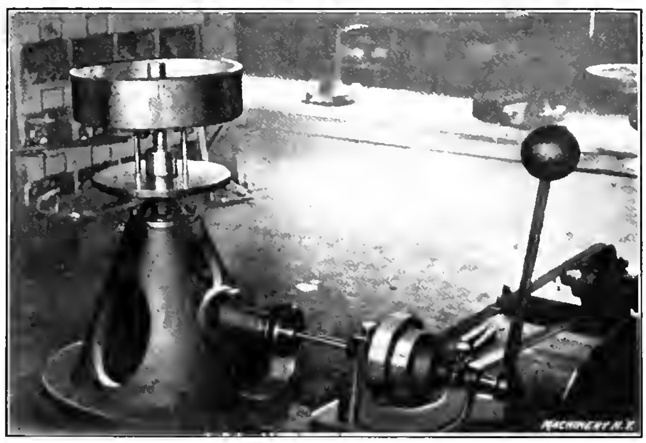

Fig 20. Balancing Machine with Flywheel in Place

have been pinned into the large end, the rods are placed in the pistons, but they are not put onto the crankshaft until ready for assembling as shown in Fig. 12. In connection with this last engraving and Fig. 13, the scheme used to revolve the flywheel and crankshaft, while assembling and adjusting, by means of a handled band strapped to the rim of the flywheel, is made plain. The revolving assembling stands shown are also very unique as well as efficient, the motor case being bolted to the inside of a pair of cast-iron rings resting on guides bolted to a base, which is swiveled to the top of a cast-iron stand; this arrangement always keeps the center line of the crankshaft parallel with the floor, still allowing universal movement in any other direction. Referring to Fig. 12, the flywheel band is shown at *A*, while *B*, *C*, *D*, and *E* are the ends of the wheel segments which are removed to put in or take out the motor; *F* and *G* are guides or pillows

for the wheels. In Fig. 13, H, I, and J show the wheels complete, with segments in place.

The white bronze split bushings, used on the crank ends of connecting-rods, are first chucked, bored out and reamed, and then placed on a mandrel, as in Fig. 14. The hub is turned with the tool in the regular toolpost and the flanges finished with the gang tool in the holder placed on the back of the cross-slide. After being turned, the bushings are split by being placed eight at a time on the mandrel, Fig. 15; they are clamped tight by screwing up the nuts on each end of the mandrel, and then split with a thin milling saw, the mandrel being turned half way around for the last cut.

Milling and Grinding Cam-shafts

There is a very neat fixture used in the milling machine department for milling Woodruff keyways in the cam-shafts.

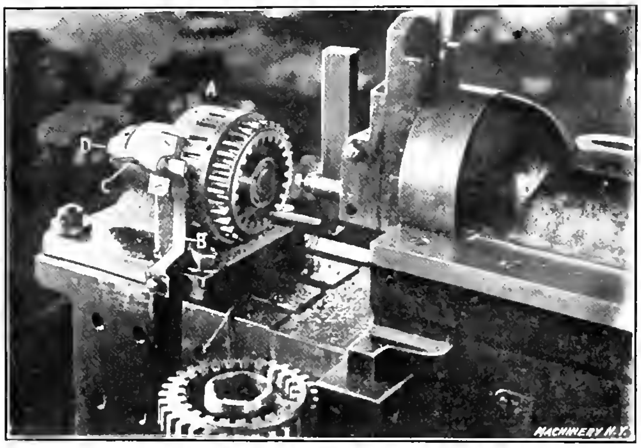

Fig. 21. Cutting Inside Clutch Teeth on a Shaper

This fixture, Fig. 16, is made with an index head A, used to give the proper position of the keyways on the shaft B, the spacing lengthwise of the shaft being obtained by carriage stops. A finished cam-shaft is shown at C. After being milled, the positions and sizes of the keyways are tested by an inspector, using the fixture shown at A, Fig. 17, which also has an accurate indexing head. The size and central position of the keyways are tested by a plug B, in the sliding part C.

The cams are ground, after being keyed and pinned to the shaft, by using a special grinding attachment fitted to a lathe,

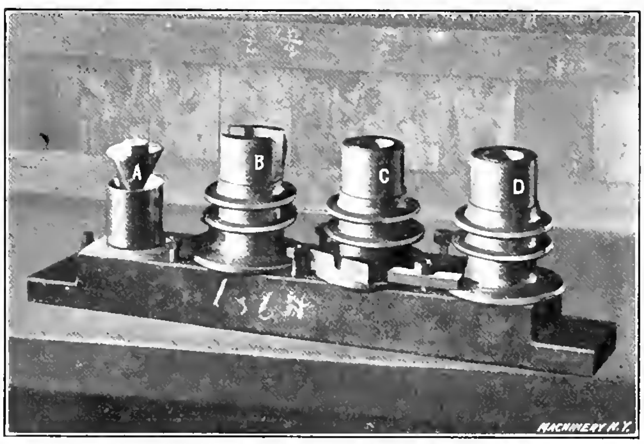

Fig 22. Milling Fixture in which Work is held on Expanding Plugs

Fig. 18. The master cam-shaft A, is geared to the lathe head so as to revolve at the same rate as the shaft to be ground. The cams on the master shaft impart motion to the carriage and grinding wheel through the roller B, the carriage being held to the work and to the master cam by the weighted cord C, which passes around pulley D and another pulley not shown. The master shaft and the shaft to be ground are both supported in the middle by the steady-rest E. The emery wheel held by the fork in the toolpost, is run by a round belt passing over a long overhead drum, and the dust is carried off through the pipe F. Very rapid and satisfactory work is done with this attachment.

Balancing Flywheels

All flywheels are balanced on a Defiance balancing machine shown in Figs. 19 and 20. Fig. 19 shows the machine with the balancing or floating head A, to which the flywheel is fastened, lying on the revolving table; this floating head fits over the pin B and is driven by the rubber-headed pins C and D, which come in contact with the part E; F is an arm used to steady the operator's hand while holding a piece of chalk to the revolving rim of the flywheel. Putty is stuck onto the inside of the flywheel rim to bring it to a running balance, and the amount of putty used forms a basis for judging the amount of metal to be drilled out. The machine is set in motion by throwing over the ball-lever G, which engages the frictions.

A Novel Shaper Device

Inside teeth on a special clutch gear, are first drilled and then shaped out, using the indexing fixture A, Fig. 21. The inside blank is, of course, counterbored to allow clearance for the cutting tool. The spacing spring B is lifted from the notch, when indexing, by means of the eccentric lever C. The gear itself is held by an expanding chuck, the taper plug of which is operated by the nut D.

An application of the expanding chuck or plug in a milling fixture is shown in Fig. 22. This fixture is made to hold fonr pieces: A shows the expanding plug; B, a slotted piece, and C and D, blanks ready to he milled. In addition to using the expanding plugs, the pieces are also clamped on the flanges by straps, as shown, the bolt holes of which are open on one side to facilitate removal.

* * *

PENSION SYSTEM OF THE WESTERN ELECTRIC COMPANY

In March, 1906, The Western Electric Co. set aside $400,000 out of its profits as a permanent fund for pensions for aged and disabled employes. Since that time another appropriation and interest has been added so that the fund now totals nearly $600,000. All employes who have reached the age of sixty and have been in the company's service for twenty consecutive years are entitled to pensions, whether able to work or not, and are not debarred from going into other business if they accept the pension privileges. Employes who have been twenty-five years in the company's service and reached the age of fifty-five, and those who have been thirty years in the service, irrespective of age reached, may be granted a pension on the recommendation of the president. The annual allowance for employes retired on account of age is one per cent of the average annual pay during the ten years preceding retirement for each year of active service. The pension board may, however, base the pension upon the average annual pay of the ten consecutive years of service during which the retired employe was paid the highest rate of wages. The pension is paid monthly until death, and at the discretion of the board may be continued to the widow or orphans for a period not exceeding one year. The Western Electric Company employs about 20,000 men.

* * *

Halley's comet, which was a disappointing spectacle to the comparatively few who saw it in April and May, is said to have been traveling at the rate of 1000 miles a minute when nearest the sun. This enormous speed, fifty times that of a cannon ball, is practically the same as that of the earth in its orbit about the sun. A 0.22 caliber (short) rifle bullet weighing 30 grains moving with the same velocity would have enormous energy and penetration. Substituting the values in the kinetic energy formula, $E = \frac{Wv^2}{2g}$ in which $E =$ energy, in foot-pounds; $W =$ weight, in pounds; $v =$ velocity, in feet per second; $g =$ acceleration of gravity in one second or 32.2 feet, we have $E = \frac{30 \times 88{,}000^2}{2 \times 32.2 \times 7000} = 515{,}000$ foot-pounds. The penetration would be about 28,000 pine boards $\frac{7}{8}$ inch thick if at this high velocity it were proportional to that of rifle bullets at common velocities!

WEIGHTS OF CYLINDRICAL PRESSURE TANKS*

By C. R. WHITTIER†

As the gallon is the common unit of capacity for liquids, it is a great convenience and saving in time to be able to state the weight of a tank in terms of gallons without first converting this into the usual linear dimensions. In general, the weight of such tanks will vary anywhere from two to eight pounds per gallon capacity. It is possible, however, to obtain closer estimates than this when the diameter is known, and a method of stating weight in terms of gallons, pressure and diameter is of great assistance in shortening calculations. This method is worked out below.

First, let us consider the weight of a seamless tank with flat heads. Let

G = capacity in gallons,
T = thickness of shell in sixteenths of an inch,
D = diameter in feet,
L = length in feet,
P = pressure in pounds by gage,
W = weight in pounds.

The steel used in pressure tanks weighs about 490 pounds per cubic foot, and the plates vary in ordinary practice by steps of one-sixteenth of an inch. This is, therefore, the most convenient unit for thickness. A plate of steel, one foot square and 1/16 inch thick, weighs about 2.55 pounds. The ordinary method of estimating the weight of this tank would be to estimate the weight of the shell and heads independently. It will, however, be more convenient for our calculations to estimate the heads in terms of length of shell, just as the length of rivet necessary to form the rivet head is commonly taken as one and one-half diameter.

The area of one head is $\frac{\pi D^2}{4}$. The circumference of the tank is πD. Let x equal the length of shell, the area of which is equal to the area of the head. Then,

$$\pi D x = \frac{\pi D^2}{4}, \text{ and } x = \frac{D}{4}.$$

Hence, the length equivalent to both heads equals $\frac{D}{2}$. The weight of the tank may then be expressed as follows:

Weight = 2.55 × thickness in 16ths × circumference × (length + one-half diameter),

or,

$$W = 2.55\ T \times \pi D \times (L + 0.5\ D) = 8\ DT\ (L + 0.5\ D).$$

To save bracing, the heads of pressure tanks are commonly dished to a radius equal to the diameter of the shell. To find the area of the spherical segment, assume for simplicity that the diameter of the tank equals 2. The distance from the center of the sphere to the original flat head is given by solving the right-angled triangle whose hypotenuse equals 2 and one side equals 1. This distance, therefore, equals $\sqrt{4 - 1} = 1.732$, and the height of the segment $= 2 - 1.732 = 0.268$. The area of this spherical segment = height × circumference of a great circle $= 0.268 \times 2\ \pi D$, and, as $D = 2$, the area $= 1.072\ \pi$. The area of the flat head was $\frac{\pi D^2}{4}$, and as $D = 2$, the area $= \pi$.

We thus see that the area and weight of the spherical head is about 7 per cent more than the flat head. This holds true for all dimensions. In riveted pressure tanks varying from 4 to 8 feet in diameter, however, the dished heads are commonly made 1/16 inch thicker than the shell. As the shell thickness averages ⅝ inch and the head thickness 11/16 inch, the heads are, on an average, 10 per cent per square foot heavier than the shell. This is sufficiently close for our present purpose. Multiplying the two percentages: $1.07 \times 1.10 = 1.18$; that is, for ordinary dished heads, to obtain the equivalent length of shell, the increase over the equivalent length for the flat heads first mentioned is 18 per cent.

In the same manner, the manhole, nozzles, reinforcing plates, inside pipes, supports, etc., which are commonly used in such tanks, can be estimated in percentages, and transformed to an equivalent length of shell. Without going into these numerous details, it will be sufficient to state that it is found that these factors increase the equivalent length of shell from $L + 0.5\ D$ to $L + D$, very closely. The formula therefore now stands:

$$W = 8\ DT\ (L + D)$$

Having thus determined the general form of our equation and its main factors, it now becomes necessary to make an allowance for the increase in weight due to joints, rivet heads, variable thickness of metal, etc. Of course, this could also be reduced to equivalent length of shell, but this allowance can also be made by increasing the numerical coefficient by a certain percentage, and this method gives the most convenient formula. It is best done by comparison with the actual finished weights of tanks which have been constructed. Ordinarily, in place of 8, it will be found necessary to make this coefficient between 9 and 10. It can be easily determined for any tank by dividing its actual weight by $DT\ (L + D)$. For instance, in a line of tanks, nearly one hundred in number, varying from 5/16 inch to ⅞ inch in thickness, from 4 to 8½ feet in diameter, and from 5 to 50 feet in length, with pressures varying from 50 to 200 pounds per square inch, it was found as the result of the above determinations that the coefficient 10 gave the closest average for all the tanks, the maximum variation being very slight each way. We, therefore, have for this line of tanks:

$$W = 10\ DT\ (L + D).$$

This is an exceedingly simple formula for determining the weight of similar tanks when the diameter, thickness of shell and length are known. It now remains to substitute gallons and pressure for length and thickness.

Ignoring, for the present, the additional capacity given by dishing the heads, the capacity in cubic feet of our cylinder = area × length $= \frac{\pi D^2}{4} \times L$. As 7.481 gallons equals one cubic foot, the capacity in gallons is:

$$G = 7.481 \times \frac{\pi D^2}{4} \times L = 5.876\ D^2 L.$$

Adding about 2 per cent as a fair average for the additional capacity obtained by dishing the heads, we have:

$$G = 6\ D^2 L.$$

These tanks are usually designed with a factor of safety of 5, using steel of 55,000 to 60,000 pounds ultimate tensile strength.

The standard longitudinal seams are as follows:

A. A double strap, triple riveted butt joint, of an efficiency at the common thicknesses varying from 83 to 88 per cent.

B. A double riveted lap joint, with an efficiency ranging from 60 to 74 per cent.

C. A single riveted lap joint, with an efficiency from 51 to 59 per cent.

The process of reduction is too long to be given here, but by plotting and deducing the equation for the ordinary diameters, thickness and pressures, the following formulas can be deduced:

For A, $T = 0.01\ PD$
For B, $T = 0.013\ PD$
For C, $T = 0.016\ PD$

For the double strap, triple riveted joint, we therefore have:

$$W = 10\ DT\ (L + D) \qquad (1)$$
$$T = 0.01\ PD$$
$$G = 6\ D^2 L$$

By substituting the value of T in (1) we have:

$$W = 10\ D\ (0.01\ PD)\ (L + D) = 0.1\ PD^2\ (L + D) = 0.1\ PLD^2 + 0.1\ PD^3.$$

As $\frac{G}{60} = 0.1\ D^2 L$, we have by substitution:

$$W = P\frac{G}{60} + 0.1\ PD^3, \text{ or } W = P\left(\frac{G}{60} + 0.1\ D^3\right)$$

* With Data Sheet Supplement.
† Address: 204 W. 111th St., New York City.

In a similar manner; for the double rivet lap joint:

$$W = P\left(\frac{G}{46} + 0.1\ D^3\right)$$

For the single riveted lap joint:

$$W = P\left(\frac{G}{37} + 0.1\ D^3\right)$$

Summary of Formulas

We have, then, the following simple formulas for determining the capacity, thickness and weight of tanks of the class referred to:

For capacity $G = 6\ D^2 L$.

For double strap, triple riveted butt joints, $T = 0.01\ PD$

For double riveted lap joints, $T = 0.013\ PD$

For single riveted lap joints, $T = 0.016\ PD$

Then by dimensions:

$$W = 10\ DT\ (L + D)$$

By capacity:

For double strap, triple riveted butt joints, $W = P\ (G/60 + 0.1D^3)$

For double riveted lap joints, $W = P\ (G/46 + 0.1D^3)$

For single riveted lap joints, $W = P\ (G/37 + 0.1D^3)$

Example

For example, assume a tank 5 feet diameter by 20 feet long, for 200 pounds pressure, with double strap, triple riveted longitudinal seams:

By linear dimensions:

$T = 0.01 \times 200 \times 5 = 10$ sixteenths, or 5/8 inch.

$W = 10 \times 5 \times 10 \times 25 = 12{,}500$ pounds.

$G = 6 \times 25 \times 20 = 3000$ gallons.

If capacity, diameter and pressure are given, we have by the capacity formula:

$W = 200\ (50 + 12.5) = 200 \times 62.5 = 12{,}500$ pounds, which is the same result as before.

For all preliminary work, this short-cut method will be found sufficiently accurate. It can be readily supplemented by the ordinary summation method when desirable. Three of the Data Sheets accompanying this number contain tables and diagrams of the data here deduced.

CONE VS. GEARED DRIVE*

By R. K. LeBLOND†

Some years ago, I wrote an advertisement which appeared in trade papers, in which I stated that a double friction back gear was the best drive that had ever been applied to a machine tool. I suppose when the committee was looking around for different modes of entertainment and instruction, some member suggested that we could have a debate on the relative merits of the cone and geared drive, and as I had so fearlessly expressed my opinion, some one suggested my name. I did not like to show the "white feather," so I am here to-day to defend my stand as originally taken on cone drives, although we manufacture both styles of machines.

The question of cone- and gear-driven machines is very similar to the tariff—each side has a great many good points on which to base an argument. Free trade, for instance, is practically advocated by all college professors, and as a well-known writer remarked, all graduates ,as they emerge from college, are ardent free-traders, but as they get into the practical workings of life, most of them are soon converted to the tariff policy.

This condition exists in the cone and geared head proposition. Theoretically, the geared head drive has the most advantages, and the present development is along the geared head lines, but practically and commercially, the cone drive is more than holding its own, and as we gather our costly experience from miscellaneous experiments on gear-driven machines, we discover that the old reliable cone drive is still an important factor in machine tool design.

We all realize that the demand for the gear drive originated with the advent of high-speed steel; in other words, when the cutting tools were perfected to such an extent that they could stand the speeds and the heat generated by these speeds, the old-style cone drives were found lacking in power, and some of the manufacturers immediately decided upon a method of gearing to increase the power. This, in my judgment, was a temporary and poor remedy, and very costly to the manufacturer. While I am loth to say it, very few of the lighter classes of machine tools were scientifically designed, and gear drive design was begun more or less on a hit-and-miss plan.

In looking over the various gear drives that have been produced in the last few years, we are naturally surprised at the varied mechanisms employed, at the ignorance displayed in the selection of metals, the pitches of gears, the size and material of shafts, oiling facilities, etc. While this is a defect in individual construction, and not a fundamental defect of the geared head, it all goes to show that the development has been more or less experimental, and extends through the complete range of frictions, tumbling gears, sliding gears *a la* automobile, etc.

As a matter of fact, all the advantages claimed for the geared head machine, can be obtained better with a variable speed motor and comparatively few mechanical changes. The electrical changes can be obtained with a much smaller friction loss—that is, more efficiently; the change increments are much smaller and the speeds can always be obtained while the machine is in motion without stopping for changes and without a countershaft, etc. In other words, the variable speed motor drive is the ideal geared head.

The common defects in all gear-driven machines are: lack of efficiency, expense of maintenance, and the increased first cost. This holds true regardless of the changes being made in one unit or distributed in two, one being placed on the ceiling. We will take these comparisons up separately:

Efficiency of the Geared Machine

In extreme cases but 40 per cent of the power applied to the machine is delivered to the cutting tool or spindle. In the case of feeds, as shown by Mr. DeLeeuw's experiments [See "Efficiency Tests of Milling Machines and Milling Cutters," MACHINERY, December, 1908.] the friction on the shafts and gears has reduced this as low as 2 per cent and under the very best conditions, 20 per cent of the power applied. Of course, this is an extreme case and is due primarily to the fact that the reduction is so great and that the power has to pass through a screw, which as we all know, is a very inefficient method of power transmission. But in the construction of various designs of geared head machines, we see the worm and worm-wheel, and bevel gear, as well as spur gear.

I recently visited a large machine tool plant. In going through the shop with the superintendent, we stopped at their single pulley driven 16-inch lathe. As we were standing there, an office boy brought a copy of an order for one of these machines to which the purchaser wished to apply a one-horsepower motor. The superintendent immediately said this was impossible, because it takes more than one horsepower to turn the machine over. This was a friction head construction. At the same time, tests made on these lathes by different authorities, under the old belting conditions, resulted in establishing the power consumption of one half horsepower under actual working conditions.

Efficiency of Cone Drive

Now in comparison with this, take the old-fashioned cone. On the direct speeds, or open belt speeds, we can obtain an efficiency as high as 95 per cent, and in the extreme cases of transmitting power through the back-gear it is very seldom lower than 75 per cent. This difference in efficiency has to be taken up by the machine itself. In other words, it is a destructive element. It means friction on the journals, friction on the gears, heat generated which has to be taken up by the body of the machine, and wear in general, from all of which the user obtains no benefit and which goes into the maintenance charge.

Of course, it is an easy matter for the exponents of the geared drive to say that the power factor in machining costs is so slight that it is not to be considered. That is true, to a great extent, but when analyzed it will be found not to be simply the difference in the coal bill.

As an instance, a production man in one of the largest plants in the East, had formerly purchased all all-geared ma-

*Paper read before the National Machine Tool Builders' Convention, Rochester, N. Y., May 24-25, 1910.

†Address: R. K. LeBlond Machine Tool Co., Cincinnati, Ohio.

chines. At that time he was simply serving the concern in the capacity of equipment purchasing agent. His position later was changed, and he was given charge of not only the purchasing of tools, but the maintenance as well, whereupon, after thorough investigation, he quit purchasing geared head machines entirely, and purchased nothing but cone-driven machines. The reason given was that he found that the maintenance of the geared head machines outweighed and outclassed the advantages of quick-speed changes, the increased driving power, and all other claims made for the tools.

I think you will find, if you will carefully investigate your overhead charges, that the increased cost of the geared head machine added to the increased maintenance cost added to the increased power cost, will more than outweigh all the advantages claimed by exponents of the all-geared machines.

Fallacy of Instantaneous Speed Changes

I would like to say a word about speed changes. The advocates of the geared machines always harp upon the advantages of instantaneous speed changes. As a matter of fact, one of the best known makers in this country places a plate on his machine, on which he states positively that the machine must be stopped when changing speeds. Another builder has to throw in and out back gears when making the change of speeds which necessitates the stopping of the machine. The only instantaneous change machines are the friction clutch machines, which are always more or less a cause of annoyance and trouble.

Another claim made for this type of machine, which is not lived up to except in a very few cases, is that the machines can be driven direct from the lineshaft and require no countershaft or overhead works. This is more of a theoretical than a practical advantage, as nine out of ten times the machine has to be placed so it requires a special jack-shaft and I have always found it the best plan, when machinery was idle, to stop it as close to the lineshaft as possible, and not have moving parts on the machine.

The "Old Reliable" Cone Drive

Now for the "old reliable" cone drive. When I say "old reliable," I do not mean the old-fashioned cone which was small in diameter and of narrow face. I mean, as I stated in the original proposition, the double-friction back-geared cone, which can be made of large diameter and proper face, the two ratios of back gearing enabling a cone to be designed so the old small step is entirely eliminated. With this type of drive, twice the power can be delivered to the spindle as with the same size pulley on a geared drive.

While I realize that the geared drive can be constructed so that the size and speed of the pulley is practically limitless, the fact remains that all the designs on the market today, are fairly well within the range of the modern cone sizes, used on similar machines. Further than this, there is no limit to the power that can be obtained by the cone drive. The Alfred Herbert Co. of Coventry, England, has demonstrated this in some of its new design machines in which they use the cone running at a very high speed, as a driver, and use the double back gear, never using the direct cone speeds. Of course, this construction is simply a development of the old style drive with which we are familiar on Lincoln type millers and machines of that description, but this combination of the cone drive, will give more power than is required by any machine in the market to-day, and will give it with less friction loss; in other words, with greater efficiency than any geared head machine on the market.

As to the belt-shifting feature on the cone-driven machine, that can be easily eliminated with a belt-shifting device, and is eliminated without that device where the belts are of moderate width and length, by the operator. He does not have to stop his machine to make the changes and practically performs an instantaneous speed change. The ideal drive today is large cone diameters with not overly wide steps.

As an example of the drift of actual practice in this line, I would like to cite planers. In our shop we have used four different designs of geared speed devices on our planers, all of which have been uniformly unsatisfactory. We have recently noticed that a prominent planer maker has "dropped" to this condition and is going back to a cone for his cutting changes. There is also one of the best planer makers in the United States who has always used a cone variator. We also know a prominent boring mill manufacturer who has found that the most practical way to obtain speed changes is through a cone.

In these instances, it is not a question of original cone design. It has been a development in which the cone has actually been found to be the most satisfactory method of obtaining these speed changes. This has also been exemplified in feeds. For instance, take grinding machines. Brown & Sharpe Mfg. Co. and Norton Grinding Co. are both using cone belts on their feed changes, after both had experimented and tried out different forms of gear changes.

Effect of Belt Pull on Spindle

Now I will speak about the fallacy of the belt pull on the spindle. With the geared head machines, of course there is no belt pull on the spindle, but there is the gear pressure, which in slow speeds, is multiplied many times and is considerably more than the belt pull. Further than this, on a cone-driven machine, the belt pull is not a detriment, but a possible advantage. It simply serves to counterbalance the weight of the moving parts, namely the cone and spindle. In my machine tool experience, I have never heard of a lathe spindle wearing upward. We know positively from our experience with second-hand lathes, that the spindles are invariably lower than the tailstocks, so this would positively determine that the wear of the spindle is downward in spite of the belt pull.

It is an indisputable fact that in ninety-nine machines out of every hundred, the cone drive is capable of furnishing much greater power than is required for the machine as operated, that is, the machines of to-day are not worked to fifty per cent of their pulling capacity; if they were worked to capacity, it would be a mighty bad thing for the machine tool builders, and would be the means of "calling a great many bluffs," as we all realize that there are a great many guarantees made with the absolute knowledge that the machines cannot stand up to the work continuously, and after the first trial, there will be no attempt to continue production on the same scale, which simply proves that the excessive pulling power, in ninety-nine cases out of a hundred, is not a legitimate requirement. The purpose of machining to-day is not to make shavings, but to do accurate work.

I maintain that you cannot get as good average production with a geared machine as you can with a cone-driven machine. I realize that on certain jobs a saving in time might be shown on a geared machine, but if two shops, one equipped with double-friction back-geared cone machines and the other with all-geared-head machines, both under equally efficient management, were taken as examples, the cone drive shop would be found to produce more work, or to produce the same work at a much lower cost.

In summing up this matter we arrive at the following conclusions: The advantages claimed for the all-geared machines have not been obtained; there is not a single all-geared machine on the market to-day in which instantaneous speed changes are obtained, or the required number of speed changes, without a multiplicity of friction clutches; there is not a geared machine on the market in which proportionate efficiency is realized; there is not a geared machine on the market for which the maintenance charge is not greater than for the cone head machine; there is not a geared machine on the market which can be produced for anything like the same first cost.

For the cone-driven machine, we can get a larger proportion of speed changes than is permitted by the geared head designs; practically the same power at the cutting tool; eliminate vibration and excessive wear; and get a cheaper first-cost machine.

* * *

It is stated by Mr. William W. Bird in the *Journal of the Worcester Polytechnic Institute* that belts of single thickness will stand a stress of 60 pounds per inch of width with only occasional taking up and will have a fairly long life, provided the pulleys are not too small. The permissible stress for double and triple belts would be 105 and 150 pounds, respectively.

A FEW FORGING OPERATIONS

PRACTICE IN THE C. H. & D. R. R. SHOP, LIMA, OHIO

By ETHAN VIALL*

A number of interesting forging operations are to be seen in the blacksmith shop of the C. H. & D. R. R., in Lima, Ohio, not the least of which are those pertaining to the making of drawbar pockets; the bulldozer forming tools for making them and the various operations are illustrated in Fig. 1. The first operation after the bar is cut to length and one end heated, is to punch the four holes and bend the gib, which is all done at one stroke of the bulldozer ram, using the tools *A* and *B*. *C* is a stop for the stock, so made that it springs back out of the way as the end of the gib-former strikes it, and returns again to position as soon as released. The springs shown on each side of the member *D* are used to operate the strippers on the face of the punching die. Usually the end of the gib is trimmed at the same heat and immediately after bending, using the trimming shears *E* and *F*. If a number of pockets are to be run through, they are all finished on one end in this way, by which time the ends of the first ones have been cooled enough to be handled easily, when the other end is heated and finished in the same manner. For several reasons it is not advisable to depend on stops to locate the middle of the pocket while forming the loop, so it is obtained by measurement, being marked with a chisel. The pocket is then bent in the forming punch and die *G* and *H*, in which it is located by means of the chisel mark just mentioned and a corresponding mark on the former, being clamped in position by an eccentric clamp operated by the lever *I*. It will be noticed that the former used here is solid and not of the wing type so frequently seen, and the results are just as good, apparently, as those obtained by using the more elaborate formers, no dangerous straining or tearing of the metal being noticeable. The pockets are riveted onto the drawbars by first heating the long rivets red hot, driving them home, and then upsetting the end in the pneumatic machine shown in Fig. 2. This machine is operated by an old air cylinder and the end of the upsetting plunger is cupped out to the shape required on the head of the rivet. In Fig. 2 a drawbar and pocket with one rivet in place, is shown resting on its side, held up by the chain hoist.

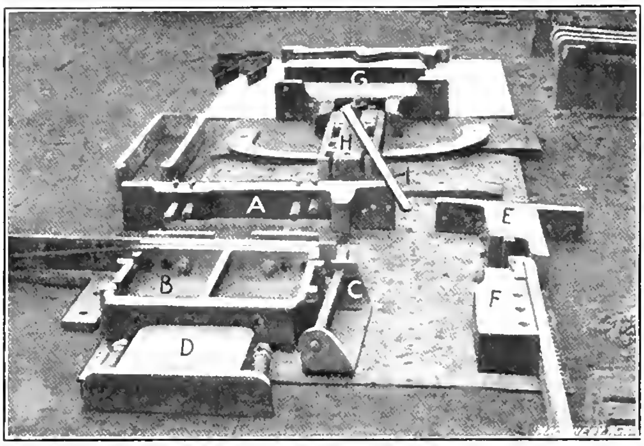

Fig. 1. Drawbar Pocket Forming Tools

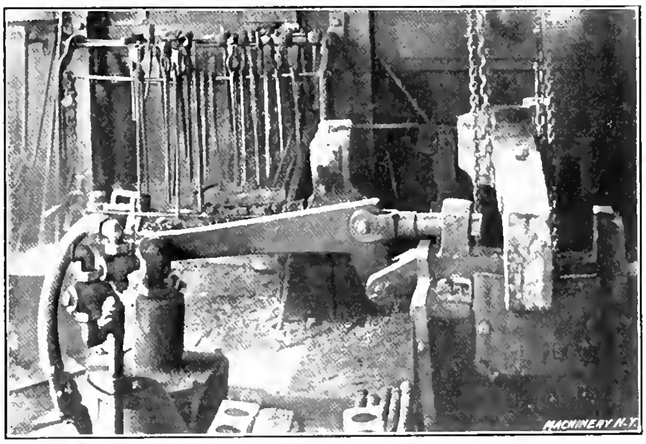

Fig. 2. Pneumatic Device for Setting the Rivets at One Stroke

Fig. 3. Front View of Bolt Heating Furnace and Forging Machine

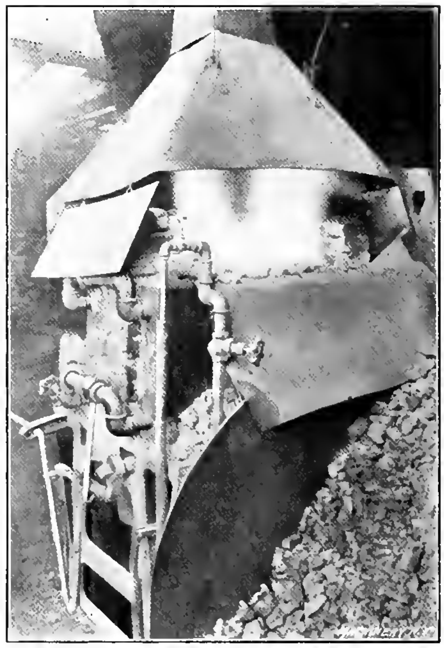

Fig. 4. Rear View of Water Jacketed Heating Furnace

The long rivets or bolts used for the foregoing job as well as other kinds, are headed in a regular forging machine fitted with suitable dies, the heating being done in the special coke burning furnace, shown in Fig. 3, which is the design of A. L. Woodworth, the blacksmith foreman, who is also secretary of the International Railroad Master Blacksmiths' Association. A rear view of this furnace is shown in Fig. 4. The furnace consists of a cast-iron frame 24 x 48 x 30 inches high to which is attached a blast box 12 x 12 x 48 inches long. This box is closed at the bottom with a door which fits closely to prevent the blast from escaping. At the top is a dump grate which supports the fire. This grate is level with the top of the frame and, when dumping, it swings down into the blast box. The top of the furnace consists of two cast-iron boxes, or water front and back, and these are 4 inches thick, 24 inches wide and 48 inches long, and are connected at each end with $1\frac{1}{4}$-inch pipe so as to allow a free circulation of

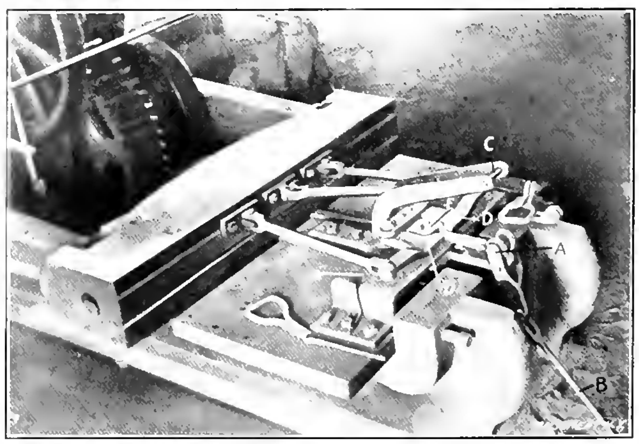

Fig. 5. Brake Hanger Former in Position at Forward End of Stroke

* Associate Editor of MACHINERY.

water, which keeps the furnace cool and comfortable for the operator. The front casting has a slot 3 inches wide by 36 inches long, left so that blanks may be fed in and heated for the bolts. This furnace is very satisfactory when coke is used for fuel.

Mr. Woodworth also designed a unique bulldozer attachment for forming brake hangers. This attachment is shown in operation in Fig. 5 forming the hangers similar to a large cotter. The rod is cut off to the desired length and then inserted between the stops at *a*. As the ram advances on its forward stroke the two wings or formers *D* bend the rod around the block *E*, forming the loop. A pin is then inserted

Fig. 6. Brake Hanger Former in Position at End of Return Stroke

at *A*, around which the second loop is formed, and the rod *B* connected to pin *C*. The slide is shoved in close and as the ram returns on the backward stroke, as shown in Fig. 6, it forms the loops on the end of the hanger. The pin at *A* is now pulled out, the slide pulled back and the finished piece removed, leaving the former ready for the next piece. It should be mentioned that these hangers are bent while red hot, of course. The working parts of this attachment shown fastened to the bulldozer are clearly illustrated in the line engraving shown in Fig. 7.

* * *

The increase in the sizes of warships is proceeding at a rapid rate. The English cruiser battleship *Lion*, which is now being constructed, will displace 21,000 tons and have a total length of 700 feet. The engines will develop 70,000 horse-

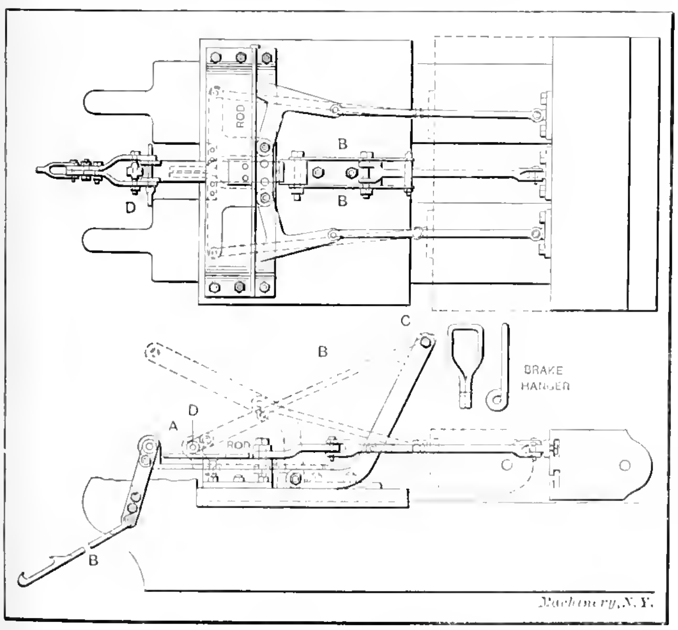

Fig 7 Details of Brake Hanger Former

power. The speed of the vessel is expected to be twenty-seven knots and it will be equipped with ten 12-inch guns. As an example of the possibilities of engineering this battleship is a wonderful achievement, but from the point of view of the purpose of engineering it is one of the paradoxes of the age, because the purpose of engineering is to construct means for easy production—not for destruction.

PROPERTIES OF SECTIONS FOR PUNCH AND SHEAR FRAMES*†

By ALTON L. SMITH‡

The convenience of the tables of properties of rolled steel sections as published in the structural steel makers' handbooks impresses anyone who has occasion to compute the strength of such material. Machine frames cannot be standardized sufficiently to permit of similar tables which would be useful to the designer of machinery, but it is with a view to the simplifying of the work of selecting proper sections for punch and shear frames that the table in the accompanying Data Sheet Supplement has been compiled. The values were computed by slide rule, and it is believed that they are accurate enough for all practical purposes.

To illustrate the use of the table, consider the punch frame shown diagrammatically in Fig. 1. The "reach," or distance from the center line of punch to the back of gap, is 24 inches. Assume that the maximum pressure, *P*, tending to force the jaws apart is that due to punching a 1-inch circular hole in soft steel plate 1 inch thick, or say about 157,000 pounds. Consider the section at *TX*. The action of *P* is such as to produce a tensile stress on the section to the left of the neutral axis *N*, with a compressive stress to the right of *N*, both due to flexure; and, besides, there is a tensile stress distributed uniformly over the section.

It is usually sufficient to determine the maximum tensile stress to the left of *N*.

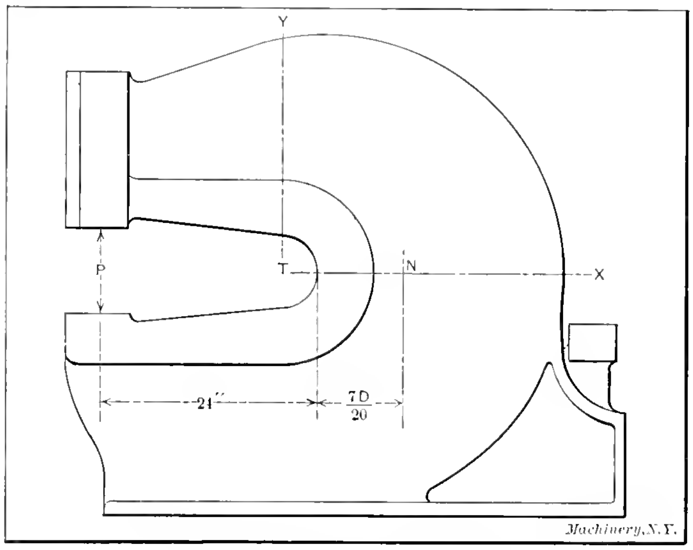

Fig. 1. Diagrammatical View of Punch Frame

Maximum tensile stress = flexure tensile stress + uniformly distributed tensile stress.

$$\text{Flexure tensile stress} = \frac{\text{Moment of } P \text{ about } N}{\text{Tensile section modulus of section } TX}.$$

$$\text{Uniformly distributed tensile stress} = \frac{P}{\text{Area of section } TX}.$$

Assume 3,000 pounds per square inch as the allowable maximum tensile stress for cast iron.

Trial Solution

Assume that D in Fig. 2 is about 30 inches. Then $\frac{7D}{20} =$ $10\frac{1}{2}$ inches. If the stress due to flexure only is considered, the required section modulus for tension would be

$$\frac{157{,}000 \times (24 + 10\frac{1}{2})}{3{,}000} = 1{,}800, \text{ about.}$$

As no allowauce has been made for the additional tensile stress uniformly distributed over the section, a section must

* With Data Sheet Supplement.

† The following articles on the design of punch and shear frames have previously been published in MACHINERY: "Design of Punch and Riveter Frames," Novemoer, 1905, engineering edition; "Strength of Punch and Shear Frames," February, 1907, engineering edition; "The Designing of Machine Frames," August, 1908, engineering edition; "The Design of Curved Machine Members under Eccentric Load," December, 1909, engineering edition. See also MACHINERY'S Reference Series No. 21, "Examples of Calculating Designs," Chapter II.

‡ Professor of Machine Design, Worcester Polytechnic Institute, Worcester, Mass.

be selected whose tension modulus is somewhat greater than 1,800, say about 2,500.

The table in the Data Sheet Supplement gives a great variety of shapes and proportions, the only dimensions common to all being the depth of section, D, and the distance of the neutral axis from the extreme tension fiber. This location of the neutral axis represents average practice and insures an economical distribution of metal. Generous fillets and rounded corners should, of course, be used on the final section.

Suppose that a deep narrow section is desired, similar to that in Fig. 2, in which the dimensions are as follows: $D =$ 10 inches, $B = 7$ inches, $b = 4$ inches, $H = 1.98$ inch, $\frac{t}{2} = h =$ $\frac{5}{8}$ inch, A (area) $= 26.3$ square inches, and S_t (section modulus for tension) $= 78.6$. This section of the table is not, of course, large enough, but a similar one which is large enough may be found easily as follows:

If two sections A and B are similar in all respects, then

$$\frac{\text{Area of } A}{\text{Area of } B} = \frac{(\text{Any dimension of } A)^2}{(\text{Corresponding dimension of } B)^2}, \text{ and}$$

$$\frac{\text{Section modulus of } A}{\text{Section modulus of } B} = \frac{(\text{Any dimension of } A)^3}{(\text{Corresponding dimension of } B)^3}.$$

$$\frac{\text{Required section modulus}}{\text{Modulus of section from the table}} = \frac{(\text{Required } D)^3}{(D \text{ of section from the table})^3}$$

Hence, $\frac{2{,}500}{78.6} = \frac{(\text{Required } D)^3}{(10)^3}$. This last equation solved for D gives $D = 31.7$ inches, nearly. As the large section will be exactly similar to the small one, the area of the large section is found from the equation

$$\frac{\text{Area of required section}}{26.3} = \frac{(31.7)^2}{(10)^2}$$

and area $= 264$ square inches, about.

The neutral axis will be $\frac{7}{20} \times 31.7$, or 11.1 inches from the extreme tension fiber.

This trial section may now be tested for the maximum stress on it.

$$\text{Flexure tensile stress} = \frac{157{,}000 \times (24 + 11.1)}{2{,}500} = 2{,}200$$

pounds per square inch, about.

$$\text{Uniformly distributed tensile stress} = \frac{157{,}000}{264} = 594$$

pounds per square inch, about.

The total tensile stress is, therefore, 2794 pounds per square inch.

If this result had not been near enough to the 3,000 pounds per square inch assumed, another section could have been selected and worked out in the same way to get a closer result. The depth D of the required section being 31.7 inches as compared with 10 inches of the similar section given in the table, each of the dimensions of the required section will be 3.17 times the corresponding one given in the table. Hence $D = 31.7$, say 32 inches, $B = 22.2$, say 22 inches, $b = 12.7$, say 13 inches, $H = 6.3$, say $6\frac{1}{2}$ inches, $t/2 = h = 1.98$, say 2 inches. The webs thicken gradually from the neutral axis to the tension flange so as to avoid too sudden a change in the section. For selecting the section at TY, Fig. 1, the procedure would be the same except that there would be no uniformly distributed stress to be added as in the case of section TX.

The method here given for determining the stress on the section TX is the one which has been commonly used. It is correct for straight beams and until recently has been considered approximately correct for curved beams. Investigations by Bach and others, however, indicate that the maximum stresses in curved beams of ductile material are very much greater than those found by the method used here; but a quick and accurate way of applying the new theory to general sections has not yet been devised. Cast-iron punch frames whose sections have been determined by the old analysis have apparently stood up under their loads for years, although the maximum stresses in them as determined by the new analysis are so great as to threaten serious injury. [See article by Prof. Rautenstrauch in the Journal of the

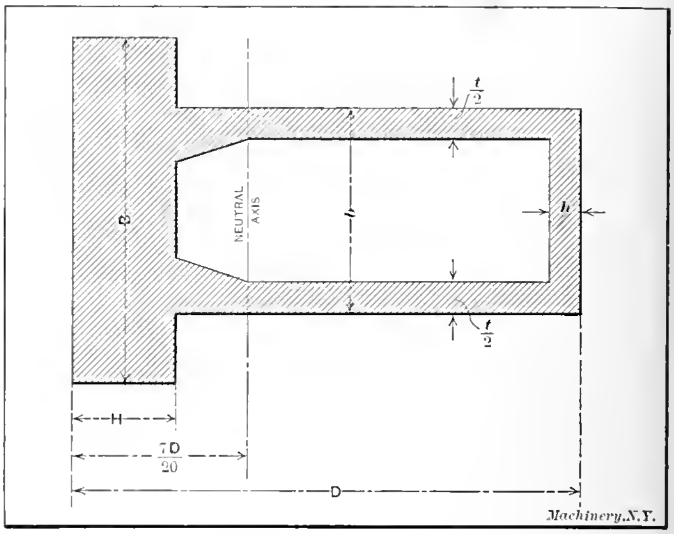

Fig. 2. Section of Punch Frame

American Society of Mechanical Engineers for mid-October, 1909. See abstract in MACHINERY, December, 1909, engineering edition: "The Design of Curved Machine Members Under Eccentric Load."] Until the new theory has been more thoroughly verified by experiments, however, the old method will doubtless be used by most designers.

CANCELLATION OF ORDERS*

By C. WOOD WALTER†

There is no force so potent in the manufacturer's daily "struggle for existence" as the machine-tool order. We are all smiles on a "big-order day," full of optimism after a "big-order month," and ready to enlarge our plant, increase our force, and bring out a new line after a "big-order year"—all of which would show good judgment if orders always turned into shipments—but there are times when they do not. It does not take a long memory to go back to the fall of 1907, when orders vanished from our books like a beautiful dream, and (to quote the immortal bard) "like an unsubstantial pageant faded into thin air." Our fat order books shrank into nothingness—almost over night—and instead of being six months behind on orders, as we were wont to boast, most of us, in about sixty days, got six months ahead. As a result we were obliged to cut down the working force and increase the costs, thereby cutting out profits. This deplorable condition was due to the fact that the demand fell off, but it was also largely due to the fact that many of the orders on our books were not contracts, but simply *guesses* as to what the buyers *thought* they *might* need.

There are two classes of orders, so-called, in the machine-tool business:

1. Orders from the machine-tool dealers for stock. This kind of order, when not limited, does not have a high degree of validity—and perhaps necessarily so—for no manufacturer should force his agent to take stock when the agent's sales do not justify his previous estimate. In so doing we are simply using the agent's money, thereby crippling our selling department and increasing the costs of marketing our goods. The agent's stock order is not good business—stocks can be more economically and more intelligently carried and maintained by the manufacturer at one central point in his warehouse than by his agents in their expensive stores at various points. This is not inconsistent with the policy of carrying a proper line of sample machines on the agents' floors. Agents' stock orders, for the most part, serve only to record the agent's judgment as to what the future demand may be in his

*Paper read before National Machine Tool Builders' Association Convention, Rochester, N. Y., May 24-25, 1910.
†Address: Cincinnati Milling Machine Co., Cincinnati, Ohio.

territory. Many manufacturers, therefore, no longer accept agents' stock orders. Where they *are* accepted, it should be for limited quantities only, and they should be made not subject to cancellation.

2. Orders from the actual purchaser, the user of the machines, placed with the dealer or with the manufacturer direct. Many manufacturers are coming to regard this as the only order that is truly significant. But even this order, as commonly understood, falls short of being an actual contract. A large percentage of machine-tool buyers, to-day, place their orders with the mental reservation that they can easily meet a change in their plans, or a change in the market demand, by a cancellation of the order any time prior to shipment date. To some extent this cancellation privilege has been written into the order with the sanction of the dealer, or against his protest. To some extent the dealer has encouraged the buyer to reserve machines, subject to cancellation, and such reservations have been turned in as orders to the manufacturer who forthwith proceeds to invest his money to fill "the large orders on his books." I do not speak of the cancellation based on failure to deliver or on any legitimate grounds.

Now it does seem as though the machine-tool order as it exists to-day, might most profitably be subjected to a reform, so that it shall represent a contract, not subject to cancellation—the option of granting a cancellation to rest entirely with the vendor. The time to work this reform is now, while the demand is strong and there is no anticipated decline in sight. Consider what an added stability would be given to our industry to-day, if the unfilled orders on our books represented actual contracts not subject to cancellation! Consider what a change such a condition of our order books would have made in the fall of 1907, when the slump struck us—and yet this is just what an order means in many other lines of business. Why not in our line?

Let us review a few of the evil results that follow from the present practice of filling our books with so-called orders which do not represent binding contracts:

1. The manufacturer invests his money in materials and wages to finish machines on order, only to find when they are finished, that he may not have orders for them.

2. The manufacturer increases his production schedule to keep pace with his big order book. When his order book suddenly collapses under wholesale cancellations, he is left with a big stock on hand and coming out, with consequent heavy interest charges and often with heavy contracts for materials which he himself cannot cancel. This situation forces him to curtail immediately and run on a losing basis. It is bad enough to suddenly strike a market where new orders are scarce, without having to face a wholesale disappearance of the orders on hand.

3. Manufacturing on the basis of an artificial demand (as reflected in an artificially padded order book) makes also an artificial demand for material and labor, and a consequent increase in their cost. This is equally true for the dealer, who pays out his money to sell the goods, and increases his salesman's wages because the salesman is piling up big sales—which finally may largely disappear under cancellations.

4. Most disastrous of all, these wholesale cancellations under a slump in the demand, leave the manufacturers with such an over-production on hand, that the stability of prices is immediately and most seriously threatened. It becomes a matter of self-preservation for the weaker concern to cut prices. It is a matter of credit to this organization, that a disastrous and demoralizing break in prices did not follow the wholesale cancellation of orders and cessation of buying in the fall of 1907. This was prevented largely through the educational propaganda carried on by this association among its members to arouse them to a study of the real cost of the manufacture and sale of machine tools, and the right of every manufacturer to a decent profit beyond that cost—if he is to perpetuate himself in the business.

But our industry should not be subjected to such a strain as this. Once a demoralizing break in prices of this kind takes place, it takes years to recover. Now it is my opinion that we will take a long step in the direction of preventing this possibility, if we will cut out the cancellation privilege. Consider some of the benefits which would follow the establishment of the practice that would make a machine tool order not subject to cancellation.

1. The manufacturer may make his contracts for materials, arrange his manufacturing schedule, regulate the growth of his plant, with an actual knowledge of the amount of his product which he has absolutely sold, and which will stay sold.

2. The machine-tool dealer or agent may proceed with the development of his business, with the definite knowledge that he has earned so much profit based on his sales already made, instead of facing the possibility of a threatened and finally absolute loss when he is confronted with a flood of cancellations.

3. If the manufacturer can regard orders as actual and absolute sales, he can then intelligently and economically govern the amount and variety of stock he shall make, since he may approximately measure the actual and real demand for his various items of product.

4. Under a slump in the demand (which in the beginning is often more or less artificial), the orders remaining on the books, if actual and collectable, may be sufficient, in the whole industry, to bring about at least a partial resumption of business and restoration of confidence—at least the manufacturer would have time to reorganize his production without the disaster of sudden and drastic curtailment. This same benefit would accrue to the dealer as well.

Perhaps the simplest manner in which to bring this about, is for the different groups of competitors in this association to agree together to notify their agents that, beginning with a certain date, all orders on the manufacturers' books, and all orders to be entered in the future, must be considered "not subject to cancellation." This makes it possible and reasonable for the dealer to insist upon the same conditions from the consumer—and the consumer will find that he is asked to meet a regulation which is only reasonable and economic, and which is presented to him by all dealers and manufacturers alike, and he will soon yield to it as an established custom of trade, and ask in turn the same conditions of those who buy from him.

MAKING AN AUTOMOBILE STEERING WHEEL

By M. E. DAWSON

The steering wheel on an automobile, to the average person not familiar with the building of the entire machine, appears as only a drop in the auto manufacturing bucket, and yet if this small part of the automobile were manufactured in a shop by itself, the shop would be considered quite a large plant.

A section of the steering wheel ring on one of the leading makes of automobiles is shown in Fig. 1. The arms, center hub, and outer ring comprise the spider or metal portion and to this spider is secured a wooden ring of mahogany or other suitable wood. This wooden ring is "built up" and finished in two separate sections, each section having four segments. In the wood portion of this steering wheel only the best mahogany is used, and high-grade aluminum is used in the metal spider. The finished wheel must go through a critical inspection; defective material or workmanship, bad joints, "dutchmen," putty fillers, etc., are all causes for the inspector to put his blue-pencil mark on the wheels. In order to reach this stage of perfection in the construction of the wheel, and to turn them out in numbers sufficient to meet the requirements, every detail piece of work is done by special tools. I will not attempt to show more than one of these special-built tools, but from this may be learned to what extent this special tool building is carried on.

In the plan view, Fig. 2, is shown a reconstructed turret lathe, having an attachment for shaping the hand ring, a half of which is shown chucked on the faceplate. No change whatever is made in the tailstock or rather the turret head; the headstock, however, is set over so as to bring the center line of the stock to be turned in line with the center of the turret head. The cast-iron bracket *A* has two bearings which support the cutter spindle of the attachment. The cutter head consists of two steel collars—one butting against a shoulder

and the other loosely mounted on the spindle. Between these collars are clamped the cutter knives by means of the set- and lock-nuts as shown.

The cutter spindle is driven by quarter-turn belt, running over a deep-flanged pulley on the overhead countershaft, which is the same shaft that drives the lathe. The driving pulley on the countershaft is so located that the belt becomes tight as the cutter spindle approaches the work and loose when it is drawn away, thus relieving the constant high tension on the bearings, which saves wear and tear on both the bearings and belt. An emery wheel attachment is mounted on the end of the spindle and is a part of the lathe outfit. So as not to interfere with the movements of the operator, the emery wheel spindle is removed when it is not in use.

The first operation on the rim includes facing the joint and cutting the rectangular recess in which the metal rim of the wheel fits. The work is held during this first turning operation by pinch dogs, such as are shown at *B*; during the second operation on the opposite side, the rim is held by screws *C*, which pass through the faceplate and into the wood. The cutter spindle revolves at a high rate of speed, while the faceplate revolves more slowly, the speed being in proportion to that of the cutter spindle. The cut is gaged by collars on the cutter spindle, which come against the faceplate.

In Fig. 3 is shown a detail of the shield or cover which is over the cutter-head. This shield is automatically operated by the reciprocating action of the turret carriage, through the medium of a rod which is attached to the shield and passes through a stationary bracket as shown. When the cutter is at work, the shield is held in a position clear of the faceplate, and at the same time it directs the chips away from the operator. The shield is hinged, and on top of it there is an arm having a slotted hole through which the lifting rod passes. This rod, as indicated, is threaded to provide for adjustment. When the operator is in the act of removing the finished rim from the faceplate, it is impossible for any part of his person to come in contact with the cutter, owing to the protection of the shield.

* * *

An interesting optical instrument has been introduced in Paris. It is made in the form of a walking stick provided with optical devices which enable a person to look over a crowd, the hats of ladies, fences, walls, etc. The stick consists of a hollow tube near the top of which is mounted half of a small field glass. The rays of light pass through the lenses and strike a prism inside of the stick, by means of which they are reflected at right angles to another prism at the lower end where they are again reflected in a horizontal direction, so that the objects open to the view of the field glass can be clearly seen by the eye.

OPERATION AND CONSTRUCTION OF THE SUB-PRESS DIE*

By ROY PLAISTED†

When constructing a blanking die, the class of work for which it is intended and the amount required should determine to a great extent the cost of the tool and the degree of accuracy necessary. Where only a limited number of blanks are required and a variation of a few thousandths is allowable, a die can oftentimes be made very cheaply that is good enough; for instance, in the manufacture of cheap jewelry where only a few thousand blanks of a certain kind are wanted, a die of cheap steel, three-eighths thick, soldered to a plate and run with a soft punch, meets all the requirements. On the other hand, on a class of work where accuracy is the essential feature and the die is in constant use until worn out, the best of material and workmanship is necessary. In shops where this class of work is handled, the sub-press die is usually depended upon to produce it. A die of this type is shown in the accompanying engraving. It is doubtless familiar to many of the readers of MACHINERY, as dies built upon this principle have been extensively used in nearly all the watch factories in this country for several years, and are constantly growing in favor in most shops where high-grade dies are used, though as yet they are not in general use to the extent that they would be if the many advantages to be derived from their use and the saving that could be effected were better known. It is true that the first cost of a die of this kind is considerable, but the long life of the tool and the excellence of its work make it a profitable investment.

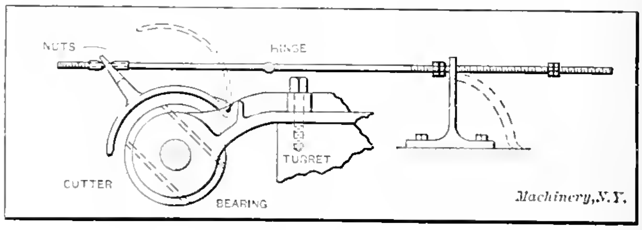

Fig. 3. Cutter Guard with Automatic Adjustment

A brief description of a sub press die for producing the blank shown at *A* follows: The upper half of the casting or cylinder *B*, is shouldered onto the base *C* to which it is attached by screws *D*; it is also doweled in position by the two pins *E*. The plunger *F* runs in a casing of babbitt shown at *G*, the wear in which is taken up when necessary by screwing down the tightening nut *H*, which forces the babbitt down and in at the same time, as the cylinder is bored on a slight taper. The plunger has three semi-circular grooves milled along its length to prevent its turning. Attached to the plunger is the die *I*, which cuts the outside of the blank, and the small punches *J* which are held in the back-plate *K* and supported by the shedder *L* which is backed up by the heavy spring *M* the tension on which is obtained by screwing down screw *N* which nas a small hole running through it to allow

* For additional information on the subject of punch and die work see MACHINERY, August, 1904, "Punches and Dies for Making Hinge Springs for Novelty Boxes" and "Notes on Die Making"; July, August and September, 1906, "Punch and Die Work"; July, 1906, "Progress in Simple Press Work"; October, 1906, "Blanking and Piercing Dies for Washers"; December, 1906, engineering edition, "Sub-press Work at the Sloan & Chace Shops"; February, 1907, "Making Blanking Dies to Cut Stock Economically"; March, 1907, "Construction of Split Dies for Press Work"; March, 1907, "Helpful Hints for Toolmakers"; May, 1907, "Sectional Punches and Dies"; June, 1907, engineering edition, "Novel Ideas in Die Making"; October, 1909, "Drawing Dies for Hollow Rivets"; January, 1910, "Die Beds or Bolsters for Presses"; April, 1910, "Automatic Punch Press Work"; June, 1910, "Out-of-Date Die Making Methods." † Address: 4563 Mulberry St., Frankford, Pa.

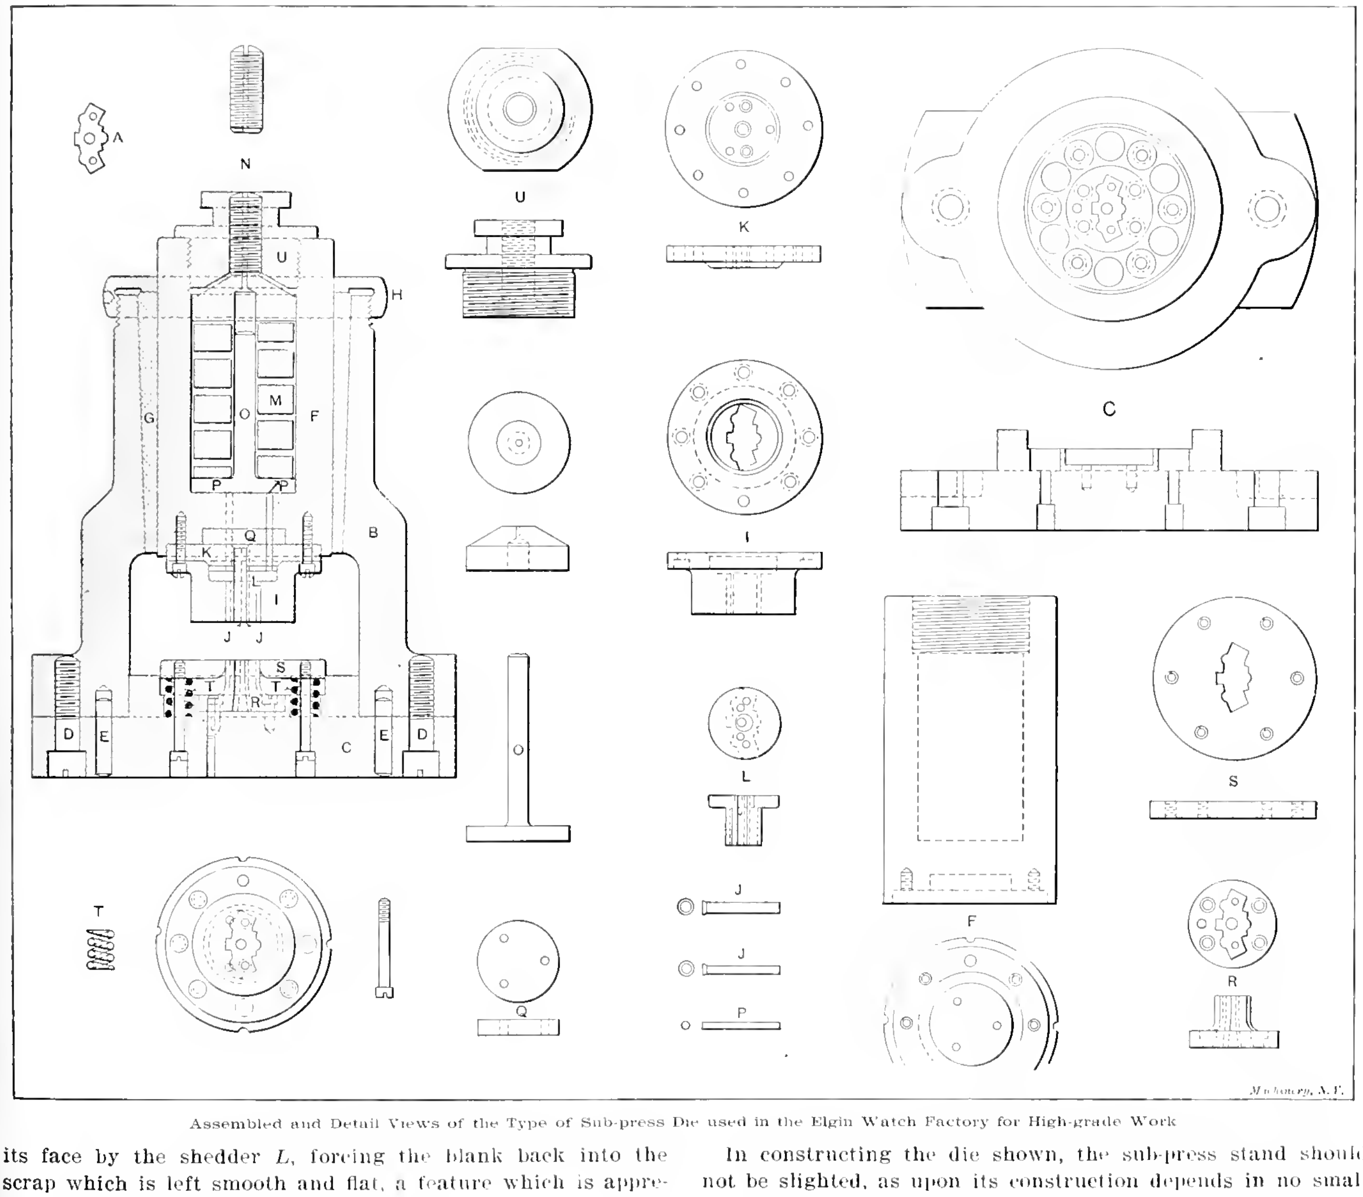
the air to escape. The center piece O and the three pins P placed between the spring and shedder, supply the tension necessary to operate the latter. The hardened disk Q is pressed into the plunger behind the back-plate as indicated, to take the thrust of the small punches. The base C is recessed to receive the base of the larger punch R which has three openings for the three small punches J, clearance being provided to allow the scrap punchings to pass through. The stripper in the lower member is shown at S, the resistance from the springs T doing the work.

In operation the plunger descends with the ram of the press and the stock caught between the two flat surfaces is held firmly in position at the time it is struck, thereby preventing any creeping or distortion of metal during the blanking. The outside of the blank and the pierced holes are cut simultaneously. Upon the return stroke of the ram, the tension from the small springs T forces the stripper S back over the punch R which still has the blank pressed firmly against part of the press work is entrusted (through a mistaken idea of economy) to an inexperienced operator who has a very vague idea of the cost of the tools he is setting and to whom the shearing of a die is only a part of the day's work. Another point in favor of the sub-press is the fact that owing to the small punches being supported nearly their entire length, it is possible to pierce smaller holes in comparatively thick stock, than can be accomplished with any other die, it not being unusual to successfully punch holes in stock considerably over twice the diameter of the punch. A narrower bridge can also be left between blanks and a much better blank obtained than with any other form of die. The blanks are not only free from burrs, but they are always of a uniform size, the die being straight instead of having clearance, as is the case in the open die (where the blanks have to pass through) so that the first blank punched is an exact duplicate of the one produced when the die is worn out, which, obviously, means a longer life for the die.



Assembled and Detail Views of the Type of Sub-press Die used in the Elgin Watch Factory for High-grade Work

its face by the shedder L, forcing the blank back into the scrap which is left smooth and flat, a feature which is appreciated wherever the reel-feed is used.

The many advantages of this type of die over the open die are apparent to anyone seeing it in use. The fact that the sub-press is a self-contained tool, being in nowise dependent upon the ways of the power press in which it is run, and the consequent ease with which the die can be set, means a great saving in time, as all that is necessary is to attach the cap U to a T-slot in the gate of the ram, clamp the base to the bed of the power press, and adjust the stroke. Not only is it a time-saver, but it also possesses another distinct advantage in that it does not necessitate a careful lining up of punch and die, as dies of this kind are always in perfect alignment. This makes it impossible to set a sub-press die up so as to "shear" it, a feature which should not be overlooked, as usually this

In constructing the die shown, the sub-press stand should not be slighted, as upon its construction depends in no small measure the proper working of the die. If the stands are well made, they can be used indefinitely for different dies, owing to the means provided to adjust for wear. It is a disputed point whether the plunger should be babbitted before or after the punch and die are fitted. Some prefer to make the punch and die first, enter the punch into the die attached to the plunger, and pour the babbitt, but it is generally conceded that the better way is to babbitt the plunger first; in fact, most manufacturers at the present time buy them already fitted up from one of the several companies manufacturing them for the trade. One advantage in having the plunger babbitted first is that it can be run continuously for a day or so to free it up well and secure a good bearing, the large nut being set up occasionally. In this "working out," the

plunger is sure to creep a trifle, probably caused by the babbitt not flowing evenly and, obviously, it is much better for this change to take place before the alignment of the punch and die. In recessing the cylinder to receive the base, the proper way is to place the plunger on the centers of the lathe with the cylinder attached and recess and face out on the bottom, using the plunger for a mandrel. With this method one has the assurance of knowing that the plunger is exactly central and in a vertical position with the base, which cannot be said when the plunger is babbitted last.

In milling the three grooves in the plunger, it is well to space them unevenly, as it will then be impossible for the aforementioned press operator or anyone to insert it in any but its proper position. In locating the holes in the back-plate and shedder, a round master plate is usually used, thus insuring greater accuracy. This master plate can be laid away for duplicating the die. In boring the holes in the master plate, they should be made a trifle larger than the largest hole in the work, which gives clearance for the boring tool to pass through. When boring the back-plate, it and the master plate should be set perfectly central with each other and then fastened with a drop of soft solder on opposite sides. Having done this, a taper pin is inserted in the center of the face-plate of the bench lathe, and turned up on the end that projects, to the size of the holes in the master plate. One of the holes in the master plate is then wrung onto the pin, after which the master plate is clamped to the faceplate and one of the holes bored. No further indicating is required, as it is simply necessary to change from one hole to another upon the pin until all are bored. The holes should be left small, so as to correct the error from hardening, by grinding.

When grinding, the work is placed upon the master plate in the same manner and position as when boring, the grinding being done by means of a steel lap several thousandths smaller than the hole, the enlarged end of which is charged with diamond dust. [This process is more fully described in Mr. A. L. Monrad's excellent article in MACHINERY for December]. In separating the die from the master plate, the best way to remove the solder is to turn it off with a brass lathe tool before the work is removed from the faceplate.

When making the die *I*, great care must be exercised, as the die is straight and the templet must be worked through without any clearance; not only is this necessary for reasons before mentioned, but to allow an even sliding fit for the shedder. In case it is impossible to avoid a little clearance, it can sometimes be corrected in the lapping operation after hardening.

* * *

MEAN RADIUS OF THE FRICTIONAL FORCES OF A DISK BRAKE

By JOHN S. MYERS*

In the article on friction disk brakes on page 485 of the engineering edition of MACHINERY for February, the author assumes the center of tangential force to be at the center of gravity of the narrow sectors into which the disk may be imagined to be divided, while the editor inserts a note explaining that formulas have been found to give better results which assume the center of tangential force to be at the mean radius of the disk. As the writer has seen these two different ideas elsewhere, it was thought well to investigate the subject mathematically. The results confirm the statement as given by the editor. The assumptions upon which the investigation is based are as follows:

1. The coefficient of friction remains constant for varying pressures.

2. The wear of any one element of the surface is proportional to the work done upon it, *i. e.*, proportional to the pressure and velocity.

3. The disks remain flat under service, *i. e.*, they wear as fast at the outer edge as at the inner edge.

Assumption (1) would be far from true for conditions of perfect lubrication, but for slightly greasy surfaces such as those of a brake it is approximately correct. Assumption (2) would also be far from true for perfect lubrication, but seems reasonable for the ordinary conditions met with in disk brakes. Assumption (3) is almost self-evident, for, if one portion of the disk were to wear faster than another, it would be relieved of the load, thus equalizing the wear.

Let w = wear per unit pressure and velocity in unit time,
W = wear at any radius r,
N = revolutions in unit time,
P = pressure per unit of area.

$$\text{Then } W = wP2\pi rN \text{ or } P = \frac{W}{2\pi wrN} \qquad (1)$$

Now, using in the following demonstration the methods of calculus, let dA = area of any ring having a radius r and a breadth of dr, r being variable.

$$\text{Then } dA = 2\pi r dr. \qquad (2)$$

and if dF = the pressure on this ring,

$$dF = PdA = \frac{W2\pi rdr}{w2\pi rN} = \frac{W}{wN}\,dr. \qquad (3)$$

Let D = diameter of disk, then integrating (3) we have

$$F = \frac{W}{wN}\int_0^{\frac{D}{2}} dr = \frac{WD}{2wN} \qquad (4)$$

Now let dm = the moment of the ring about the center; then

$$dm = rdF = \frac{W}{wN}\,rdr. \qquad (5)$$

Integrating (5) gives

$$m = \frac{W}{wN}\int_0^{\frac{D}{2}} rdr = \frac{WD^2}{2wN4} \qquad (6)$$

Now let R = the lever arm of the total force F; then

$$R = \frac{m}{F} = \frac{WD^2 2wN}{2wN \times 4WD} = \frac{D}{4} \qquad (7)$$

which is the distance from the center of the disk to the center of gravity of the normal pressure on the disks. According to assumption (1), the coefficient of friction remains constant for varying pressures; hence the center of the tangential or frictional forces coincides with the center of the normal pressure as given by equation (7). The significance of equation (7) is, that for a complete disk the mean radius of the frictional forces is equal to the arithmetical mean radius of the disk.

Such disks, however, are seldom complete disks, but are annular rings in which the inside diameter is sometimes as great as half the outside diameter. For such disks let

D = outside diameter
D_1 = inside diameter,
m_1 = moment of the disk about the center,
F_1 = total normal pressure on disk,
R_1 = the lever arm of F_1 = also the mean radius of the tangential frictional forces.

From equation (6) we may write

$$m_1 = \frac{WD^2}{8wN} - \frac{WD_1^2}{8wN} = \frac{W}{8wN}(D^2 - D_1^2) \qquad (8)$$

From equation (4) we may write

$$F_1 = \frac{WD}{2wN} - \frac{WD_1}{2wN} = \frac{W}{2wN}(D - D_1) \qquad (9)$$

$$\text{Then } R_1 = \frac{m_1}{F_1} = \frac{W(D^2 - D_1^2)}{8wN} \times \frac{2wN}{W(D - D_1)} = \frac{D + D_1}{4} \qquad (10)$$

Now $\frac{D + D_1}{4}$ is the arithmetical mean radius of the disk, and hence unless the disks are working under conditions approximating those of perfect lubrication, they will wear in such a manner as to make the mean radius of the tangential frictional forces at least approximately equal to the arithmetical mean radius of the disk.

* * *

According to the *Brass World*, an aluminum alloy containing an average of 96 per cent aluminum, 2.5 per cent copper, 0.75 per cent manganese and 0.75 per cent silver can be rolled and drawn and is then much stronger than pure aluminum. The rolling may be done either hot or cold.

* Address: 2456 Almond St., Philadelphia, Pa.

GRINDING ECONOMY*

H. DARBYSHIRE†

Being one who is much concerned with grinding processes I was naturally interested in Mr. Thacher's useful contribution, "Economy in Grinding," in the May issue.

His remarks on the hints which are afforded by demonstrators being disregarded or forgotten by operators are to my own knowledge too true, but I would like to venture a friendly criticism on one point in his contribution which I trust he will receive in the spirit in which it is tendered. Mr. Thacher in speaking of spotting work off for steady-rest purposes seems to recommend it especially for hardened work, and if this is his general practice his experiences must be of a happier nature than my own or of those I usually encounter. As these experiences of his are a result of observations made in the works of the Brown & Sharpe Mfg. Co. we may assume that in this particular case it may be good practice and may be due to some special process of hardening or annealing.

It is, however, common knowledge that pieces of work which are hardened almost invariably contain internal stresses. To spot places off to within 0.001 inch of the finished size would mean disaster in general cases. Further than that it is within my own experience that this characteristic is not confined to hardened work but may be met with in soft pieces which have been machined by the more modern methods. I refer more particularly to work done on the modern turret lathe, and have found that pieces machined by this means are not to be relied on without a consistent previous rough grinding process over the whole surface. Cold-drawn material will display similar peculiarities, and the inference in both cases is fairly obvious. In the case of cold-rolled stock we may safely assume that the severe process it goes through in the course of manufacture is the cause of the trouble, and the pressure of the steadies in the bar turret lathe may very easily account for difficulties met with in grinding work which comes from the bar turret lathe. A case in point is the ordinary sensitive drill spindle shown in Fig. 1. I have had these spindles come from the engine lathe (made from forgings), and ground them without trouble; other batches which come from the turret lathe have displayed what I may term a devilish peculiarity. If I roughed down say portion *A* to within a finishing limit this portion would be some 0.003 inch out of truth when portion *B* was ground to size, or *vice versa*. In fact I found the only possible way was to rough off the skin in the first place on both *A* and *B*. With all due respect to Mr. Thacher's experience I think that economy in steady shoes is of less account than is quality and truth of work in the grinding machine. The real advantages of grinding might well be described as follows, in which will be used some of my previously written matter:

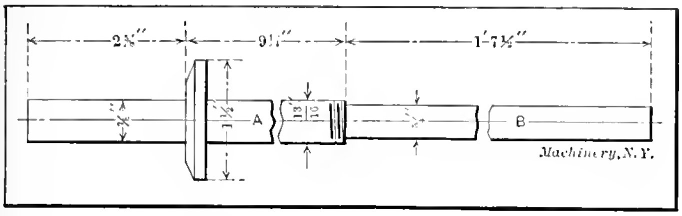


Fig. 1. Sensitive Drill Spindle which gave Trouble when ground after being turned in a Turret Lathe

The gratifying advantages which may be obtained from the use of high-speed steel are limited to a certain point, that point being where a very small amount of material must be left and extreme care exercised in arriving at the precise dimensions. For this final finishing it may be claimed that the grinding machine is the most rapid and economical tool to use, for the following reason: It removes this small amount of material in the shortest comparative time; it arrives at the desired dimensions by a series of rapid and minute chips which cover the whole surface repeatedly and whose depth is under perfect control, any variation in its shower of sparks being constant and visible evidence of its change of form either through distortion or accident; and finally it allows of the actual surface finishing being the last operation, thereby removing all those errors and distortions which may be a result of hardening on other previous operations. The fact that a ground surface is superior to that produced by a file or water cut is indisputable, and the rapid manner in which a fixed dimension may be obtained is another recommendation; that the result is effected by a series of minute chips with a visible index of their depth is another point in its favor. In order to start a finishing cut in the lathe and control its size, the length of its traverse, in most cases, requires a sense of touch which may have taken years to attain; to obtain a similar result, but a better surface, in the grinding machine is a far easier matter because another of the senses is enlisted. Given a few days' practice with a grinding machine, an operator can judge to 0.001 inch the depth of cut he is taking by the shower of sparks displayed.

We are indebted to Mr. Thacher's contribution for some valuable time-saving hints which those who may adopt will find of some value, but there is also an economic side to the grinding question which he does not touch on and which may be well worth consideration.

In some six years' experience as a demonstrator of grinding processes, it has been my privilege either to work in or to have entry into most of the principal shops in Europe, and with a few happy exceptions I have not seen a grinding plant run on what I consider truly economic lines. Most of these places are factories where I have personally installed machines and have made special efforts to instruct and hustle operators into making time and, incidentally, getting a better quality of product than I produced myself. In a few instances, on revisiting these factories it has been my pleasing experience to find that the said operator has excelled both my own and his former efforts and is doing both my company and myself a service. This, however, is the exception rather than the rule and it may be profitable to consider some of the causes which may lead up to these deplorable exceptions:

The prime causes are the apathetic attitude of the supervision or the skepticism of the management which fails to recognize the advantages of the old saying that "what is worth doing is worth doing well," and so fail to give as much attention to a plant which, although a somewhat modern innovation, is certain to give large returns if properly handled. We live in an age where "time is money" and much valuable time may be lost on a grinding job with either improper gaging methods, the absence of gages or an absurdly restricted limit of tolerance.

Piecework seems to be a necessity, owing to a failing in human nature, for it is easier and fairer to pay a man for what he does than it is to get him to do what he is paid for. This being the case, it is as necessary on a grinding job as it is on any other, and to get the maximum output requires that the operator should be assisted as much as possible.

It is the duty of the demonstrator to prove that a given job can be done in a given time without superhuman exertion, and after this it is up to the shop supervision to see that the standard of efficiency is adhered to. Apart from speed this said standard of efficiency should be maintained by a careful system of gaging with as much limit as is compatible with the quality of work required, and for this purpose a system of limit or tolerance gages is admirable; those inanimate pieces of metal with their "go on" and "not go on" have to my own knowledge reduced the amount of bad language and ill-feeling which was prevalent in many shops. They do away with that friction between the grinding and inspection departments which comes from depending on the individual sense of feeling with the micrometer caliper. To be more explicit, an examiner may have the delicate sense of touch of a lady and the grinding operator that of a navvy.

I have mentioned the necessity of giving as broad a tolerance as possible, for it is quite apparent that if this be done the output of an operator may be materially increased; as an illustration of this I may cite a case which is still fresh in my mind. A few weeks ago a 6-inch by 32-inch Norton plain grinder was put in a local factory for the grinding of the valve stem shown in Fig. 2. The stems were made of a high quality of cast steel and were hardened with about 0.012 inch

* For previous articles on grinding see "Economy in Grinding," May, 1910, and the previously published articles there referred to.

† Instructing operator, Norton Grinding Co., 73 Broomfield Road, Coventry, Eng.

to 0.015 inch left on their diameters for removal by grinding. Now a valve stem is given a few 1/1000ths inch play, and it would seem as if a tolerance of 0.001 inch would be as fine as would be necessary. However, this particular firm is very nice over its work and bears a reputation for quality which is second to none in Europe and so it insisted on a limit of 0.00025 inch, + and —.

The slot on the radial end of the valve was very convenient for using a thumb nail driver on the catch plate of the grinder and 80 per hour were produced to the limits demanded. A 24 L alundum wheel of 2-inch face was used and the automatic cross feed was two teeth, or 0.0005 inch per stroke of table. The wheel would duplicate about 20 turns before losing its size but the rather fine limit required some extra care and judgment of the sparking towards the last chips. If the tolerance had been double that demanded it would have been easily possible to produce 100 per hour, for practically no gaging would have been required.

A little knowledge is proverbially a dangerous thing and it has been my own experience to be often tied down to limits so fine as to be absurd when the class of work was taken into consideration. It is generally those "rule-of-thumb" people

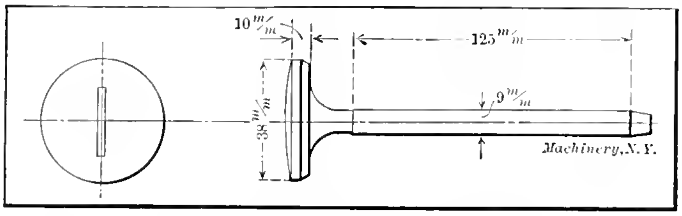

Fig. 2. Valve for Motorcycle Engine, Production of which was greatly reduced because of the Small Tolerance allowed

who make this mistake and in the fulness of their knowledge they despise all modern gaging methods. The first expense of installing a proper gaging system would seem to have terrors for them and the want of it may be costing them thousands of dollars per year. They ask for work of so accurate a nature that it may demand the patience and skill required for standard gage making and so limit the production of a machine as to make it painful to watch the operator who is tending it.

A great time-saving factor in the work of a grinding machine is the manner in which the work is prepared for the machine's reception; the modern grinding machine is undoubtedly a rapid stock remover and within certain limits will beat the lathe all hollow, but if some amount of judgment is not exercised in preparing work its full economic advantages may not be realized. It is, of course, impossible to lay down any fixed rule for grinding allowances, for these must depend on the shape and condition of the work, but I find that the leaving of an allowance of 0.015 inch to 0.030 inch on a diameter is the most economical for general work on a modern machine.

There are at the present time many engineers who are skeptical on the grinding subject and I suppose that until the end of time we shall have the old fogy element with us.

On the other hand there are those who are too optimistic and either expect too much or have mistaken notions as to the grinding machine's mission. Here is an illustration of how some little tactful suggestions proved of service in one of many parallel cases. A 20-inch by 30-inch by 168-inch Norton plain machine was installed in a factory, mainly for the purpose of grinding chilled rolls for the oil seed crushing trade. The rolls, Fig. 3, which were 16 inches face by 48 inches long came into the factory rough turned and were bored to the required dimensions; steel axles were afterwards forced in by means of a hydraulic press until they took the shape, when finished, as shown in the sketch. The principal of the firm was a smart business man and had a scheme outlined for a revised method of manufacturing these rolls which at first sight seemed quite reasonable. He proposed to turn the shafts to size for the press fit and leave 1/16-inch on the axle portion for finishing, which was to be removed by grinding. The first two experimental rolls were put through in this manner but they failed to clean up on the axle portion, this no doubt being due to distortion caused by the high pressure required for forcing in the axles and probably also some little error in alignment of holes in the rolls; the roll portion also took an excessively long time to grind. It was proposed to the principal that in the future he have ¼ inch left on the axle portion and that after forcing in he have them recentered true with the roll portion and a rough turning cut taken over the ends, but with a perseverance worthy of a better cause he proposed to adhere to his method, but to leave 3/32 inch on the axle ends; this was done for the next pair of rolls and as a guarantee had been given with the machine the time test was taken. This guarantee, by the way, was to grind a roll and axle ends complete in 2 hours, removing 1/32 inch of material from the diameters. In spite of the excessive amount (3/32 inch) left on the axles, two rolls were ground complete in 3 hours 50 minutes, this including getting out the fillets with wheel turned to shape. Since this incident occurred, the principal of the firm, being a reasonable man, has recognized that his scheme did not work out profitably and acting on suggestions offered he now prepares his work in the following manner:

He turns the axles to size for the press fit but leaves ¼ inch on the end portion; they are afterwards centered true by gripping one end in a chuck and running the roll portion in a fixed steady; the axles are then turned to within 0.030 inch of size. By following this scheme he is enabled to save some 60 per cent of the grinder's time and a similar amount in his annual cost of grinding wheels.

There is a little matter connected with a grinding plant where serious losses often occur and when the reasons for what I may term a mistaken idea of economy are analyzed it resolves itself into an absurdity.

In this I am referring to the provision of diamonds which are a necessity for the truing of the grinding wheels. I have seen some grinding plants where there have been from 20 to 40 operators at work and it has been the rule to provide one diamond truing tool for some five or six operators. There would, in these cases, seem to be an impression that something is saved by restricting the supply of these apparently expensive but necessary tools. It would almost seem as if the word "diamond" has some cabalistic qualities and that its weight compared with its price is a kind of bogy to men who are otherwise sane.

The question resolves itself into this: If five men have the use of one diamond tool, the said tool is likely to have the

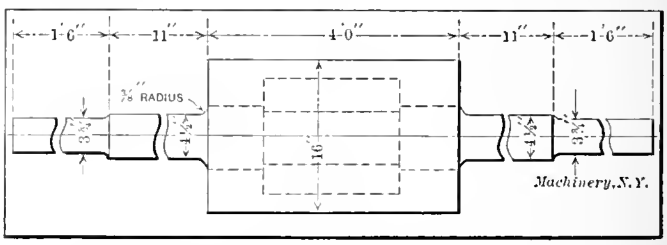

Fig 3. Chilled Roll for Oil Mill that made Trouble in Grinding until Procedure in Operations was changed

wear and tear of five tools and so far there is nothing gained by this parsimony; on the other hand there are likely to be some losses which may easily occur and perhaps be unnoticed. A wheel may become glazed and so be somewhat ineffective until the diamond is applied. Here the individuality of the operator will display itself; he may have that "tired feeling" and prefer to put up with the defect in his wheel to his employers' loss rather than search amongst his mates for it. Another class of operator is so socially inclined that he may be unable to make this search without having a few seconds' chat with each of those he inquires of as to the diamond's whereabouts; if five men have the use of one diamond tool no one can be truly made responsible for it if it gets lost, and when this does occur the whole plant is inconvenienced and delayed until it is replaced. Another point to consider is that if only a single diamond is allowed to five operators it will get dulled more rapidly. Now a dull diamond has caused and still causes endless trouble and losses in a grinding plant. It is responsible for much of the skepticism which exists on grinding matters generally, and like all other cutting tools it should be kept in the proper cutting condition.

MACHINE SHOP PRACTICE*

CHIPPING

The finishing of surfaces by chipping and filing is practiced comparatively little to-day, as the improved tools now in use have largely eliminated such work, though at times even in a modern shop it is necessary to resort to the hammer and chisel, particularly in erecting and general repair work. To reduce a plain surface by chipping, requires considerable skill which can only be acquired by practice. A few general suggestions, however, will doubtless be of value to anyone who desires to become proficient in this particular work.

The various types of chisels commonly used for chipping are shown in Fig. 1. The flat chisel *A* is used for a general class of work. The cutting edge *e* is either ground straight for light work or made slightly convex for heavy chipping to prevent the corners from breaking. The angle at the end should be about 60 degrees, though a greater or less angle is advisable when the metal is either exceptionally hard or soft. A cape chisel is shown at *B*. This has a narrower cutting point than the flat chisel, and is used principally for cutting grooves, etc. The side chisel *C* differs from the flat type *A* in that it is ground and beveled on one side only, which permits it to be used on surfaces which could not be reached with a double-angle end; it is also used for chipping the sides of keyways, slots, etc. The diamond point shown at *D* is adapted to chipping V-grooves, squaring corners, etc., while the grooving chisel *E* is for cutting oil-grooves or for similar work. The half-round chisel *F* is known as a gouge, and, as its shape indicates, is used on curved surfaces.

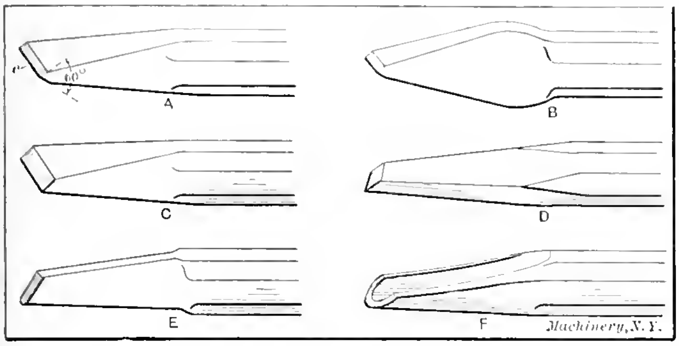

Fig. 1. Different Types of Chipping Chisels

Most workmen who are not accustomed to chipping, proceed very awkwardly, principally because of fear of striking the hand, and in order to avoid this, the eyes are continuously fixed on the head or striking end of the chisel. It is not necessary, however, to look directly at the chisel head in order to hit it, as a little practice will show, but it is important to continually watch the cutting end, as the chip being removed determines whether the chisel should be raised or lowered to increase or decrease the depth of the cut. The hand holding the chisel should be quite close to the striking end to obtain better control, and it is well not to grip the chisel shank with the thumb and forefinger as an accidental blow on the relaxed muscles will be less painful than when the chisel is gripped tightly by the entire hand.

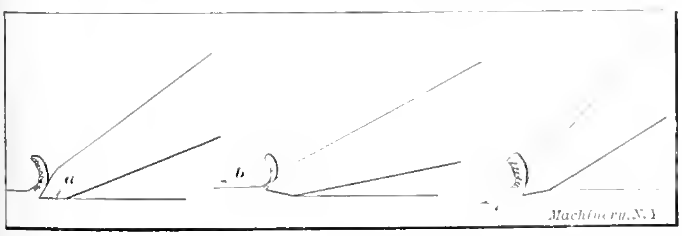

Fig. 2. View showing how Depth of Cut is altered by Position of Chisel

The way in which the position of the chisel alters the depth of the cut is illustrated in Fig. 2. As each successive blow is struck, the chisel tends to move along the plane of the supporting surface *a*, so that lowering the striking end causes the point to move upward, and raising it has the opposite effect, as illustrated by the arrows *b* and *c*.

When it is necessary to reduce a broad flat surface by chipping, a number of grooves *d* of uniform depth are usually first cut across, as illustrated in Fig. 3, and then the metal remaining between these grooves is removed by a broader chisel of the flat type. By this method, the broad chisel cuts more easily as there is no resistance at the corners and sides. It is advisable before chipping a surface that needs to be carefully finished, to chamfer the corner where the cuts end (as at *f*) to prevent the stock from breaking out below the depth line.

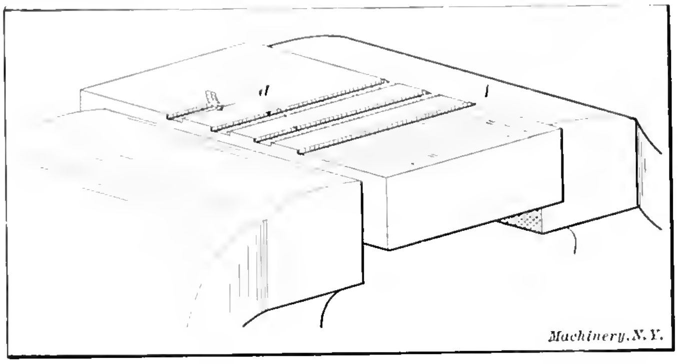

Fig. 3. Method of Chipping a Flat Surface

Whenever there is considerable chipping to be done, a pneumatic hammer, a type of which is illustrated in Fig. 4, should be used if one is available. The chisel, with the shank inserted in the hammer, is held in the left hand and the hammer with the right. By manipulating the lever *l*, the admission of air to the cylinder and consequently the speed of the hammer blows is regulated. The small flexible hose through which the air is supplied is connected at *h*. When beginning a cut, the hammer should be started gradually so that the movement of the chisel may be more easily controlled. Both hammer and chisel should be held firmly against the work and at an angle which will depend on the depth of cut desired. When the hammer is working at full speed, the cutting movement of the chisel is almost continuous, owing to the rapidity of the blows. This continuous cutting action makes it possible, of course, to take a smoother cut and to work more rapidly than is possible by hand chipping. The pneumatic hammer is also widely used for riveting, beading boiler flues, and for many other kinds of similar work. When used for these various purposes, special tools are, of course, employed.

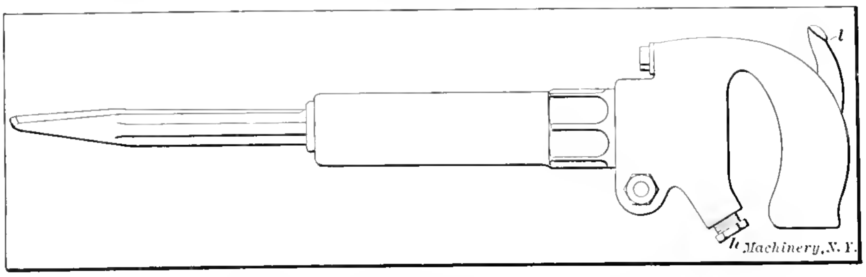

Fig. 4 Pneumatic Hammer arranged for Chipping

* * *

The German Consul-General at Budapest reports to his government that, owing to the large demand for metal working machinery and metal goods in Hungary, the home factories cannot keep pace with the orders. He states further that the Hungarian Parliament, therefore, has decided to build five machine tool works, which will employ 860 men, and that arrangements have also been made for the erection of twenty other works and foundries which will employ from 4,000 to 5,000 men. It would appear from these reports that Hungary would, at the present time, offer a good field for machine tools.

LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY

TIPPING SHOP TOOLS WITH HIGH-SPEED STEEL

In no shop that I have been in is the practice of using small pieces of high-speed steel to tip tools made of an inferior grade of steel carried out to a greater extent than it is in the shop of Wm. Barker & Co., Cincinnati. Mr. Barker makes lathe, planer and shaper tools and special drills, by using machine or a low grade of carbon steel for the body and making the cutting edge of a small piece of high-speed

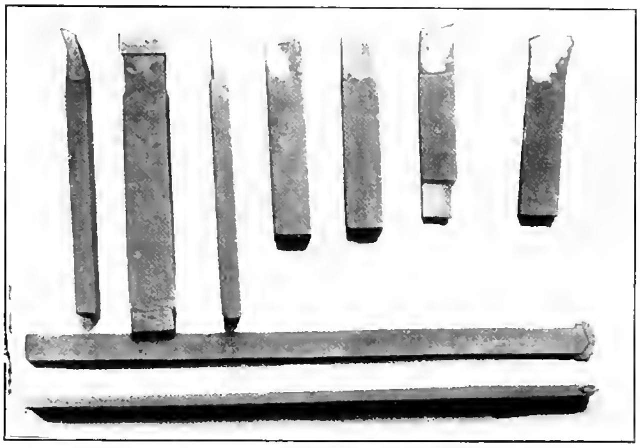

Fig. 1 Lathe and Planer Tools, and Spindle Drills tipped with High-speed Steel

steel "brazed" on. Of course, nothing original is claimed for this, as it has been done in many railroad shops and other places for some time, but Mr. Barker has carried the idea farther than is usual.

In Fig. 1 are shown a number of lathe and planer tools and two long drills used for drilling out lathe spindles, tipped in this way, while in Fig. 2 are four drills, a lathe tool, and a wide channeling tool for the planer, which is tipped on each end of the crosspiece with a cutter. In tipping a tool with high-speed steel, the piece should be so fitted that a close union is made when brazed. It will be noted that the drill tip is fitted into a slot in the end of the bar, and it is usually a good plan to pin the tips in place on the other tools,

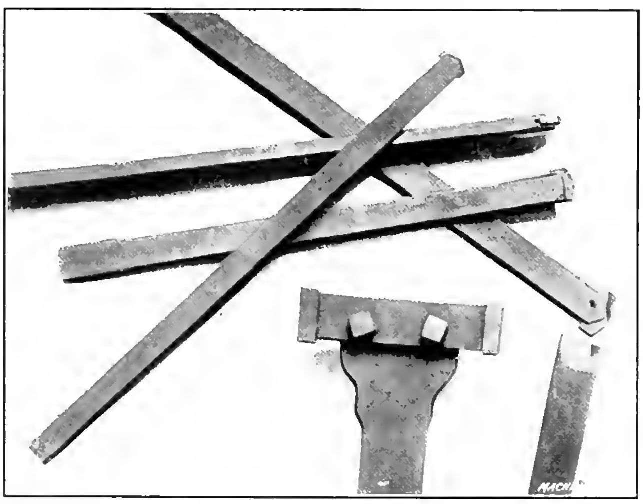

Fig. 2 Spindle Drills and Large Double-tipped Channeling Planer Tool

with a small pin, so that they will not slip out of position while in the fire. Ordinary brass spelter is not suitable for high-speed steel; copper should be used instead, with borax as a flux. A convenient way to obtain good copper for brazing is to take a small piece of electric wire, scrape off the insulation and file a small slot in the recess of the tool for it to lie in. Brazing is, of course, done in the usual way except that the heat should be higher. Tips put on tools in this way will stand considerable rough usage without coming off; in fact, if the work is well done one has trouble loosening a piece with a hammer, if one cares to try the experiment.

Cincinnati, Ohio. ETHAN VIALL

METHOD OF MAKING BLUE-LINE PRINTS

In the May number of MACHINERY a process by which blanks can be printed on blueprint paper, giving as a result blue lines on white background, is described. I desire to submit an entirely different and simpler method which I have made use of, that will doubtless interest draftsmen and office men in general.

All the material necessary is a sheet of some ordinary grade of carbon paper, a No. 6 or 8 drafting pencil having a blunt, smooth point, a blank sheet of common typewriter paper, and a smooth, hard drafting-board or table.

After the desired form or sketch has been carefully laid out and all the lettering finished lightly in pencil on the blank sheet, place the carbon paper with the carbon side upon the table. Then lay the blank paper (with sketch up) on top of the carbon and after fastening both to the table with thumbtacks, proceed to trace the sketch with the hard pencil, being careful to press quite hard and uniformly as the lines of the sketch are followed.

By examining the carbon it will be found that wherever lines have been drawn, no matter how small a letter or figure was made, a good impression was reproduced on the face of the carbon. The latter may then be used the same as a tracing

A Blue-line Print made by using Carbon Paper as a Negative

to print through. It should be exposed from 2 to 3 minutes, according to the speed of the paper used, and after the latter has been washed out thoroughly, the desired result will be accomplished.

Carbons prepared in this manner, which I have been using for some time, appear to be as good as when made. In order to save time in printing, several carbons can be made from the original sketch or by tracing over prints. By placing these in a large printing frame, a number of blanks can be printed simultaneously on one large sheet. By filing these carbons in indexed envelopes or between indexed sheets, they will last almost indefinitely and will be convenient to get when needed.

The accompanying engraving shows a fair sample of the prints produced by this method. A. G. PANCOST

Elkhart, Ind.

CLEARANCE SPACE OF GAS ENGINE CYLINDERS

In designing the cylinders of a gasoline motor, one of the first things to determine is the volume of the clearance space. In order to find this, the compression which the motor is to have must be known. In automobile motors the compression varies all the way from 60 pounds to 100 pounds per square inch gage. The formula most generally used for finding the clearance space is:

$$\frac{p_1}{p_2} = \left(\frac{v_2}{v_1}\right)^n \quad \text{or} \quad p_1 = p_2\left(\frac{v_2}{v_1}\right)^n$$

where p_1 = compression pressure in pounds, absolute,
p_2 = initial pressure,
v_1 = volume of clearance space,
v_2 = total volume of cylinder (piston displacement plus clearance space).

The value of n given varies from 1.21 to 1.41. This value of n varies with the engine speed, valve timing, valve diameter,

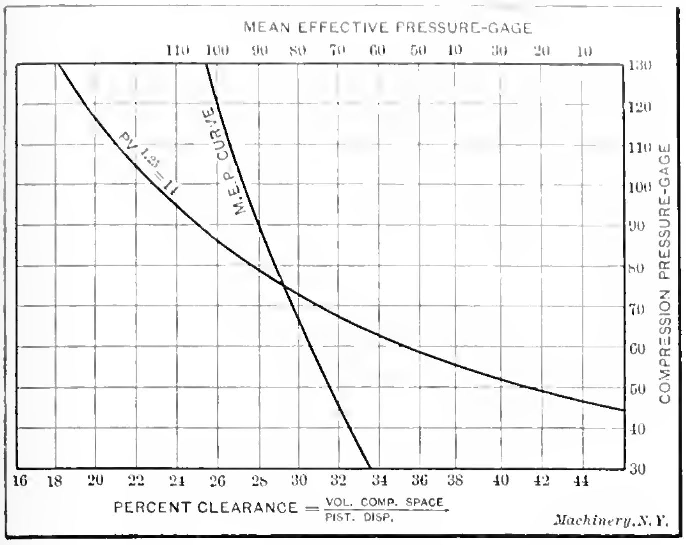

Chart for Determining Percentage of Clearance Space in Gas Engine Cylinders

valve lift, size and shape of the inlet pipes, and temperature of jacket walls. It will be seen from this that the compression cannot be calculated exactly, since it depends on so many variable quantities. It has been found by making tests of a number of gasoline motors that a value of n=1.25, when the initial pressure is 14 pounds gives very close results.

Using this value the accompanying diagram was plotted. To find the percentage of clearance for a given compression, find the compression in pounds gage in the column at the right, and follow across to the compression curve, thence to the bottom of the diagram where the percentage of clearance is read.

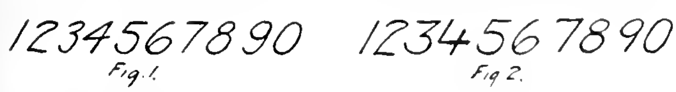
To find the mean effective pressure for a given compression, take the compression in the column to the right, as before, and follow across to the M. E. P. curve, thence to the top where the mean effective pressure is read.

These curves give values which come very close to the average for automobile motors. HERBERT C. SNOW

East Cleveland, Ohio.

PLAINER LETTERS AND FIGURES IN THE DRAFTING-ROOM AND SHOP

I agree with Mr. W. S. Rowell in his statement in the May issue of MACHINERY regarding the importance of plainer letters and figures in the drafting-room and shop. In our shop we have met with difficulties common to all in arranging our standard style of figures, and as the above writer has expressed a wish to have this matter discussed in your columns,



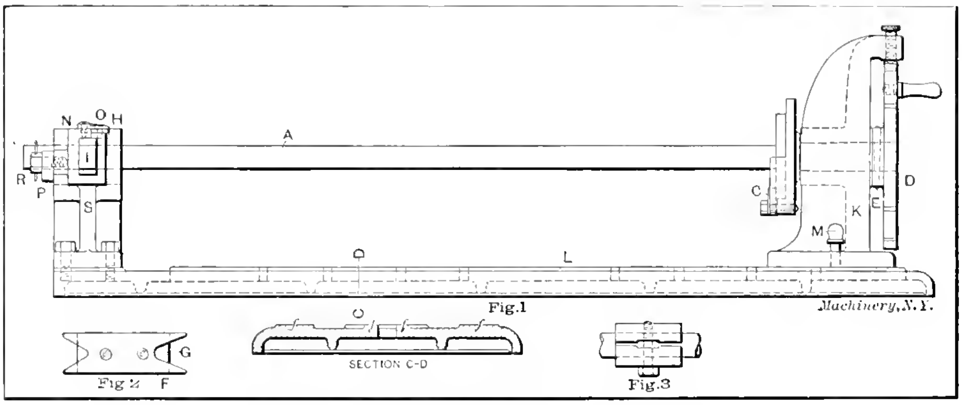
the benefit of my experience in this subject may be of interest to your readers.

Each man in our drawing-room, previous to the introduction of more modern methods and standardization in the drafting department, was allowed to use whatever style of letters and figures he was most proficient in. This, in itself, tended to confuse the workmen in the shop, and a standard style, as illustrated by Fig. 1, was adopted, and religiously adhered to. This style, we thought, was just about the "real thing," being in our estimation the easiest to make and the plainest set of figures we could adopt. When carefully formed, the figures, as illustrated, show clearly and unmistakably on original drawings and tracings, but we soon found that due to occasional blurring of blueprints in spots, the figures were not so easily distinguished on the prints. The first common mistake discovered was the taking of 1 for 7. To remedy this, we simply added a small projection to the horizontal line of the 7, as shown in Fig. 2. The second difficulty was caused by the 3 and 8, which was overcome by changing the shape of the 3 as shown. The next step was to change the 9, making it with a straight tail to avoid confusion with the 6 and 0. After these changes had been made, we thought we had a practically "fool-proof" set of figures, but we found that some of the toolmakers persistently read the 9 with the straight tail as 4, so we were obliged to make the latter figure as used in ordinary writing, with the top open.

The result of our efforts is shown complete in Fig. 2, and, as finally adopted, this set of figures has been in use for several months with a surprisingly small number of mistakes. I believe the figures are hard to improve upon and might well be adopted by many firms. DESIGNER

FIXTURE FOR LOCATING CAMS ON CAM-SHAFTS

An inexpensive fixture by means of which cams may be quickly located on their shafts for drilling and reaming the taper pin holes, is illustrated in the accompanying engraving. All the cams are placed in their relative order on camshaft A (Fig. 1) which is attached to the dividing-head shaft



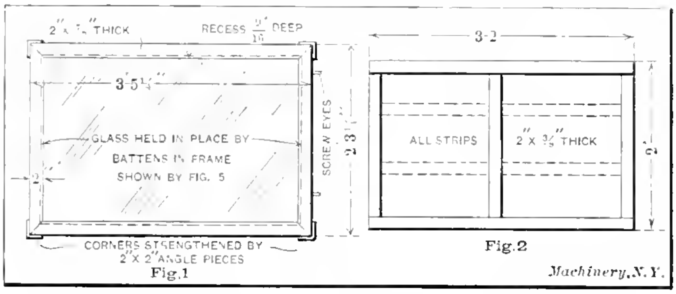
Figs. 1 to 3. Fixture for Locating Cams on Cam-shaft

by a clamp C as shown. Cam stop F, Fig. 2, is milled out to receive the exhaust cam on one end and the inlet cam on the other end. The plate G is to hold the cam in the proper position for drilling, under the bushing H. The stop F is inserted in the slot I, after which the dividing head K is moved along on the table L to the first division, which is located by the pin M. D is the dividing plate with which a pin engages to locate the cam-shaft at the proper angle. After drilling, the latch N is moved to one side, and plate O is removed so that the hole can easily be reamed. A lock P with a recess in the center the size of the cam-shaft is provided to support the shaft while drilling and reaming the holes. The end of this supporting piece is dropped down by loosening screw R, the other end being on a pivot; after the next cam is located for drilling, P is replaced. This fixture may be used for milling keyways in cam-shafts by replacing the casting S with one having a slot in the top as shown in the plan view, Fig. 3. C. G.

A CONVENIENT BULLETIN-BOARD

In presenting the work in machine drawing at the Worcester Polytechnic Institute it has been found very desirable to have a place in which references and data may be posted for the student's use. Blueprints, MACHINERY'S data sheets and numerous other data can thus be posted from time to time as

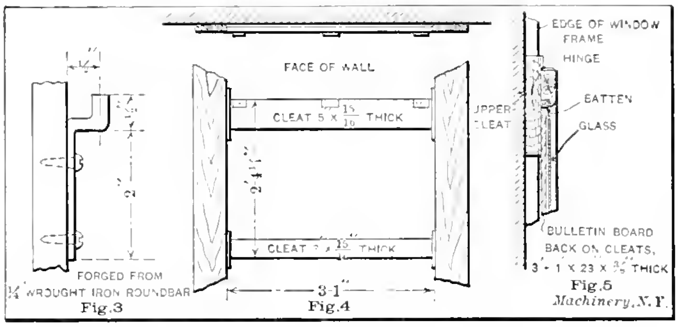
various lines of work are taken up. Bulletin-boards are used for this purpose, being placed about the drawing-room in the open spaces between the windows. As these boards were originally made they were rather inconvenient, it being necessary to remove them from their fastenings on the wall when it was desired to take out or put in new material. The original form of the board is shown in Figs. 1 and 2. The frame was supported by means of screw hooks and eyes. The back-board



Figs. 1 and 2. Original Form of Bulletin-board with Improvements

shown in Fig. 2 (solid lines) was held in a recess cut into the back of the frame, by means of buttons. It was made up of 2-inch by 3/8-inch strips, covered with canvas. The prints or drawings were pinned or pasted onto the canvas.

The question then arose concerning the best and least expensive plan for the alteration of these frames. After some thought the changes were made as shown by Figs. 1, 2 and 3. The corners of the frame which holds the glass were strengthened by 2 inch by 2 inch angles. The supports shown by Fig. 3 were substituted for the screw hooks, and four additional strips were put into the back-board (shown by dotted lines)



Figs. 3, 4 and 5 Improvements which made the Bulletin-board more Convenient

to be used for receiving thumb tacks. The back-board was then hinged to the supported end of the frame.

One of the frames was changed as shown by Figs. 4 and 5. The chief advantage of this frame over the others is the solid white pine back-board, and the cost for making the changes was much greater. The drawing shows the frame supported from above, but it could be supported at the ends just as well.

Worcester Polytechnic Institute. JAMES C. DAVIS

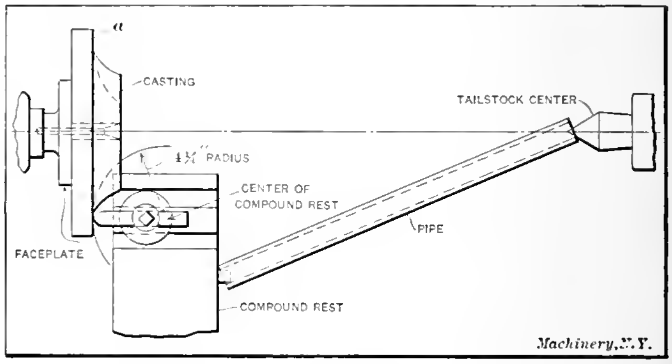
METHOD OF PREPARING TRACING CLOTH

It is a well-known fact that neither the glossy nor the dull side of tracing cloth takes ink readily without being prepared in some manner. The usual way is to sprinkle powdered soapstone or chalk on the tracing cloth and rub it over the surface with a piece of cloth. This helps somewhat, but not enough to be perfectly satisfactory. After trying various methods, I have found a way which gives excellent results, and that is to sprinkle the powdered soapstone on the cloth as usual, but rub it in with a blotter instead of with a piece of cloth, using a circular motion and considerable pressure; of course it is necessary to brush away the superfluous powder. The use of a blotter has an abrading effect and it is just harsh enough to give the cloth a surface which will take the ink readily and still leave the pens unharmed. I find it to be an advantage to repeat this process each morning in case the tracing is not finished the day it is started; the rubbing of the blotter over the lines already inked in does absolutely no harm and, if anything, makes the lines more dense. A trial will convince the draftsman that the cloth will take the ink better by this method, than by any other.

Chicago, Ill. ROBERT A. LACHMANN.

TURNING A RADIUS WITH A COMPOUND REST

The accompanying illustration shows a method of turning a radius on wheels which were used for centrifugal pumps. These castings were larger than the standard size; and having only a few of these and as in all probability we would never have an order for a larger quantity, it was thought impractical to make a special fixture for machining them. The following method was used: The wheels were bored and faced on each side and the part at *a* turned parallel to the starting point of the radius. A small drawn-in chuck was then used for holding the castings tightly against the faceplate, as shown. The two bolts used for keeping the compound rest from revolving were released just enough to allow it to revolve freely, and the tool set in the tool-post at right-angles to the faceplate, and at a distance out from the center pin of the compound rest, equal to the radius required on the casting. The carriage was then fastened to keep it from moving. Then one of the screws which was used to hold the gib in the compound rest was removed and a stud inserted in its place. A length of pipe, as shown, was then placed on



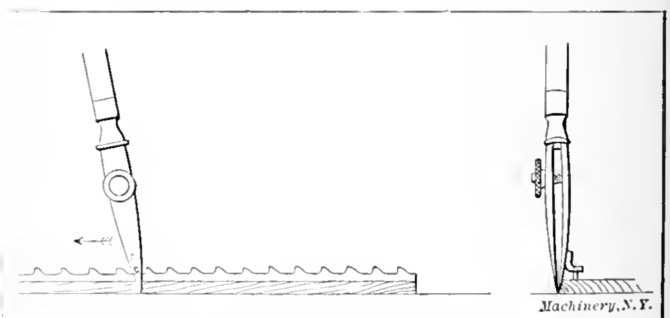
Turning Radius on Centrifugal Pump Casting

this pin and on the tailstock center. By bringing out the tailstock center, the pipe forces the compound rest around in a radius, turning off the superfluous stock and producing the correct radius on the piece. 1/64 inch was left for finishing and after all the castings had been roughed out they were then put on again and the finishing cut taken.

Toronto, Canada. JACK E. HAILSTONE

A SIMPLE DOTTING ARRANGEMENT

The illustration shows a dotting device which the writer uses in place of the expensive wheel and other dotting pens which are sold. The advantage of this is its cheapness, and the fact that either dotted or full lines can be drawn without any change whatever. A little rack with a series of rounded



Pen Attachment and Rack for Drawing Dotted Lines

teeth is attached with cement or other adhesive to the face of a straightedge or T-square, a little way back from the edge. On the back of the inner pen blade a small piece of brass is soldered, with its end turned at right angles to lie parallel with the face of the straightedge. This brass pin is set to such a height that when the pen is tilted over, about as illustrated, the pin just clears the bottom of the grooves in the rack, consequently permitting the pen to ink on the paper. In use, the pen is moved along, keeping it at the angle shown, and the teeth cause it to jump up and down, producing a series of dashes on the paper. A dotted line can be drawn in this way as fast as a full one, and without any of the fatigue, and fidgetiness which is caused when one dots

in the usual manner. The pen should be held lightly, to let it rise and fall in an easy manner. By simply bringing the pen into a vertical position, the brass pin will clear the tops of the rack teeth, and a full line can then be drawn. Probably if a roller were fitted on the pin, the pen would work along the rack in an easier manner, but the writer has not tried this. The rack was made from a piece of hack saw blade by reducing its width, taking out each alternate tooth, and rounding off the remainder to suitable outlines. Of course any form of dotting may be produced by shaping the teeth suitably. FRED HORNER

Bath, Eng.

SPEEDS AND FEEDS FOR CARBON OR HIGH-SPEED TWIST DRILLS

To obtain the maximum cutting power and life from a twist drill it is essential that the speed and feed be adapted to suit the particular material being drilled. The accompanying charts give actual working speeds and feeds and represent good general practice.

In drilling, the aim should be to use moderate speeds and heavy feeds, as chips take a great deal less power to produce than powder. The rubbing action which takes place with fine feeds soon spoils the cutting edge. For drilling steel a good supply of lubricant should be maintained. Speeds and feeds should be reduced when drilling hard materials.

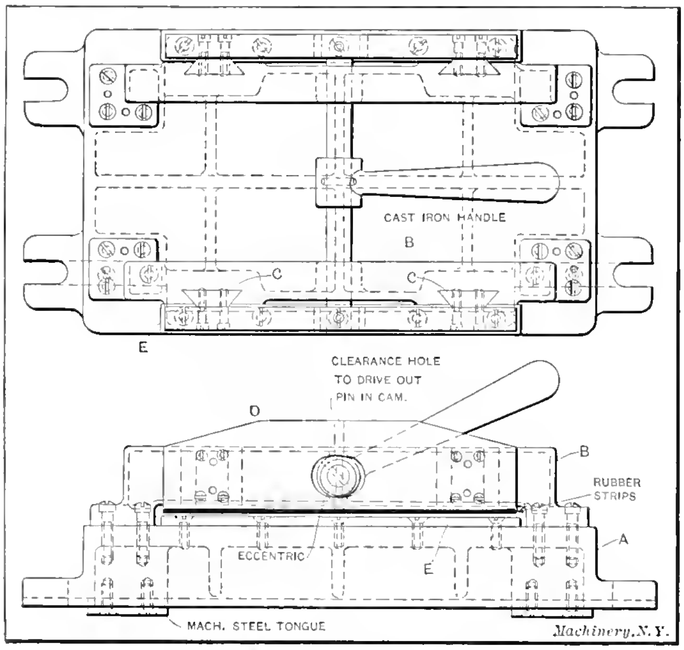
A FIXTURE FOR STRADDLE MILLING

For straddle milling thin castings such as cabinet parts for adding machines, typewriters, etc., where there are no machine surfaces on which to clamp or locate the work, milling fixtures of a type similar to that herein described and illustrated may often be successfully used, as they are quickly operated, rigid in construction, and comparatively inexpensive. The fixture shown in the accompanying illustration is designed for use on a double-headed milling machine to straddle mill the two sides of a thin brass casting, and is constructed as follows: The base of this fixture marked *A* is a gray iron casting of the box type, suitably ribbed internally, and also externally, to give it the necessary rigidity, and provided at its ends with feet which have slots in them to receive the clamping bolts used in attaching the fixture to the platen of the milling machine. It is also provided on its under surface with two steel tongue blocks which fit into the groove on the milling machine platen, serving to align the fixture properly.

The casting *A* is machined on the top and bottom, and to its upper surface the cast-iron brackets *B* are fastened by means of heavy fillister head screws and dowels. These brackets are stiffened by suitable ribs, and are provided on their outer sides with dove-tailed ways, in which slide vertically the steel guides *C*, to the outside of which are attached the long clamp strips, *D*. These strips are of steel and are channeled on their lower edge for the full length of the strip, and into these channels are inserted heavy rubber pressure shoes, which serve to conform to the irregularities in the surface of the unfinished casting which is being clamped, and to hold it securely upon the tool steel resting strips *E*. In the center

of each of the clamp strips D are elongated holes in which operate eccentrics of hardened tool steel; these are attached to the end of a steel shaft which runs across the fixture and has a bearing in each of the cast-iron brackets B. To the center of this shaft is attached an operating handle of cast iron by which the clamping strips are depressed forcibly enough to secure the work; when at this position the eccentric is thrown over its dead center, retaining the clamps in their positions during the machining operation.

A modification of this fixture may be designed to be operated by compressed air instead of by hand, by making its general construction the same as the device shown in the accompanying illustration, but replacing the operating handle by a lever at whose extremity is a piston which operates in a suitable air cylinder, the air inlet and outlet of which are controlled by a small valve of the taper plug type, equipped with a small lever handle. This, of course, makes the operating of the fixture very much easier than by hand, and when the character of the work is such as to warrant the extra expenditure, this valve may be so located that it will be tripped by a projection on some part of the milling machine in such a manner that, when the machine platen returns after the cutting stroke is made, to a point where the work is out from under the cutters, the clamps will be automatically released, leaving the fixture in a loading position. It is then only necessary to place the work into position and throw in the power feed on the milling machine table, whereupon the air



Straddle Milling Fixture for Thin Castings

valve will be tripped, clamping the work before it reaches the cutters. Of course, these air operated fixtures can only be used in factories which are supplied with compressed air, properly piped to the various machines, but they are great labor- and time-savers, and where the character of the product will permit of their usage, the saving of time will soon pay for their cost. C. Nosrac

ESTIMATING WEIGHTS OF ROLLED STOCK

To arrive mentally at the weight of round steel per foot of length without recourse to tables (which are not always at hand) it is sufficient to know that by squaring the number of quarter inches in the diameter of the bar and dividing the result by 6, the answer gives the weight in pounds per foot of length. Expressed as a formula this would be $\frac{(4d)^2}{6}$, where d = diameter of stock in inches of tool steel.

Anyone who wishes to work this out for a round machine bar with an area of cross-section of 144 square inches will find that it is based on 489 pounds per cubic foot. On ⅛-inch sizes like 1⅛-inch, for instance, it will be easier than squaring 4½ quarters to take even figures and say $4 \times 5 = 20 + (\frac{1}{2})^2 = 20.25 \div 6 = 3.375$ pounds per foot.

In dealing with large diameters and squaring the larger numbers, the method of squaring by the use of the nearest tens simplifies the procedure. For example, take 4½-inch round; 4½ = 18 quarters and in squaring 18 consider it as two less than 20. This difference of 2 from 18 leaves 16 for the other multiplier. $16 \times 20 = 320$, and adding the square of the difference which is $4 = 324 \div 6 = 54$ pounds per foot. For a proof to the eye of the correctness of this method of

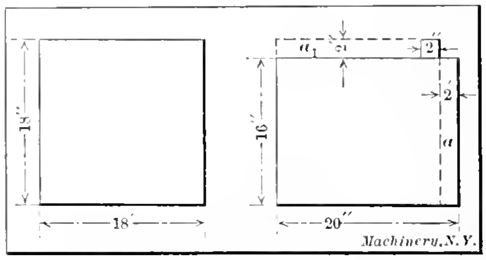


Diagram Showing Correctness of Squaring

squaring refer to the accompanying diagram; here the dotted position a of the rectangle would manifestly fit in at a_1, and complete the square.

Hexagon stock is about 10 per cent heavier than round; square stock, about 28 per cent heavier than round. It is, however, easier to get the weight of square or rectangular sections by multiplying the area per square inch of cross-section by 10, which will give the weight per yard of length. This is based on 480 pounds to the cubic foot, the weight of iron and a unit of length which was in common use when iron was generally used. "Weights per yard," however, have almost entirely disappeared except in connection with rails, and section books now give the weights of material in pounds per foot. The weight per foot is easily arrived at by taking 1/3 of the figures given above for iron and by adding 2 per cent for weight of steel.

The weight of sheet iron is found by using the number of thousandths of thickness considered as a whole number and dividing by 25 for the answer in pounds per square foot. Hence ⅛-inch plate = 125 thousandths ÷ 25 = 5 pounds. This, too, is based on 480 pounds per square foot and is 2 per cent too light for steel, which would then weigh 5.1 pounds in the above example. The result obtained by using a block 12 inches thick is

$$\frac{12 \times 1000}{25} = 480 \text{ pounds, for iron,}$$

To this add 2 per cent for sheet steel $= 480 + 9.6 = 489.6$ pounds.

By using the foregoing simple formulas one is entirely independent of tables and is equipped for work whenever it appears, without book aid in each case. Robt. S. Brown

New Britain, Conn.

DIVIDING A CIRCLE INTO EQUAL PARTS

In the May number of Machinery a method was given by Robert Wilkinson for dividing a circle into any number of equal parts, and readers were called upon for a geometric proof.

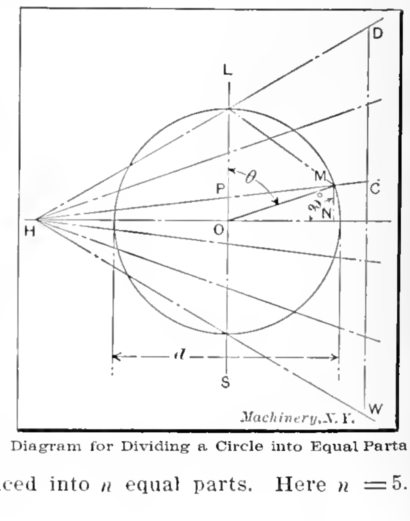

Diagram for Dividing a Circle into Equal Parts

The method as given is neat and interesting, but it is an approximation and exact only for certain particular cases. There is no geometric proof for it. The line AB of Mr. Wilkinson's diagram is a method for spacing the diameter LS into a given number of equal parts, and is not a part of the problem. In the figure given herewith the diameter LS is spaced into n equal parts. Here $n = 5$.

The point H is located by describing an equilateral triangle on LS, making the lines LH and SH equal to LS and equal to d. The line HPM is drawn through the second division P; then LM is the desired nth part of the whole circle. A variation, perhaps an improvement, would be to draw the line DW. Extend HL and HS to DW. Space off the distance DW and draw HMC through the second space C (new section). To prove that LM is in the general case an approximation, we will compute its true value. Draw HON, OM, and MN. We then have $OMN = LOM =$ angle θ, which is the angle to be computed. $MN = OM \times \cos\theta$. $ON = OM \times \sin\theta$.

$$LP = 2\frac{LS}{n} = 2\frac{d}{n}, \quad OP = \frac{d}{2} - 2\frac{d}{n} = \frac{d}{2}\left(1 - \frac{4}{n}\right)$$

$$HO = \frac{d}{2}\sqrt{3}.$$

From the similar triangles MNH and POH we get the proportion:

$$\frac{MN}{PO} = \frac{ON + HO}{HO}$$

and when the values are substituted this becomes the quadratic equation

$$\sin^2\theta\left[3 + \left(1 - \frac{4}{n}\right)^2\right] + 2\sin\theta\left(1 - \frac{4}{n}\right)^2\sqrt{3}$$
$$= 3 - 3\left(1 - \frac{4}{n}\right)^2$$

giving the desired angle.

$$\sin\theta = \frac{\sqrt{9 - 6\left(1 - \frac{4}{n}\right)^2} - \left(1 - \frac{4}{n}\right)^2\sqrt{3}}{3 + \left(1 - \frac{4}{n}\right)^2}$$

Testing this equation for various values of n, we get,

for $n = 2$ $\quad\sin\theta = 0$ $\quad\theta = 180$ degrees. Exact
for $n = 3$ $\quad\sin\theta = \frac{1}{2}\sqrt{3}$ $\quad\theta = 120$ degrees. Exact
for $n = 4$ $\quad\sin\theta = 1$ $\quad\theta = 90$ degrees. Exact
for $n = 5$ $\quad\theta = 71$ degrees, 57 minutes, 20 seconds.

This is 2 minutes 40 seconds too small, for $\frac{360}{5} = 72$ degrees.

The error is $\frac{1}{8100}$th of the whole circle and is negligible for graphical purposes.

for $n = 6$ $\quad\sin\theta = \frac{1}{2}\sqrt{3}$ $\quad\theta = 60$ degrees. Exact
for $n = 7$ $\quad\theta = 51$ degrees, 31 minutes, 5 seconds. Not exact, because $\frac{360}{7} = 51$ degrees 25 minutes, 43 seconds.

for $n = 360$ $\quad\sin\theta = 1$ degree, 5 minutes, 48 seconds, but $\frac{360}{360} = 1$ degree.

MAKING EMBOSSING ROLLERS

In reading the article entitled "The Detail Engineer" in the May number of MACHINERY, I was much impressed by the answer of Mr. Steelworth when he replied to the "old man" that he did not believe in "modern practice." In these days when special machines and advanced methods are available for doing different classes of work, the same methods are not followed that were a decade or so ago, and figuratively speaking, what is standard practice to-day, is an obsolete method to-morrow. Now I will ask, "What is modern practice? Can we follow it and how far?" To give an illustration of this, I had charge of a shop a few years ago and an order came in for a pair of rollers which were to be used for embossing straps for boxes. I had previously instructed one of the toolmakers to carry out my orders in making these rollers, but when he saw that my method was contrary to "modern practice," he sought to enlighten me and said that it would be impractical to make the rollers in this way. He claimed that to make these rollers accurate, a universal milling machine was required, and it would also require an expert diesinker. I came to the conclusion that the job was beyond his skill and relieved him of it. I may mention that this man was also a graduate of the "modern practice" school. After determining the size of the rollers, I bored, turned and keyseated them. After this I coppered the faces of the roller, and laid them out for an equal number of projections. Then, with a parting tool, I removed the superfluous stock at A, leaving ridges around the periphery of the roller. The superfluous stock at B was removed by putting the roller on an arbor and then placing this on the centers in a shaper, and planing out the remaining material. This left a series of small squares around the periphery of the roller. The roller was now put in the vise and each projection carefully filed around to the line which was made with the dividers. After rounding all the projections to the marks, I filed them as spherically as possible. Then I made a female punch of the exact shape required and used this for forming the projections into a spherical shape. The roller was then hardened in the usual manner. The female roller was laid out for an equal number of indentations to correspond to the male roller and the holes drilled with an ordinary twist drill and reamed to the size required, which would be equal to diameter of the projections on the male roller, plus twice the thickness of the material. This roller was also hardened in the usual manner. Some will probably say that this is not "modern practice," and perhaps it is not, but as one toolmaker could not make the rollers with any kind of practice, and as by using this method the rolls were made in an accurate manner, which was satisfactory to the customer, I would like to know what others have to say about "modern practice." I believe a better term for this would be "common sense practice."

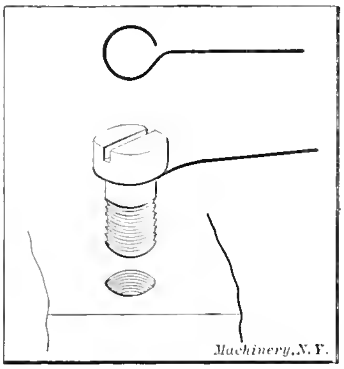
SHOP KINKS

PRACTICAL IDEAS FOR THE SHOP AND DRAFTING-ROOM

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary

INSERTING SMALL SCREWS

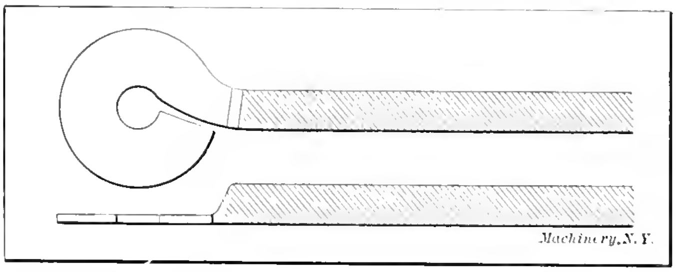
The illustration shows a method of holding very small screws ready for insertion in their holes, when one finds it clumsy and difficult to hold them with the fingers and manipulate the screw-driver. Take a piece of fine wire and bend the end into a loop equal in diameter to the body of the screw. When the latter is dropped into the ring thus formed, it will be supported steadily so that it can readily be inserted into the hole. After two or three turns with the screw-driver, remove the wire by simply pulling it, which will straighten it and free the screw.



Bath, Eng. FRED HORNER

SCRAPER MADE FROM SQUARE FILE

For several years I have used a scraper, made from a square file, that has been very serviceable for scraping babbitt boxes in getting clearance for the shafts. I find that I can rough

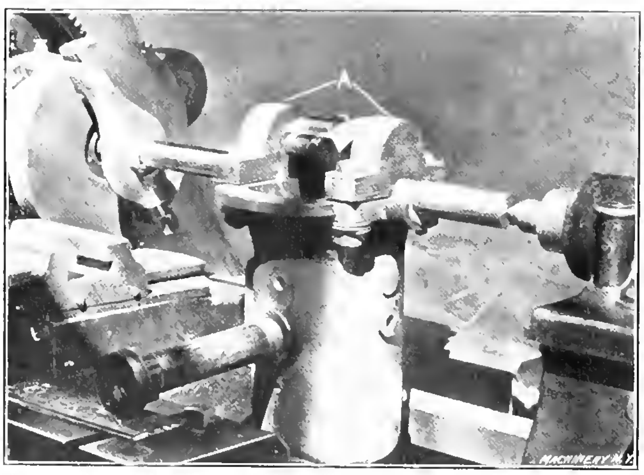


scrape a box quicker with one of these scrapers than with any other I have used, finishing up with a smoothing scraper. The scraper illustrated was made from a $\frac{3}{8}$-inch square file. The scraping end is $1\frac{1}{2}$ inch in diameter and $\frac{1}{8}$ inch thick. The size of the end will depend, of course, on the size of file used.

J. T. CROMACK

METHOD OF LAPPING PISTON RINGS IN A LATHE

The accompanying illustration shows a simple and effective method of lapping piston rings and cylinders of small gas engines. The piston rings are pinned in place, and the crank-



shaft assembled. The piston is then inserted in the cylinder and the crankshaft placed on the centers of the lathe, wooden blocks *A* being used instead of regular caps to hold the crank-shaft in place. A mixture of pulverized glass and lard oil used as an abrasive gives very satisfactory results.

Cleveland, Ohio. JOHN W. WICKERMAN

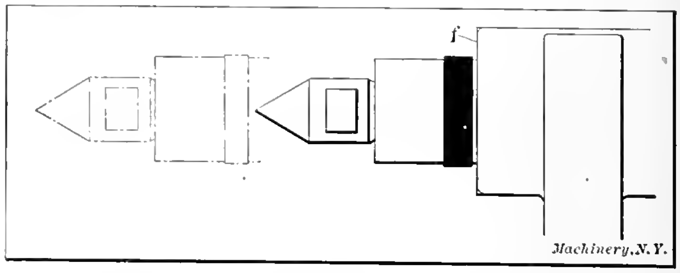
USING BROKEN TAP SHANKS FOR HACKSAW PINS

The shanks of No. 6 taps make excellent pins on which to stretch hacksaws either in hand or power frames. Ordinary soft pins are generally used for this purpose, and it is well known that they will only stand up for a few weeks when in constant use. Tap shanks are to size, and tempered just right, and they out-wear soft pins many times.

Middletown, N. Y. DONALD A. HAMPSON

DEPTH GAGE FOR TAILSTOCK DRILLING

When the tailstock of a small lathe is used for feeding up drills, there is no way of gaging the depth to which the drill has penetrated, unless the spindle happens to be graduated, which is far from usual. A kink which may not be known generally is to use a stout rubber band on the spindle as a



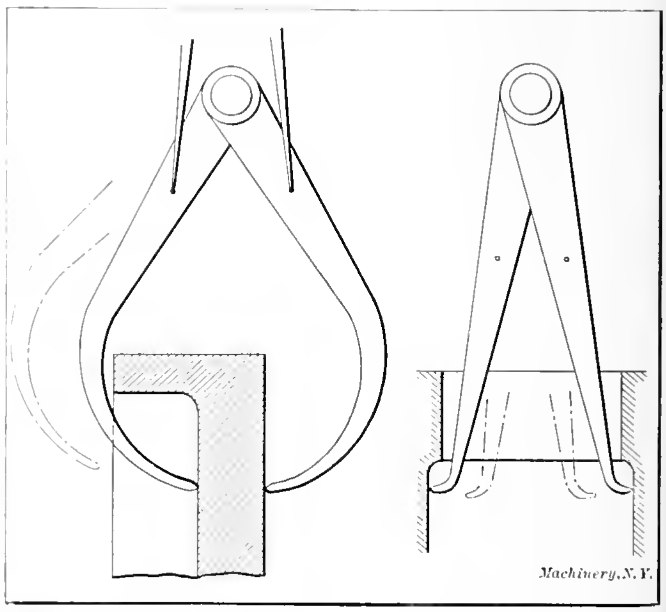
gage. When the drill begins to cut, this band should be against the face *f*; it is then easy to determine the amount of feed by measuring the distance that the band stands away from this face, as indicated in the drawing by the dotted out-line.

FRED HORNER

Bath, Eng.

CALIPERING OVER FLANGES

When it is necessary to gage the thickness of a piece of work which lies behind a flange, the ordinary calipers are of no use, because the dimension is lost as soon as the cali-pers are opened for removal. The view to the left shows



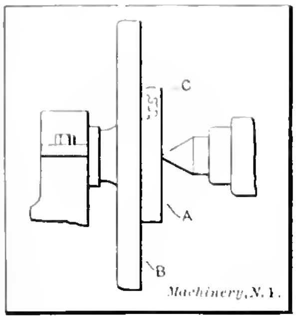
a neat method of enabling the setting to be repeated. All that need be done is to make a fine prick-punch mark on the face of each leg, and carefully measure the distance these are apart with the points of a pair of dividers. After the calipers are removed by opening them until they will clear the pro-jecting flange, they should be closed in again until the punch marks again coincide with the divider setting, when the dis-tance between the caliper points will equal the thickness of the work. If this is done with care, very accurate results may be obtained. The same method is applicable to inside calipers when taking the size of chambered recesses, etc. The caliper setting is changed (as shown by the dotted lines in the right-hand view) to get them out of the narrowed hole, and then they are again opened until the punch marks are the correct distance apart.

FRED HORNER

Bath, Eng.

FACING A DIE BLANK IN THE LATHE

In a small shop where a shaper was not available, the following method was used for facing the die blank: The die blank *A* was centered and placed on the faceplate *B* of the lathe. The tailstock center was then located in the center and a bolt *C* clamped in position against one edge, acting as a driver. While this method is not up-to-date, it appeared to me as being ingenious.

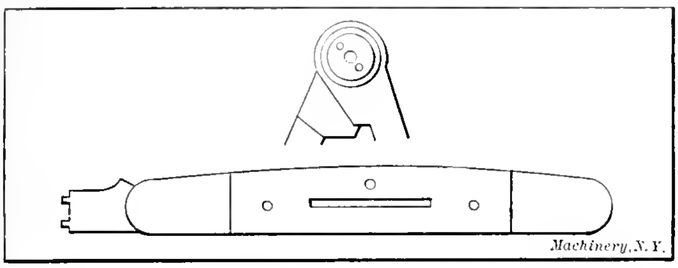


L. Rosenthal

Passaic, N. J.

COMPASS KEY

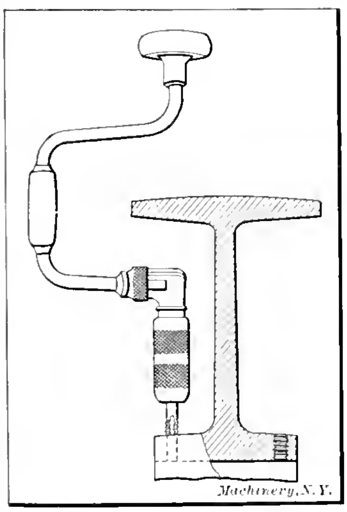
The sketch shows the novel use made of a broken knife blade, by filing the end of the broken blade to the shape shown, and using it as a compass key. In sets of instruments containing compasses with the style of joint shown, a separate key is usually provided, but the latter is small and inconvenient to use, and is often lost from the set in a little while. I keep the other blade of this knife sharpened to a razor edge for erasing.



Designer

USING A CARPENTER'S BRACE FOR TAPPING

A convenient method of tapping a hole in a position where an ordinary tapping wrench could not be used on account of the location of the hole, is shown in the accompanying illustration, the hole being in the hub of a pulley in front of a spoke. A monkey wrench could have been used for the purpose, but would have been awkward. As it was, the mechanic used an ordinary carpenter's ratchet brace for holding the tap. With the right-hand ratchet he tapped the hole, and with the left-hand ratchet withdrew the tap. This method was, of course, much more rapid than using a wrench, and also enabled the mechanic to push on the tap while tapping and pull on it while withdrawing.

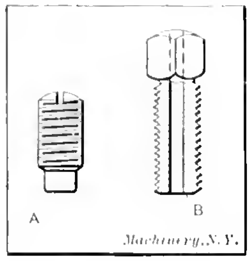


H. Prime Kieffer.

New York City.

METHOD OF SPOTTING FOR PILOT SET-SCREWS

We had some cast-iron gears to be located on a machine spindle and held in place by a pilot set-screw shown at *A*. The spindle was made from tough steel, and it was necessary to drill the hole for the pilot screw with a motor drill. We tried to spot the spindle with a tapping size drill, the result being that by the time the hole was deep enough in the spindle, the drill had cut away part of the threads in the gear. We also tried spotting the spindle with a center punch which was made the size of the tapping drill, but this also gave poor results. The screw shown at *B* was then made with a 1/8-inch hole drilled through the center and hardened. This screw was then screwed into the tapped hole in the gear and used as a jig. After drilling the 1/8 inch hole, the screw *B* was removed and the hole enlarged with the tapping size drill, without removing any of the thread. After the screw was made it was found to be useful for other jobs where pilot set-screws were used for holding handles, facing cutters, gears, etc. It was useful, not only as a jig, but also as a clamp for holding the parts in position while spotting.

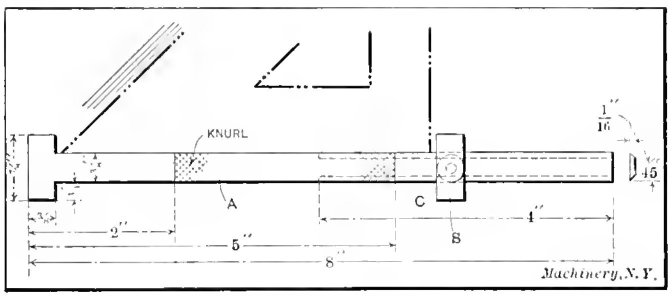


A. Nielsen

Cleveland, Ohio.

HOME-MADE SECTION LINER

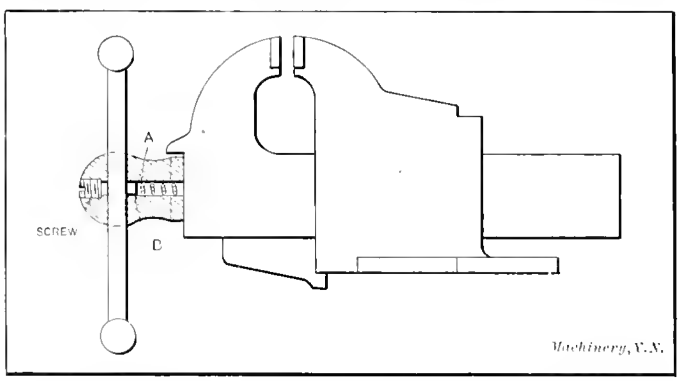
I recently visited a shop where several of the draftsmen were supplied with the home-made section liner shown in the accompanying engraving. This instrument is easily and cheaply made, as it consists of only three pieces. All the parts are made of cold-rolled steel, and are casehardened. The casehardening is not essential but will add to the life of the instrument. The bar *A* is shaped to fit the sliding block *B*, which is clamped in position by the small screw *C*. In operation, the instrument and the triangle are alternately moved along the edge of the T-square, the spacing having been adjusted by clamping the block *B* in the desired position. The end of the bar *A* should be burred slightly, to prevent the block from sliding off. A projecting pin instead of the knurling on the bar, may be preferred by some as a means of moving it along.



Designer

HAND PROTECTOR FOR VISE HANDLES

In the March issue of Machinery, Mr. A. G. Johnson shows a device for protecting the hand from a falling vise handle. His device consisted of a piece of rubber which is placed under each ball. The accompanying illustration shows another device which is used for this purpose. A spring *A* inserted in the head of the vise screw presses against plunger *B*, preventing the handle from falling.



A. Nielsen

Cleveland, Ohio.

CLAMPING STRAP FOR JIGS

For holding one or more pieces in a vise or jig where an even pressure throughout the entire length is sought, the concave strap has proved effective. A word of explanation will suffice for those unfamiliar with it. The strap is bent so as to have a uniform curve throughout, and is placed with the

convex side next to the work. Then when the bolts on the ends are tightened, holding the strap down its entire length, the parts in the center of the jig are held as securely as the ones at the end, which is not the case when a straight strap is used. Planing one side of a cold-rolled sheet-steel strap will give it about the proper curve. For example, a piece 3/4 by 1 1/4 by 8 inches long planed down to 3/4 by 1 inch will spring about 1/8 inch, which is usually a good average deflection. DONALD A. HAMPSON

Middletown, N. Y.

DIAMOND TOOL HOLDER FOR THE BENCH LATHE

A diamond tool holder for use in a bench lathe is shown in Fig. 1. This holder is attached to the tailstock and is very convenient for the reason that it enables the operator to dress the wheel without moving the slide rest when the latter is set to a position. The surface of the emery wheel is dressed flat

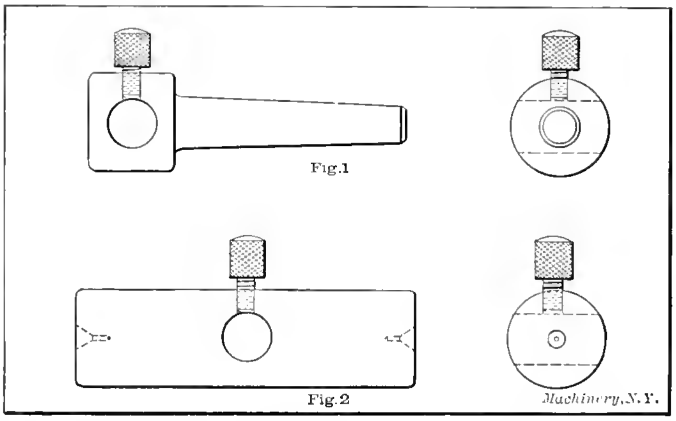


Fig. 1

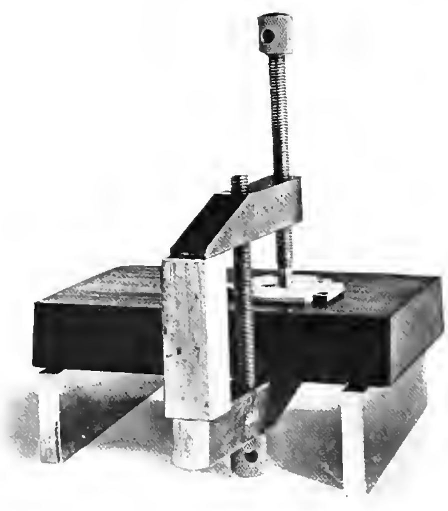
Fig. 2

and parallel by turning the handle of the tailstock back and forth. Another very handy diamond tool holder is shown in Fig. 2. This holder is held between the centers of the lathe, and the diamond tool is held stationary by placing its handle on a rest. The emery wheel is trued by moving the slide rest to and fro. The diamond tools are held in each of these holders by tightening the knurled screws shown. A. L. MONRAD

East Hartford, Conn.

CLAMPING TEMPLET TO DIE BLANK

Having recently seen in MACHINERY and other mechanical papers clamps made especially for holding templets on the face of die blanks while scribing the outline, the accompanying engraving is submitted showing the manner in which the ordinary tool-maker's clamp may be used for this purpose. The engraving is self-explanatory: One of the jaws of the clamp is reversed and a piece of wood or metal is used for

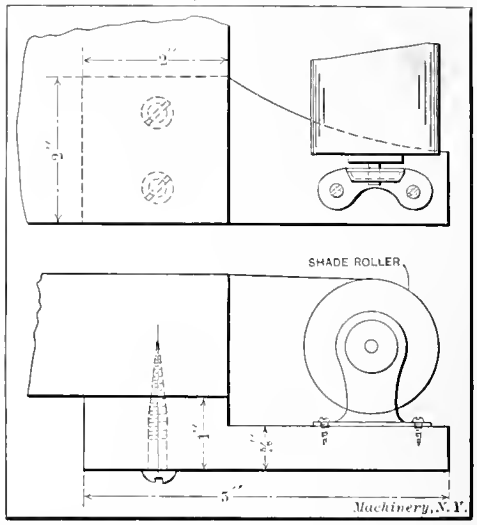


blocking up the outer end. The chief advantage of this little "kink" is that it does not necessitate the expense or trouble of adding an extra tool to the kit, as the clamp shown is a tool that every diemaker has. ROY PLAISTED

New York City.

COVER FOR DRAWING-BOARDS

The device illustrated herewith is a simple and inexpensive arrangement for protecting drawing-boards from dust and dirt. Black oilcloth mounted on an ordinary shade roller and

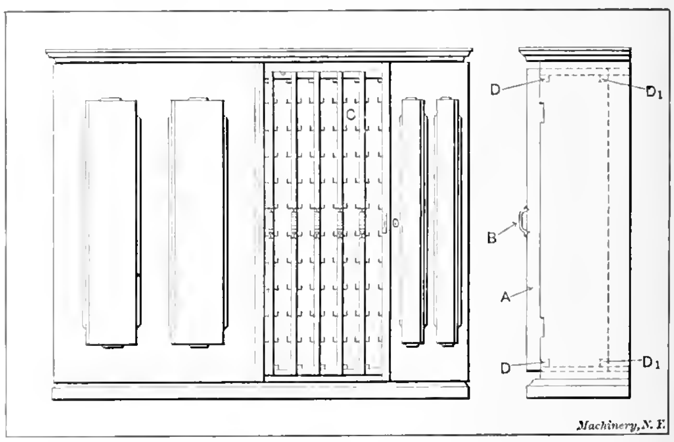


hangers on the back of the board, are used as shown. The blocks for supporting the fixtures should be arranged so as to bring the top of the roller slightly below the level of the back of the board, to keep dust from entering at the back. The roller should also project far enough from the back edge to clear whatever kind of parallel attachments are used in connection with the board.

The cover can be drawn down and rolled up like an ordinary window shade, and makes a very efficient and satisfactory covering. DESIGNER

TOOL-ROOM CASE FOR GEAR CUTTERS

A simple form of case or cabinet for gear cutters is illustrated herewith. It is specially constructed in its interior so that each cutter may be kept in an individual place. The interior is divided into compartments by slides *A*, which have rows of hooks *C* on each side, upon which the cutters are hung. Each slide is provided with a handle *B* so that it may easily be withdrawn from the case when a cutter is to be re-



moved. Blocks D_1, attached to the rear of each slide, make it impossible to pull the slides entirely out, as they strike against the blocks *D* attached to the case. The number of hooks should, of course, be determined by the size of the cutters. The advantages of using a case of this kind are as follows: The cutters can always be easily found when wanted; they are kept in good condition; the case is good for the tool check system; and last, but not least, the cutters are in an orderly condition. L. H. GEORGER

Buffalo, N. Y.

* * *

It is stated in the *Brass World* that plaster of Paris will harden rapidly if 0.25 per cent of sodium bisulphate is added to it. The sodium bisulphate should be dissolved in the water used for making the plaster. The strength of the hardened mass is also stated to be increased nearly three times.

SHOP RECEIPTS AND FORMULAS.

A DEPARTMENT FOR USEFUL MIXTURES.

This page is intended to be used only for the publication of such shop receipts as the contributors know from experience to be practicable. Receipts are solicited on the condition that the contributors personally know that they are reliable. The fact that a receipt is old and supposedly well-known does not bar it, provided it has not already appeared here.

SOLUTION FOR CLEARING BLUEPRINTS

Dissolve enough bichromate of potash in water to color the water a deep orange—or about one tablespoonful to eight gallons of water. Wash the blueprints in clear water before and after using the solution. E. RAY CROFT.

Chambersburg, Pa.

REMOVING RUST FROM STEEL

A good method for removing rust from steel is to first rub the object with sweet oil, and then after a day or two, rub it with finely powdered unslacked lime until the rust disappears. Then give it again a coating of oil with a woolen cloth, and put it in a dry place. E. W. NORTON.

ANNEALING STEEL HAVING HARD AND SOFT SPOTS

To anneal steel having hard and soft spots, remove the scale, and heat slowly and evenly to a little above a dark red. Immerse in fresh water until almost cool. Heat immediately to a dark red and anneal in the usual way.

C. F. EMERSON.

PORTLAND-TAR CEMENT

A valuable cement used in marine practice and other places where elasticity is desirable, is made by mixing Portland cement in gas tar until the consistency is that of stiff putty. It must be applied immediately as it hardens quickly. It is not affected by water and never becomes brittle, a fact that makes it very valuable around the tailshafts of steamers or wherever there is much vibration. A. L. GRAFFAM.

Fairfield, Me.

CLEANING FLUID FOR FINE FABRICS

This cleaning fluid may not be of much use in the shop, but if some machinist should get the machine shop grime on his "Sunday-go-to-meeting" trousers, he will find it useful for cleaning out the spots; it works like magic: Sulphuric ether, three drams; alcohol, six drams; chloroform, three drams; gasoline, one quart. The mixture can be used safely for cleaning the most delicate fabrics, but being highly inflammable, it must be used with caution around fires and open lights. M. E. CANEK.

REMOVING THE COLOR DUE TO THE HARDENING

If a punch, reamer or other tool is to be hardened, and the color resulting from that process is undesirable, it may be removed by the following simple method: After the part is hardened, dip it into a glass filled with muriatic acid and allow it to remain for five seconds; then plunge it into a pail of water. In this way the polish of the steel will return and the temper will not be affected. This method is much quicker than obtaining a polish by the use of emery cloth.

Buffalo, N. Y. JOHN C. MONRAD.

ELECTRICIANS' METHOD OF SOLDERING

A method of soldering that I noticed electricians using in soldering wire is as follows: The solder is melted in a pot and then poured over the joints to be soldered, by means of a small dip ladle. Then acid, paste or stick flux is applied, and the solder again applied. This makes a good joint. The solder which drops from the joint is caught by a second ladle, or in the solder pot. In some cases, when possible, the piece is dipped into the pot, the flux applied and the work again dipped. It is important in both cases to give the piece a sharp tap after the second application, to knock off any surplus solder. HERMAN JONSON

New York City.

MOTTLED CASEHARDENED ARTICLES

There are several ways of obtaining the beautiful mottled effect on casehardened articles, but one of the simplest and most effective methods is in use in the factory of the Thos. B. Jeffery Co., Kenosha, Wisconsin. Here the usual cooling tank and screen for catching the work are in use, but in addition, an air pipe is run into the bottom of the tank in such a way that when the air is turned on the water is filled with air bubbles and is violently agitated. The result of these air bubbles striking the cyanide-coated articles during the cooling process, is some of the prettiest mottled work imaginable. E. V.

RECEIPT FOR MAKING WAX TAPERS FOR CORES

Take equal parts of beeswax and powdered rosin. Melt the wax, sprinkle in the powdered rosin, and stir until well mixed. If beeswax cannot be obtained, use paraffine. This composition does not soften the core as does the ordinary paraffine taper, because the rosin goes into the core when it is baked and hardens it. If paraffine is used, it is better to make the tapers by dipping cotton wicking into the melted composition, as the paraffine makes it rather brittle. When beeswax is used, the wicking is not necessary, and the tapers can be formed in the same manner as that employed by pattern-makers in forming beeswax fillets.

Aurora, Ill. JOHN B. SPERRY.

CEMENT NOT AFFECTED BY ALCOHOL

Gold size is valuable as a cement for setting together parts of vessels containing alcohol, for it is not affected by alcohol as are some other good cements. It has been used for setting the glass covers of circular levels, the glass afterwards being burred over in the brass shell so that it is securely held mechanically. Ordinary painters' size is used, which may be prepared as follows: Boil raw oil in a pan until it smokes; then set it on fire and let it burn for a few moments. Cover the pan to extinguish the blaze and pour while warm into a receptacle containing red lead and litharge in the proportion of one ounce of each to a quart of oil. Keep at a temperature of 70 degrees for ten days and agitate once a day.

M. E. CANEK.

TO MIX LAMPBLACK AND SHELLAC

Mixing lampblack and shellac is not so simple a matter as it appears, as many an amateur and novice has found out. The tendency is to form lumps when the two are mixed, by throwing or even sifting the former into the latter. The lumps of course can be reduced and an intimate mixture obtained by considerable patience with a paddle or pestle. The whole difficulty is easily avoided if the lampblack is first wet with alcohol and thoroughly worked down into a soft paste with a paddle or spatula. The black paste is then added to the shellac and mixed uniformly by stirring. The result is a smooth flowing and working shellac. Other pigments can be treated in the same way. O. M. B.

ANTIQUE BRASS FINISH SHOP RECEIPT

It is comparatively easy to get a nice antique finish on copper or copper-plated articles, but the treatment of brass is more difficult. Most of the processes used do not give a nice, clear black, but instead, a dull or grayish black coating. When visiting the shop of the Puritan Mfg. Co., Decatur, Ill., I noticed the beautiful jet black of the brass articles made up with the antique finish, and upon expressing my curiosity as to how it was obtained, was offered the formula. The articles are first dipped into a strong, hot solution of potash, and then well rinsed in water; they are then immersed in a mixture of one part sulphuric and two parts nitric acid, and instantly rinsed in clear, cold water. Next they are placed in a bath consisting of two ounces acetate of lead and one ounce hyposulphite of soda to each gallon of water in the tank. This solution must be almost boiling when used. The brass is moved around in this until the desired black is obtained, then rinsed and dried When dry and cool spot on a rag wheel. If the brass doesn't turn black enough in the above solution, add the least bit more lead

HOW AND WHY

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details and name and address. The latter are for our own convenience and will not be published

HOW TO MAKE GEAR CUTTERS FOR JOBBING SHOPS

R. G. D.—I would like some information on how to produce a moderately accurate tooth profile, so as to be able to make gear cutters for spur and bevel gears. Being located in New Zealand where the volume of gear repair work is not great, I am unable to afford a full set of cutters which would enable me to replace any broken gear. We often have to make cutters to suit the case in hand. The usual job is to cut a gear to take the place of a broken sample. We generally manage to find some portion of the broken gear so little worn that we can make a cutter to fit. We have cut several bevel gears on these lines, but the shape of the cutter has always been a troublesome matter to obtain. When we run short of cutter blanks we have to cut up a sledge-hammer, being so far away from the world's markets, and, as we seldom have to cut more than a couple of gears with the same cutter, it does not pay to expend a great deal on special cutters. By carefully hardening the cutters made from a sledge-hammer they last all right. Any information that will help us out will be appreciated.

A.—The case is submitted to the readers for suggestions.

USE OF SUB-PRESS DIES ON THICK STOCK

D. V. Co.—We would like to know if a sub-press die can be used successfully on cold-rolled steel stock of thicknesses up to 7/32 inch?

Answered by Frank E. Shailor, Detroit, Mich.

A.—I have seen and made sub-press dies for punching stock heavier than 7/32 inch. One feature that aids greatly in stripping heavy stock is making the punches a loose fit in the dies. To obtain the proper clearance for the punch in the die for all thicknesses of stock, six per cent of the stock thickness is allowed for difference of the punch and die diameters. Therefore, on 7/32 inch stock the punch would be 0.012 inch smaller than the die. When the punch pierces the stock, the diameter of the hole is the mean between the diameter of the punch and the diameter of the die. It will be seen from this that the stripping pressure required actually decreases as the stock increases. The hole punched in the stock is cone-shaped, the top diameter being that of the punch and the bottom diameter that of the die. On account of this defect it is not considered of much benefit to use sub-press construction on heavy work except to aid in setting up in the press. If the punch were made to fit the die on this thickness of stock, the conditions would have to be exactly right; that is, the stock would have to be absolutely flat, and the stripper absolutely parallel with the face of the die in order to prevent cramping on the punches and breaking them.

POWER REQUIRED FOR BENDING SHEET STEEL AND IRON

W. J. D.—Is there any formula for the force required to bend sheet steel to a right angle? Assume for example, that the sheet is one-half inch thick and 60 inches wide, and that the force is applied $13\frac{1}{2}$ inches from the fulcrum or center of the bend. What would be the difference between the force required for bending sheet steel and sheet iron?

A.—Referring to the accompanying engraving, if we assume that the sheet to be bent is rigidly held on each side of the place where the bend is required, the force required for bending would be the force necessary to produce a bending moment which would produce a stress in the sheet steel which would somewhat exceed the elastic limit.

If P = force required for bending, in pounds,
t = thickness of sheet to be bent, in inches,
b = width of sheet to be bent, in inches,
l = distance between the application of the power and the center of the bend, in inches,
S = stress slightly in excess of the elastic limit of the material, in pounds per square inch,

then:

$$P = \frac{Sbt^2}{6l}$$

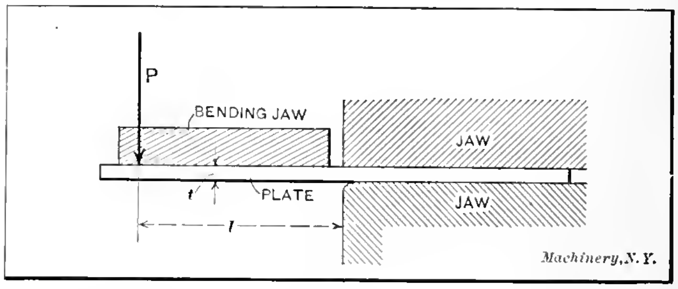
For steel plate we may assume $S = 35{,}000$ pounds per square inch and for iron plate, 28,000 pounds per square inch. Inserting the given values in the formula we find for sheet steel:

$$P = \frac{35{,}000 \times 60 \times (\frac{1}{2})^2}{6 \times 13\frac{1}{2}} = 6480 \text{ pounds.}$$

and for sheet iron:

$$P = \frac{28{,}000 \times 60 \times (\frac{1}{2})^2}{6 \times 13\frac{1}{2}} = 5185 \text{ pounds.}$$

The values of S will vary considerably for various grades of steel and iron, and also with the condition of the steel. If



unannealed the value will be higher than if annealed. This uncertainty makes calculations of this kind only approximately correct, and ample latitude must be given in designing machinery for bending to provide sufficient power for all conditions.

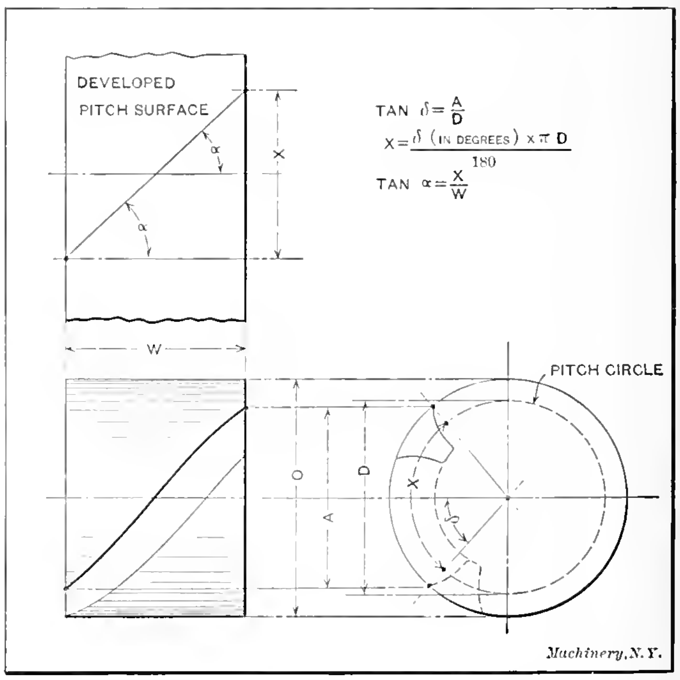
CALCULATING ANGLE OF HELICAL GEAR FROM SAMPLE

O. F. W.—There is one point I do not find explained in books on spiral gearing that I am anxious to find out about. How can you figure out the helix angle or tooth angle, when you have to make a new gear like a sample, as is often the case in jobbing and repair work, etc.? It is assumed that no drawing is furnished.

A.—To calculate the helix angle of a helical gear already cut, we will have to know the following dimensions. See the accompanying diagram:

W = width of face,
A = advance of tooth in width of face,
O = outside diameter,
D = pitch diameter.

All of these measurements are taken directly from the sample,



except that for the pitch diameter. This is obtained from the normal diametral pitch, or pitch of the cutter used, as follows:

$$D = O - \frac{2}{Pn}$$

We have first to calculate the distance on the pitch diameter which the tooth advances on the helix in the width of face. This is marked X on the diagram, and is measured on the cir-

cle as shown. To find this, we first find angle δ by the following calculation:

$$\text{Tangent } \delta = \frac{A}{2} \div \frac{D}{2} = \frac{A}{D}$$

X can evidently be found by proportion, as follows:

$$\frac{X}{2} : \pi D :: \delta : 360 \text{ deg.}$$

in which, of course, πD is the pitch circumference or $3.1416D$. This proportion may be simplified to the following expression:

$$X = \frac{\delta \pi D}{180}$$

In this, of course, δ stands for the number of degrees in the angle. If the calculation brings this to an odd number of degrees and minutes, the minutes should be reduced to decimal degrees; thus, 15° 45′ would become 15.75°.

Having thus found the advance on the pitch circle that the helix makes on the width of face of the gear, we can easily get the helical angle as shown in the development of the diagram. This development is, of course, a section of the surface of the pitch cylinder laid out flat on a drawing-board.

$$\text{Tangent } \alpha = \frac{X}{W}$$

The process we have given here is the exact one applicable to gears of any helix angle. For cases where the angle is comparatively slight, as in your case, it might be safe enough to find X approximately from A by the proportion:

$$X : A :: D : O \text{ or } X = \frac{AD}{O}.$$

This, of course, is not quite correct, as X is measured on the straight line.

DON'TS FOR THE PREVENTION OF ACCIDENTS IN THE MACHINE SHOP

By H. P. WENTWORTH*

Don't wear loose fitting garments.

Don't forget to roll up your sleeves.

Don't wear jewelry on your hands while in the shop.

Don't oil or clean a machine while it is in motion.

Don't attempt to look about you while busy at a machine—attend strictly to business.

Don't neglect to replace gear guards after removing them for cleaning, repairs or other purposes.

Don't (while at work on a stamping press) forget to remove your foot from the treadle while putting in or removing work from the dies.

Don't put your fingers in the dies to remove work; use a stick or the implement furnished for that purpose.

Don't set up or take down a job in the press until you have thrown off the belt.

Don't throw off the belt with your hand—use a stick.

Don't fail to see if the spring on the treadle is in working order before you start; it should withdraw the treadle immediately, allowing the machine to trip but once.

Don't use a weak or shaky stool or bench while working at a stamping press.

Don't allow scrap or stampings to collect on the floor.

Don't drill a piece of work until you are sure it is securely held.

Don't fail to withdraw the milling machine table far enough when removing work, to prevent the hands or clothing from coming in contact with the cutter.

Don't use a file without a handle, especially in a lathe.

Don't leave a chuck wrench standing in a chuck; always remove it.

Don't touch or jostle a fellow while he is working on an emery wheel if you can prevent it.

Don't forget to use the wheel with care as it does not take a very strenuous blow to cause it to break; especially a small one.

Don't try to stop an emery wheel with your fingers.

Don't try to talk and work at the same time; you cannot do two things at once and do them well.

Don't strike matches and throw them carelessly from you; be sure they are out.

Don't fail to report if any part of your machine is out of working order. "An ounce of prevention is worth a pound of cure."

* Address: 337 Warren St., Newark, N. J.

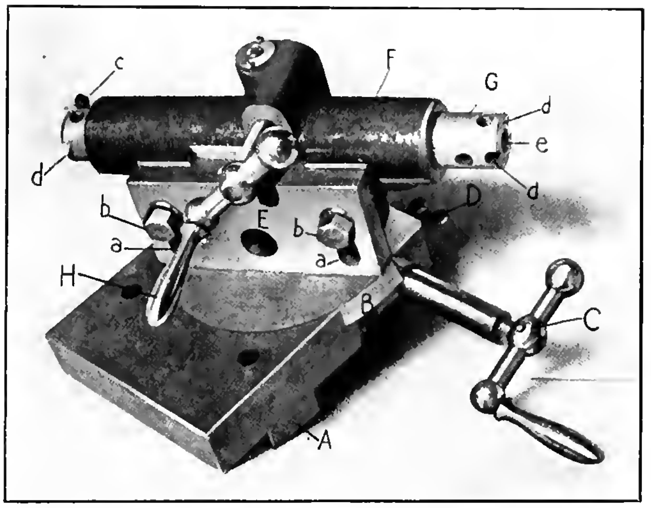
TAPER TURNING ATTACHMENT

By WILLIAM Z. BEAN*

The accompanying illustration shows an interesting attachment for taper turning, which can be used both for internal and external work. This attachment is provided with a tongue A which is located in the T-slot of the lathe, and is held by two capscrews, which are screwed into two nuts placed in the T-slot. The desired angle is obtained by rotating the handle C, thus moving the part B on which the angular graduations are laid out in either direction. When the desired angle has been obtained, the part B is securely held by wing-nut D. Slots a are provided so that the cutting tool may be adjusted vertically to accommodate any swing of lathe, the capscrews b being used for holding the movable part in the desired position. The handle H operates the spindle G shown protruding from each end of the sleeve F.



Taper Turning Attachment for Internal and External Work

In one end of the spindle G is shown a cutting tool c which is made from 5/16 Crescent steel. Small holes d are provided in each end of the spindle G for holding these tools. A small tool suitable for internal work can be inserted in hole e, which permits this fixture to bore deep holes which are smaller in diameter than the spindle G. The hole E is used for securing another attachment which is not shown, whereby balls may be turned or castings cupped out to a given radius; but to apply this attachment it is necessary to remove the sleeve F containing spindle G and its operating handle H, when the other attachment can be secured in its place. The fact that this is a portable attachment permits it to be readily applied to the milling machine by securing the tongue A in the milling machine vise, whereby collets, convex cutters, bevel gears and work of a similar character may be turned, by securing them in a suitable fixture held on the nose of the spindle.

* * *

An account of the industrial operations of the Japanese government is published in the *London and China Telegraph*, and contains some matter of interest. During the past year the government's steel works produced 20,000 tons of steel plate and 25,000 tons of rails, besides about 55,000 tons of steel bars and structural material of various kinds. According to financial reports, the net profits arising from the Japanese Government's industrial enterprises for the year ending March, 1909, amounted to nearly $31,000,000, the greater part of which accrued from the tobacco and salt monopolies.

AEROPLANE FLIGHTS—ALBANY TO NEW YORK—NEW YORK TO PHILA. AND RETURN

Glenn H. Curtiss, the well-known aviator, made a remarkable aeroplane flight May 29, when he flew from Albany to New York, for which feat he received a prize of $10,000 from the New York *World*. Two stops were made during the flight, one for gasoline at a point near Poughkeepsie and a second at 214th St., New York City, for obtaining a supply of oil. The entire distance from the starting place at Albany to Governor's Island, where the flight ended is 150 miles, which was traversed in two hours and forty-six minutes of actual flying time, at an average speed of approximately fifty-four miles an hour. This is somewhat faster than the scheduled time of the Twentieth Century Limited, between Albany and New York, as this train covers its run of 143 miles at an average speed of 49.6 miles an hour. The machine used which was of the biplane type was driven by a 50-horsepower, eight-cylinder engine, connected with a two-blade propeller, which gave a horizonal thrust of 350 pounds. Two air-tight metal caissons and five air bags were attached to the aeroplane to keep it afloat in case it dropped into the Hudson River, which latter was followed by Mr. Curtiss in his flight. The trip as far as the Catskill Mountains was made at an altitude of about 1000 feet. When the mountains were reached, perilous air currents made it necessary to glide to higher levels and it is estimated that at one time the machine was 4000 feet above sea level. The entire flight which, including stops, required 4 hours, 57 minutes, was made without an accident, though at one time Mr. Curtiss states that he temporarily lost control of the machine because of adverse air currents which caused it to lurch over sidewise and downwards with considerable rapidity. This aero trip, while not quite as long as the one made by Mr. Paulhan in England, is in some respects a more wonderful demonstration of the possibilities of aero flight, as the territory traversed offered a greater variety of perils than those encountered on the trip from England to Manchester.

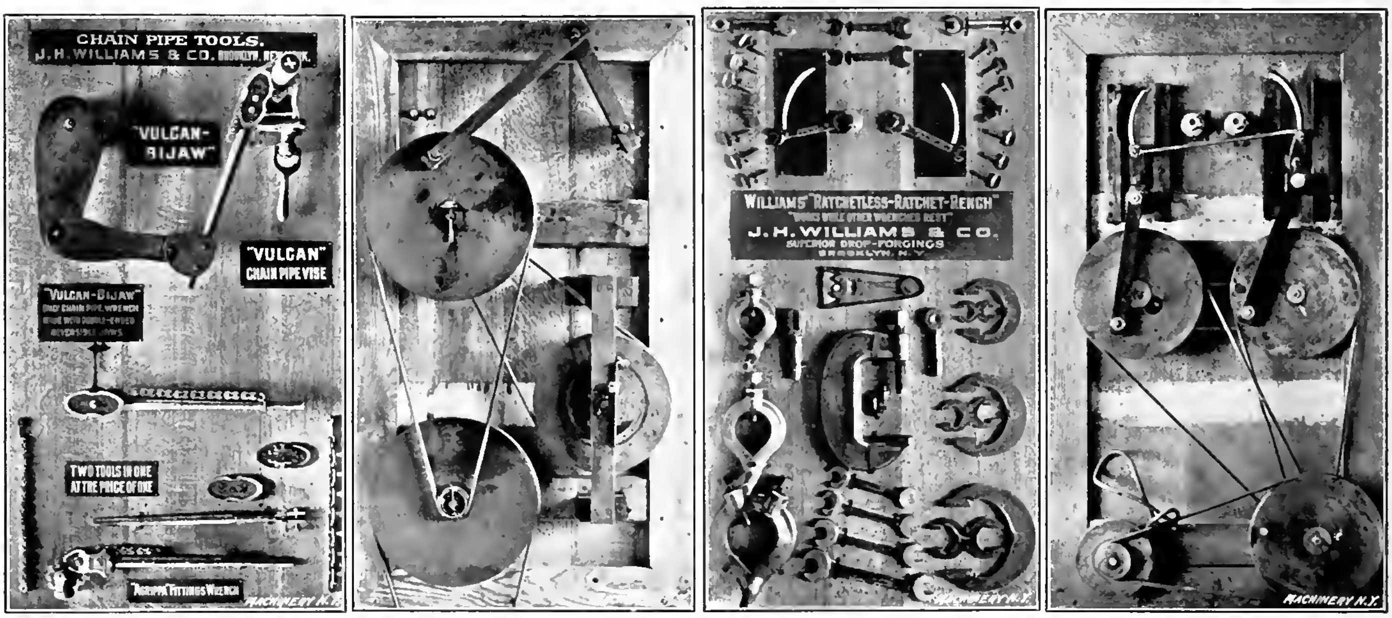
History is being made so rapidly in the progress of aviation that it is difficult for a monthly journal to keep abreast of the times. In another part of this issue is a note regarding the record of Paulhan's long-distance flight from London to Manchester. Since that portion of this issue, which went to press early in June, was printed, and the above, recording Curtiss's exploit, was written, Charles K. Hamilton made a flight from Governor's Island, New York, to Philadelphia and back the same day with a Curtiss biplane. He thereby won the prize offered by the New York *Times* and the Philadelphia *Public-Ledger* for a round-trip flight made between New York and Philadelphia in twenty-four hours. The aviator left Governor's Island at 7:36 A. M. and landed at Philadelphia at 9:26, the distance being 86 miles. He started on the return trip at 11.33 A. M. and when near South Amboy defective spark plugs forced him to descend at 12:54, the descent resulting in breaking the propeller. The propeller was repaired and the machine started again at 6:17 P. M. and reached Governor's Island at 6:40. The return distance was about 89 miles counting three miles made in the detour consequent to landing at South Amboy. Hamilton followed the line of the Pennsylvania R. R. most of the way, and a special train of three cars accompanied him going and coming.

* * *

J. H. WILLIAMS & CO.'S MOTION SAMPLE BOARDS

The accompanying illustrations, Figs. 1 to 4, inclusive, show front and back views of two classes of motion sample boards made by J. H. William & Co., Brooklyn, N. Y., for advertising their line of chain pipe tools, C-clamps, lathe dogs, standard drop-forged wrenches, Williams ratchet wrenches, snap gages, thumb-screws, etc. The motion boards were designed to illustrate the action of the Vilcan bi-jaw pipe wrench and the Williams' "ratchet" wrench, these tools being actuated by the mechanism shown in the back views. One-eighth horsepower electric motors are employed for actuating them.

The reversible feature of the ordinary chain pipe wrench with serrations at one end of the jaws only, which permits either side of the jaws to be used at will to grip the pipe is well-known, but the two-fold advantage of the double-end serrations of the Vilcan bi-jaw wrench has not yet been so generally appreciated, and the motion board was designed to show it by automatic demonstration which could be repeated *ad libitum* at small cost.



Figs. 1, 2, 3 and 4 Front and Back View of J. H. Williams & Co.'s Motion Sample Boards showing Tools and Mechanism

Many readers no doubt are unfamiliar with the "ratchet" wrench—a wrench without ratchet mechanism, but having essentially the ratchet action in use. It is a drop-forged machine wrench with one short jaw rounded so that it automatically releases the nut on the backward stroke, allowing the wrench to roll around the nut and engage the next square. The operator can use the wrench on either square or hexagon nuts without lifting and carefully adjusting it on each square as is necessary with the ordinary type. It "just naturally" falls into place on the back stroke. The motion board Fig. 3 plainly shows this action on both square and hexagon nuts.

J. H. Williams & Co. expect to show the motion boards at the leading mechanical conventions and then they will be offered to the leading machinery merchants throughout the United States for display in their stores and store windows.

* * *

According to a paper read before the Pittsburg Foundrymen's Association, large patterns made of concrete reinforced with wire have been successfully used in a foundry at Niagara Falls, N. Y. The cost of these patterns is very much less than that of ordinary wooden patterns.

NEW MACHINERY AND TOOLS

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP

Comprising the description and illustration of new designs and improvements in American metal-working machinery and tools, published without expense to the manufacturer, and forming the most complete record of new tool developments for the previous month.

THOMPSON UNIVERSAL GRINDING MACHINE

A universal grinding machine that has been designed for the purpose of combining in a single machine, efficient means for the accomplishment of every possible grinding operation that may be required in the tool-room and general shop, is illustrated in Fig. 1. This machine is manufactured by the Thompson Grinder Co., of Springfield, O.

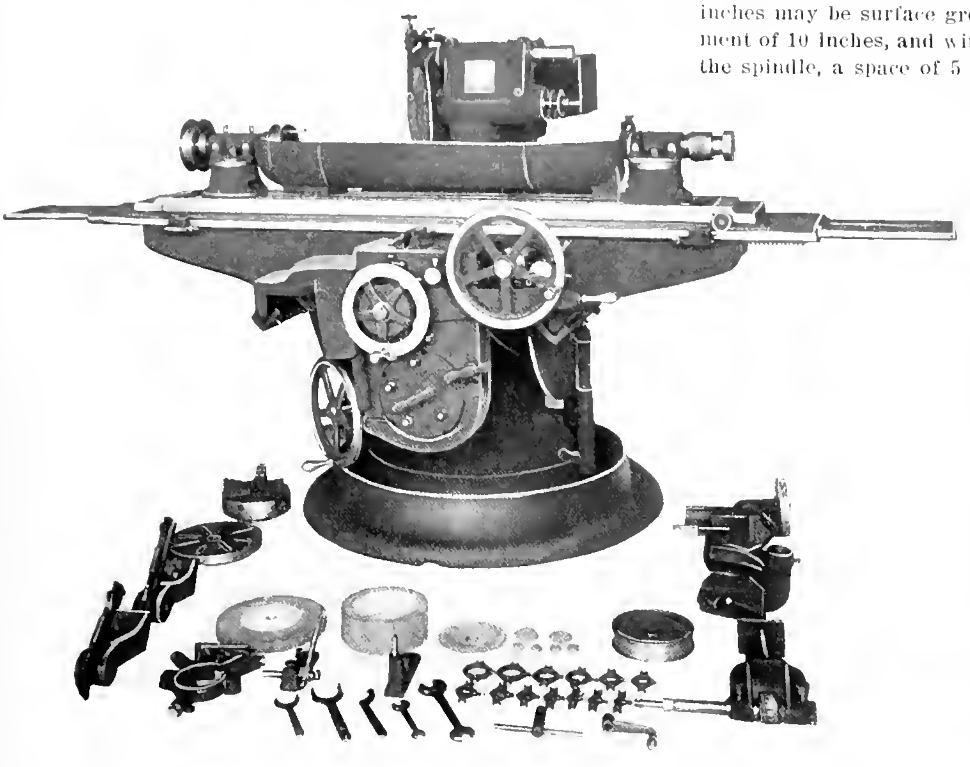


Fig. 1. Thompson Universal Grinder as arranged for Grinding Work between the Centers

The grinding wheel on this machine is maintained in a fixed position at all times, and the grinding table carrying the work to be ground, is made adjustable to any desired position relative to the wheel. The head is rigidly mounted upon a column that is solidly attached to the base, and surrounding the column is a trunk or body casting, that revolves upon a bearing on the base. This body casting carries the elevating knee, saddle casting and grinding table, which may be adjusted to a position at right angles to the spindle at either end, parallel to it, or at any intermediate position. This feature renders this machine capable of being converted in a moment's time into either a plain grinder for grinding straight or taper work between centers, a surface grinder, a knife grinder, an internal grinder, a die grinder, or a cutter grinder, each of which is perfect in its action.

Fig. 1 shows a front view of the machine as it appears when converted into a plain grinder for grinding work between centers. When so arranged, it has a capacity for either straight or taper work up to 10 inches in diameter by 36 inches long. With the table in this position, the overhead drum of the countershaft is parallel with it and, by means of a weight, the drum is automatically adjusted to the height of the grinding table, thus keeping a uniform tension on the belt.

In Fig. 2 the grinder is shown converted into a surface grinder. The spindle and grinding head overhang the table in such a manner that the full width of the table, which is 8 inches, may be passed laterally beneath the wheel. The traverse of the table is 48 inches, and therefore, work 8 by 48 inches may be surface ground. The knee has a vertical movement of 10 inches, and with a wheel 10 inches in diameter upon the spindle, a space of 5 inches will be left between the table and wheel, when the table is at its lowest level.

The internal attachment is applied to the Thompson grinder as shown in Fig. 3. The headstock and a three-jaw combination chuck are mounted on the table. The machine is in the same position as when used for cylindrical grinding. The internal attachment receives its power from a pulley mounted on the grinding spindle proper. Work 4 inches deep may be ground by this attachment.

In Fig. 4 the machine is shown set up for grinding a hob, while the illustration Fig. 5 shows it with a large faceplate mounted on the headstock spindle, thus adapting the machine for either die or surface grinding. As the engraving shows, the grinding spindle is parallel with the faceplate. Figs. 6 and 7 illustrate the arrangement of the machine for grinding end and spiral mills, respectively.

In addition to the uses mentioned in the foregoing, this grinder may he converted into a knife grinder for sharpening large paper knives. The table is swung around to a position at right angles to the spindle and a cup wheel is used. Three angle pieces bolted to the grinding table can be employed to support the knife. This simple rigging will make it possible to easily accomplish the occasional job of grinding large knives. Should the machine be used regularly for this particular work, an attachment can be furnished for holding the knife at an angle, which at the same time affords

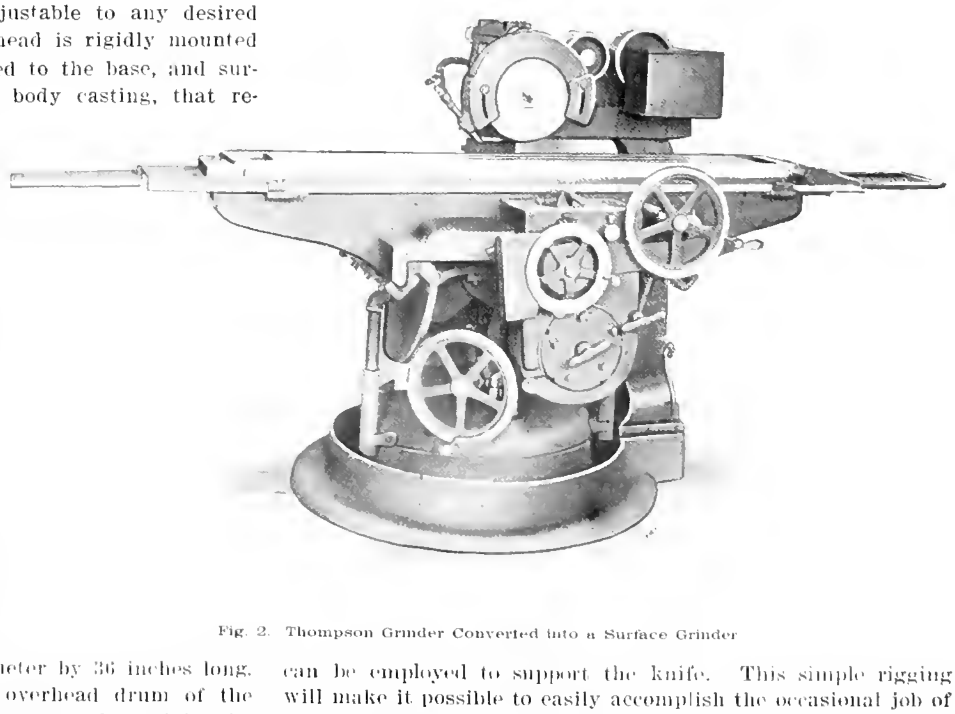

Fig. 2. Thompson Grinder Converted into a Surface Grinder

a support throughout its length.

As will be seen, this grinder, aside from being convertible into at least five distinct kinds of grinders, any of which is

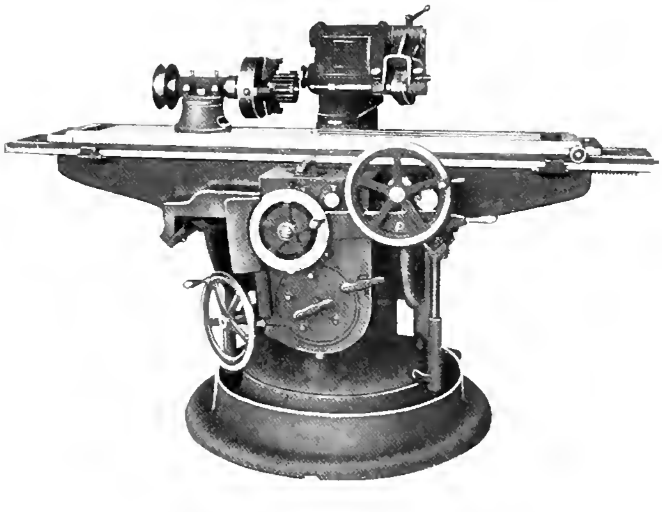

Fig. 3. Grinder Set up for Internal Grinding

capable of economical production, may also be used for many other special purposes.

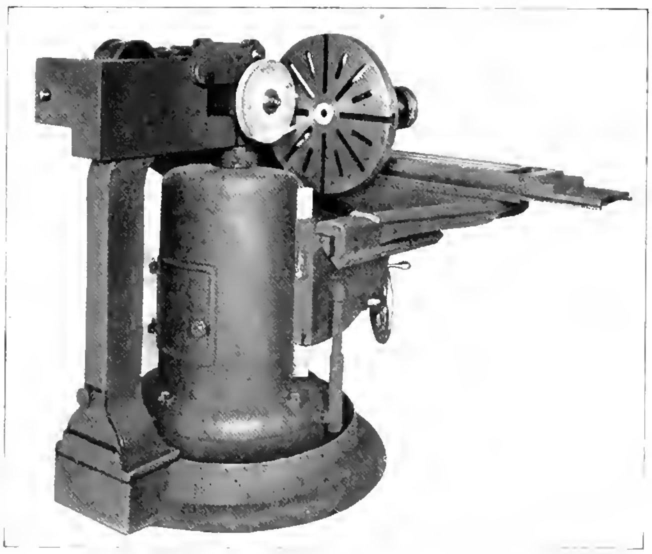

Fig. 5. Machine with Faceplate for Die and Surface Grinding

The machine has an automatic longitudinal feed to the table of 48 inches with ten independent changes, any of which is

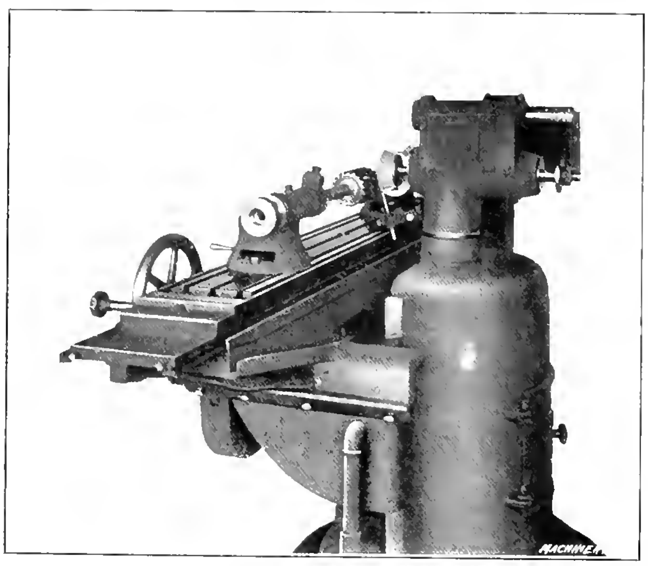

Fig. 7. Grinding a Spiral Cutter

instantly obtainable. An automatic micrometer cross-feed of 8 inches is available, and the knee has a hand vertical micrometer adjustment of 10 inches. In Fig. 8 are shown some of the interior details, giving an idea of the arrangement of the gears for doubling the number of feeds in the quick-change

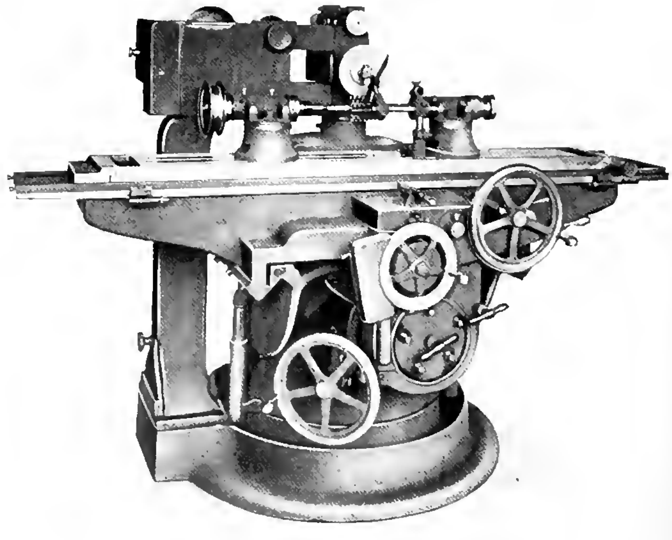

Fig. 4. Hob being ground on Thompson Grinder

gear box shown in Fig. 9. The pulleys marked A and A_1 act as idler pulleys, and the belt from the line-shaft makes a right-

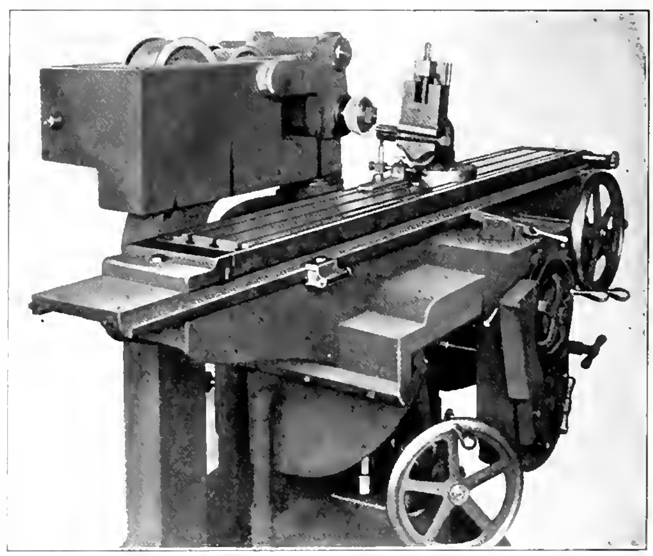

Fig. 6. Grinding an End Mill

angle turn on these pulleys, passing around the pulley mounted on the spindle B. Pulley A drives, at one end of its shaft, a

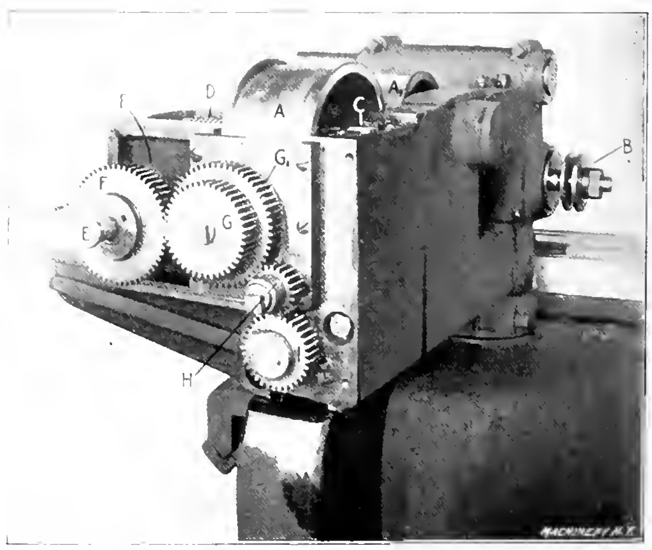

Fig. 8. Arrangement of Gears for Doubling the Number of Table Feeds

pair of 45-degree spiral gears C, which by means of a shaft extending to the base of the machine operates the pump for the water attachment. On the other end of the pulley shaft A, is

mounted the worm D meshing with a worm gear on the same shaft with the pull-pin E. Pull-pin E operates a sliding key which keys either F or F_1, to drive either G or G_1, thus giving two rates of feed. From G_1 the drive is through H and I and thence down through the body of the machine to the spur pinion J in the quick-change gear box Fig. 9. Handles K and L operate the quick-change feed mechanism, K revolving the dial, containing the five sets of change gears, and handle L being used to mesh the gears by swinging the case closed. For example, gears M and N could be made operative by turning the dial until gear M could mesh with pinion J, and gear N with O. By the engagement of slots cut in the periphery of the dial with a projecting key, the different sets of change gears are accurately located with reference to the pinion J and the gear O.

Fig. 10 gives further details of the feed mechanism, showing the way in which the reverse in the direction of the travel to the table is obtained. Gear O (Fig. 9), meshes with gear P, P

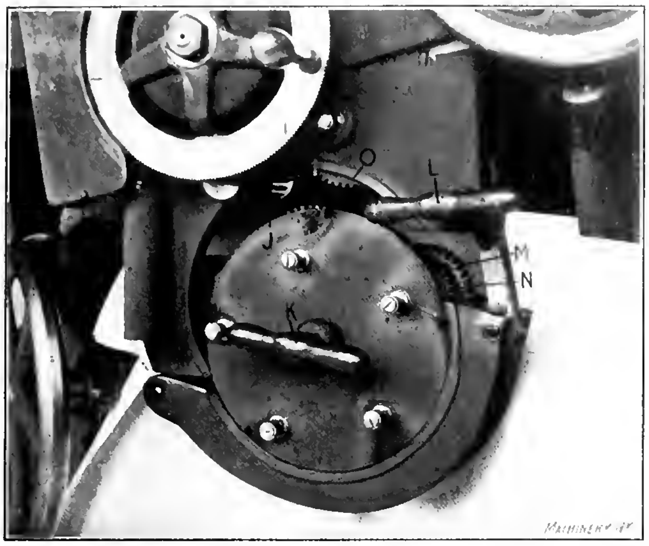

Fig. 9. Table Feed-changing Mechanism

with Q, R with S and S with Q_1. As the clutch is keyed to the shaft which operates the table travel, and gears Q and Q_1, run free on this shaft, a longitudinal table travel in both directions is obtained by means of the reversing clutch. As stated before, by this unique arrangement five changes of travel to the table are obtained by the quick-change gear box, and these

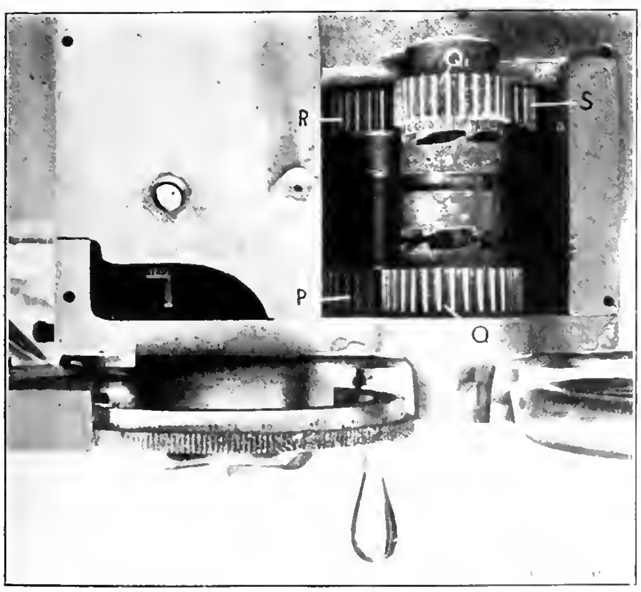

Fig. 10 Detail of Reversing Clutch Mechanism

are doubled at the back of the column by means of the pull-pin E.

Further details of the machine, especially as to the arrangement of the automatic cross feed, are shown in Fig. 11. Handwheel T operates the cross feed and handwheel U the longitudinal feed. Now when the four pawls are dropped into place in the ratchet on the handwheel T, the action of the lever V operates the cross feed. To insure engagement with the ratchet teeth of the wheel T, four pawls are used. The adjustment of the cam at W controls the amount the ratchet is advanced by the pawls, or, in other words, the

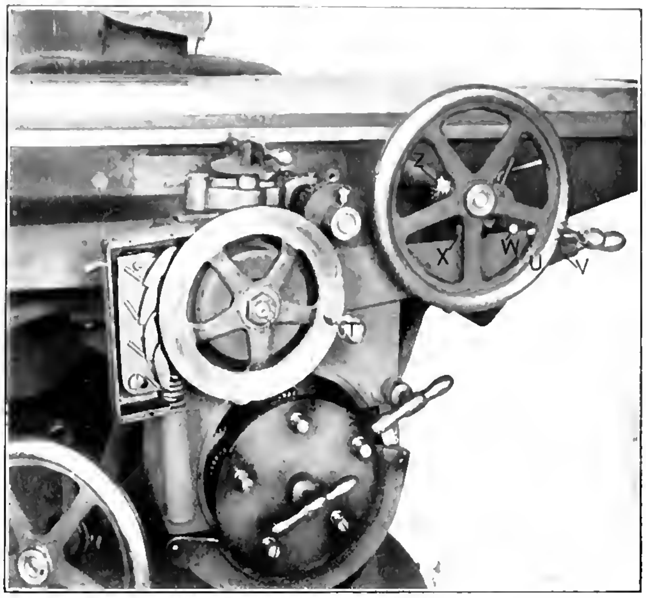

Fig. 11 Arrangement of the Automatic Cross-feed

amount of cross feed. At X is another pawl secured to the lever V. When the table travel is automatically reversed, the sprocket Z also reverses its direction, and by means of the pawl X which engages with Z, the lever V is forced down operating the cross feed automatically.

The makers have designed for this grinder a very simple countershaft as shown in Fig. 12, the drum of which ad-

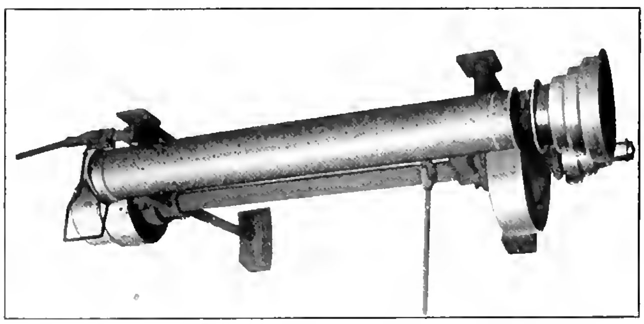

Fig 12. Countershaft and Drum with Automatic Adjustment

justs itself automatically to the difference in the elevation of the table. It is self-contained and is very easy to hang, from the fact that the bearings are held in line by a framework, which carries the drum. This framework, which also carries the bearings for the countershaft proper, has at its outer ends ball joints which rest in sockets in the hangers.

An opportunity to see one of these machines in full operation may be had by a visit to one of the demonstration shops of Hill, Clarke & Co., Inc., of Boston, Chicago, New York, Philadelphia and Cleveland.

GEOMETRIC CHASER OR DIE GRINDER

The practice of using a set of chasers or dies until they are very dull is, of course, poor, as they will not only work much more effectively if ground at intervals frequent enough to keep them sharp, but the results produced will be of a superior quality. It is also essential that the grinding be done uniformly on all the chasers in a set, in order that the work of cutting be distributed equally, and the thread produced be regular and smooth. To enable this work to be done quickly and with accuracy, the Geometric Tool Co., New Haven, Conn., has developed the chaser or die grinder illustrated in Fig. 1. This machine is adapted for grinding any make of thread chaser, whether of a stock or special type. The die to be ground is held in a universally-mounted vise, and the ad-

justments provided are such that the die may be ground square or to any radius, and the throat can also be given any desired clearance.

Before describing the method of grinding both milled and tap-formed dies in this machine, its various adjustments will be explained. The vise in which the dies are held, as is shown more plainly in Fig. 2, is pivoted to a carriage which may be moved back and forth in front of the grinding wheel by means of the hand lever *F*. The upper handwheel *C*, operates the vise for holding the chasers in the proper position for grinding, while the small knurled wheel *D* gives the proper radius for grinding tapped dies and it is set in accordance with the scale *O*, Fig. 3. The lower handwheel *A* operates the lower cross-slide and moves the vise to and from the grinding wheel. The small knurled wheel *E* is used for adjusting the vise to the right or left of the pivot to obtain the proper clearance and also for grinding right- or left-hand chasers. It is also possible to tilt the vise by means of the leveling screws *R*, which adjustment is employed when grinding Acme or square threads of coarse pitch, and also for double and triple threads. The proper length of throat or chamfer is obtained by raising or lowering the knee on which the carriage and vise are mounted, by means of a screw operated by handwheel *G*.

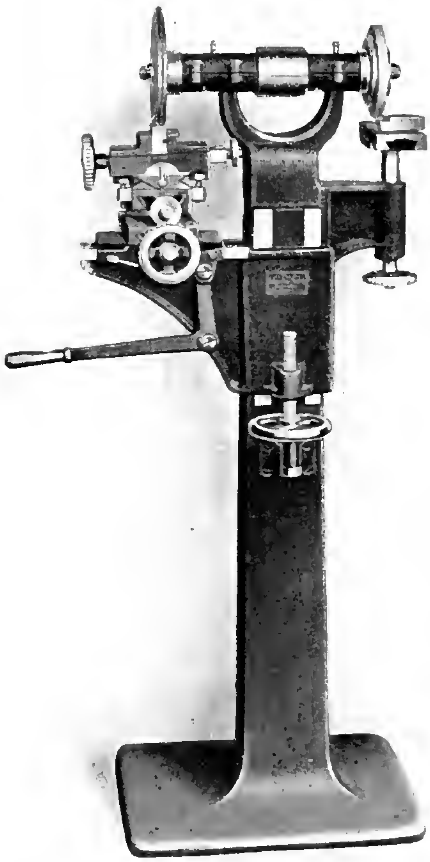

Fig. 1. Chaser or Die Grinder built by the Geometric Tool Co.

When a die is to be ground, it is clamped in the vise by means of handwheel *C*. The jaws of this vise have the same form as the clamping device of the die-head, so that the die is rigidly held in the correct position for grinding. Only one chaser is ground at a time, but as the adjustment of the vise and feed-table remain the same when once set, absolute uniformity of grinding is assured.

As milled chasers are ground mostly on the throat, the feed-table is lowered so as to bring this part of the die below the grinding wheel center. After the chaser is inserted in the chuck, it is brought up against a stop and clamped tightly. The table is then adjusted vertically by the handwheel *G* to give the proper chamfer. When a die is to be used on brass or other free-cutting metals, or if it is to be used for threading close to a shoulder, it should come in contact with the grinding wheel far enough below its center to obtain a short chamfer of, say, approximately 45 degrees. For ordinary work, the table should be set higher so that a chamfer of about 30 degrees will be obtained. When one die has been ground to the proper angle of clearance, the sleeve *B* on the lower feed-screw, which is marked with a check line, is set to indicate the amount of feed necessary. When the first die is finished and the machine is set so that remaining dies may be ground to correspond, the table is moved back for the removal of the finished die and the insertion of the second. The table is then returned to the grinding position and the die moved back and forth against the face of the grinding wheel by the hand lever *F*, while it is slowly fed forward by the wheel *A* until the check mark on sleeve *B* corresponds to a second mark on the stationary arm, with which it was previously set. When this point is reached, pins provided for the purpose form a positive stop for the feed. During this operation the swivel of the intermediate slide should be firmly clamped by handle *P*.

In addition to grinding the throat of the chaser, it is also essential that the cutting edges be touched up lightly from time to time in order to keep them clean and sharp. This is done by placing the die flat on table *K* (Fig. 2), bringing it into contact with the wheel by handwheel *J*, which controls

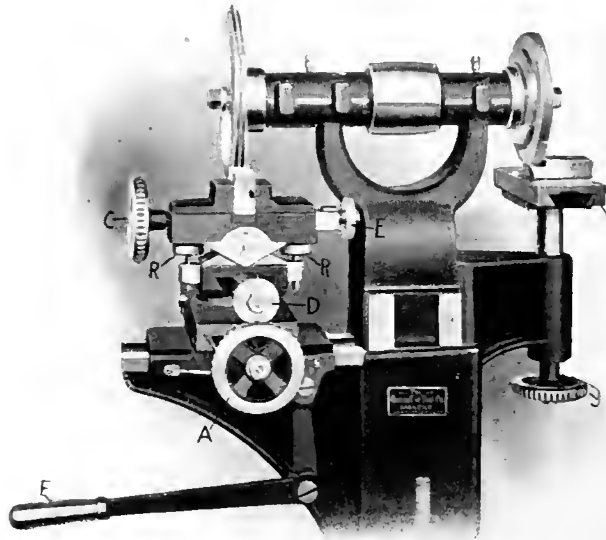

Fig. 2. Enlarged View of the Working Side of the Machine

the vertical adjustment, and moving the slide back and forth under the grinding wheel. When grinding either the face or throat of a die, all the dies of a set should, of course, be ground with the same adjustment.

In order to better illustrate the method of grinding a tap-formed die, we shall assume that a 1-inch chaser of this type is to be ground. The scale *O*, which is graduated in thirty-seconds of an inch, would first be set to the radius of the die, or to ½ inch, minus the single depth of the threads. The die is then placed in the vise against the stop and clamped. The jaws of the vise are next adjusted either to the right or left

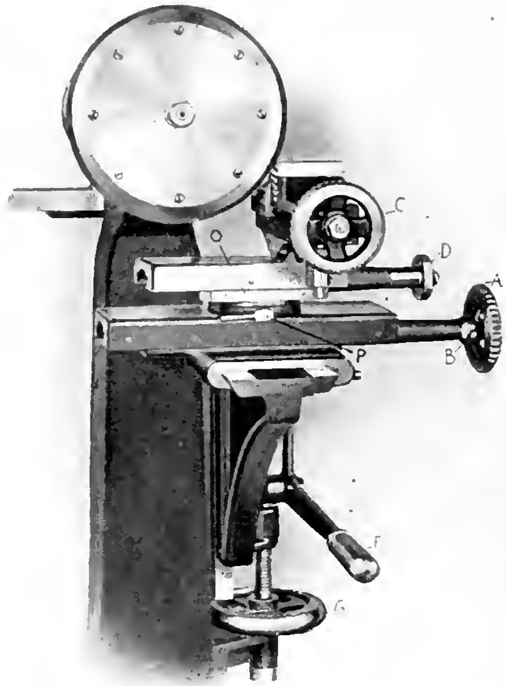

Fig. 3. End View showing Die in Position for Grinding Throat

of the center, depending on whether the thread is right- or left-hand, just enough to give the proper clearance. The swivel of the intermediate slide is then loosened and the work is oscillated about the grinding wheel, and fed in slowly by handwheel *A* until the stop is reached.

S. E. HORTON MACHINE CO.'S FACEPLATE JAWS

A new faceplate jaw has been brought out by the S. E. Horton Machine Co., Windsor Locks, Conn., that is quite different in its design from the type commonly used. This new jaw, instead of having the form of a rectangular block, is made with a broad base, which is ribbed to the body as shown in Fig. 1. This design results in a much better casting, as the metal is more uniformly distributed and, for a given weight, the support is much better, the width of the base being wider. On each side of the body, pockets are formed which serve an important purpose, in that they adapt these jaws to a wide range of work by making it possible to clamp them in positions where the ordinary jaw could not be held. As the base of the jaw is extended at each end, it may be clamped by the ends, as with the ordinary type, and the pockets provided also furnish means of clamping at the sides. Holes are drilled through the base and into the pockets on each side so that bolts can be employed when more convenient. These bolt holes also make a convenient place for dowel pins. The advantages that these various ways of clamping afford, will be apparent by referring to Figs. 2 and 3, which show the jaws mounted on a faceplate in different positions. Fig. 2 shows

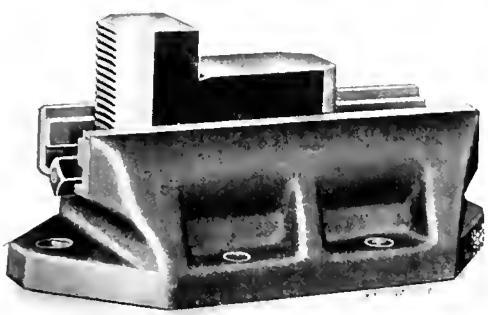

Fig. 1. Faceplate Jaw with Various Facilities for Clamping

them set in until their ends meet, in which position they may be used for holding comparatively small work. If the ordinary type of faceplate jaw were set in to the position shown in the illustration, obviously it would be impossible to clamp the inner ends as the bolt holes would be beyond the end of the T-slot in the faceplate. The pockets of this new design, however, make it easy to rigidly fasten the inner ends by simply using a strap and bolt between each pair, as the engraving indicates. These pockets also make it possible to set the jaws out to such a large radius that the outer ends overhang, as straps can then be employed, as illustrated in

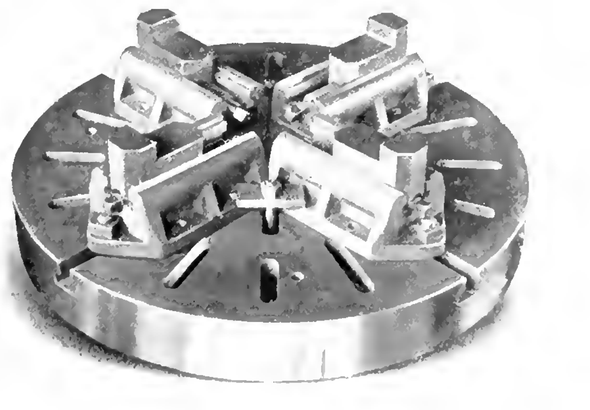

Fig. 2. Jaws Mounted on Faceplate in Position for Holding Small Work

Fig. 3, in place of the end bolt. It should be mentioned that the inner ends of the jaws are beveled to an angle of 45 degrees, so that they will fit together and support one another, when in the position shown in Fig. 2. The screws by which the sliding jaws are operated are of large diameter, and both the jaws and screws are of the same general proportions found in the heavy pattern independent chucks made by this company. The screws are provided with double thrust bearings, which reduce the wear and resulting end play to a minimum. These faceplate jaws are made either of gray iron or of true machinery steel castings, as desired. Any form of groove or rib, or double ribs, will be furnished so that the jaws will accurately fit the slots of the faceplate for which

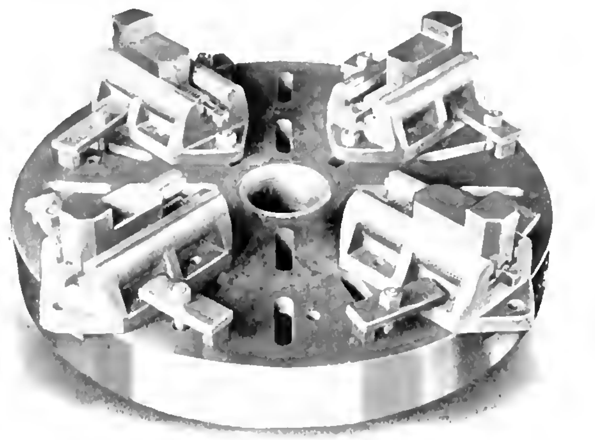

Fig. 3. Jaws set out so that Ends Overhang

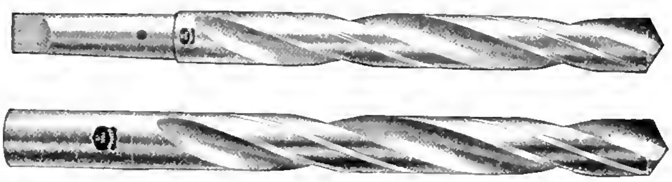
they are intended. The company is also prepared to furnish special jaws for holding odd-shaped pieces, if these are required.

STANDARD IMPROVED OIL TUBE DRILL

The Standard Tool Co., Cleveland, O., has placed on the market a new oil tube drill which differs from the drills of this type formerly manufactured by this company in having steel tubes for conveying lubricant to the drill point, instead of brass. The advent of drills made from high-speed steel, with their increased speed and heavy cuts in refractory metals, proved too severe for brass oil tubes, which were too readily cut and pulled out of place, for satisfactory results. The steel tubes show a marked improvement over those of brass, and after a thorough and exhaustive test under the most severe conditions, the oil tube drill equipped with steel tubes has proved thoroughly efficient and reliable. These steel tubes are



Standard Tool Co.'s Oil Tube Drill with Steel Tubes

fitted to connect with a hole bored through the shank of the drill. This hole in the shank, with which connection is made to the oil supply, as well as the tubes themselves, may be seen in the accompanying illustration. The oil is forced through the hole in the drill shank and flows through the steel tubes, thus giving a constant supply at the cutting edges which keeps them cool and forces out the chips. The use of this type of drill will be found exceptionally satisfactory where deep holes are to be bored in steel or wrought iron. They can also be used to advantage in screw machines or in any tool fitted with means for supplying the lubricant. If necessary, the hole in the shank can be threaded for pipe connection.

ROCHESTER HORIZONTAL BORING, DRILLING, TAPPING AND MILLING MACHINE

The horizontal boring, drilling, tapping and milling machine illustrated in Fig. 1 is the product of the Rochester Boring Machine Co., Rochester, N. Y. This machine is electrically driven and it is so arranged that it can be started, stopped or reversed independently of the motor, these movements being controlled through friction clutches operated by a lever conveniently located on the saddle. Either the spindle, column or the saddle can be traversed by hand or power and with a fast or slow motion, as desired. All the operating levers and handwheels are located on the saddle, thus making the control of the machine convenient to the operator. The spindle is so arranged that the full traverse can be obtained without resetting and it is journaled in long phosphor-bronze bearings

located at each end of the saddle, that are adjustable from the outside. All the driving and feed gears are either of nickel steel, cast steel or manganese bronze and the feeding and driving mechanism is enclosed in the saddle and thus fully protected.

The motor, which is of the constant speed type, is mounted on top of the column and drives through rawhide and steel gearing to a vertical splined shaft which transmits the power to the driving mechanism in the saddle. Secured to this vertical shaft are the two friction clutches by means of which the machine is started, stopped or reversed by a starting lever on the saddle. When these clutches, which are shown at *A* and *B* in Fig. 2, are in the neutral or central position, no power is transmitted and the driving mechanism of the saddle remains at rest. When clutch *B* is engaged, forward motion is imparted to the bar, while the engagement of clutch *A* operates in the reverse direction. Through the bevel gears with which these clutches are connected, driving power is transmitted from the vertical shaft to the speed change gears *C*. These change gears by means of a tumbler gear arrangement in combination with back-gearing, give ten speed changes for the spindle, ranging from 15 to 200 revolutions per minute in geometrical progression. The intermediate shaft carrying the clutches for driving the back-gearing, has on it a pinion that meshes with and drives the large gear *A*, Fig. 3, through which the spindle is rotated by means of two splines which engage with it. The sleeve *B*, on which this gear is mounted, has a bearing in the saddle, and as clearance is provided between the bar and the sleeve, any vibration from the gears is not transmitted to the spindle.

The Feeding Mechanism

The arrangement of the feeding mechanism is also shown in Fig. 3. The sleeve *B* has teeth cut in one end which mesh with three pinions *D*, driving a planetary gear *E*. This planetary gear, in turn, by means of pinions *N*, transmits the movement to the rotary nut *L*, which engages directly with the spiral cut in the spindle. This nut has a heavy flange which rotates between large ball thrust bearings, as shown, in order to take the end-thrust from the bar in either direction. When the feed is disengaged, this nut rotates at the same speed as the spindle, with the result that the latter remains in a fixed position. By an ingenious arrangement of the planetary gear system, whereby connection is made with the feed gearing *G*, a differential rotation can be given to the nut *L*, causing it to be either advanced or retarded. Either advancing or retarding it effects the traverse of the spindle, which is thus caused to move in the direction desired. These feed change gears are driven from the intermediate shaft which drives the gear *A* for the spindle. When the feeds are disengaged, gear *F* in which the planetary pinions *D* are mounted, does not rotate, and the nut *L* rotates with the spindle which therefore remains in the same longitudinal position. When, however, the gear *F* which is connected directly with feed change gears *G* is driven by these gears, a forward or reverse rotation, as desired, is given to nut *L* (independent of the drive), and consequently a feeding movement to the spindle. The feed change gears are arranged with back-gears, and eight different feeds for the spindle are available, ranging in geometrical progression from 0.01 to 0.25 inch per revolution of the spindle. This power feed is controlled by a friction clutch which is engaged or disengaged by the clamping nut *I*. The feed can be reversed when desired, and all the feed operating levers are mounted on the saddle, a detail of which is shown in Fig. 4. The eight feed changes are obtained by means of the levers *A* and *E*, while the feed is reversed by a lever *C* located back of the handwheel used for feeding the spindle by hand.

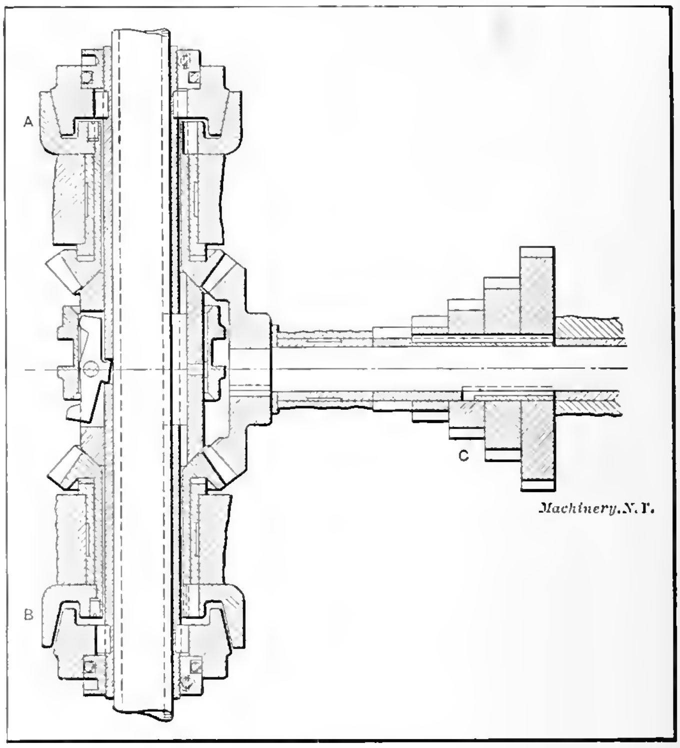


Fig. 2. Friction Clutches by means of which Machine is started, stopped and reversed

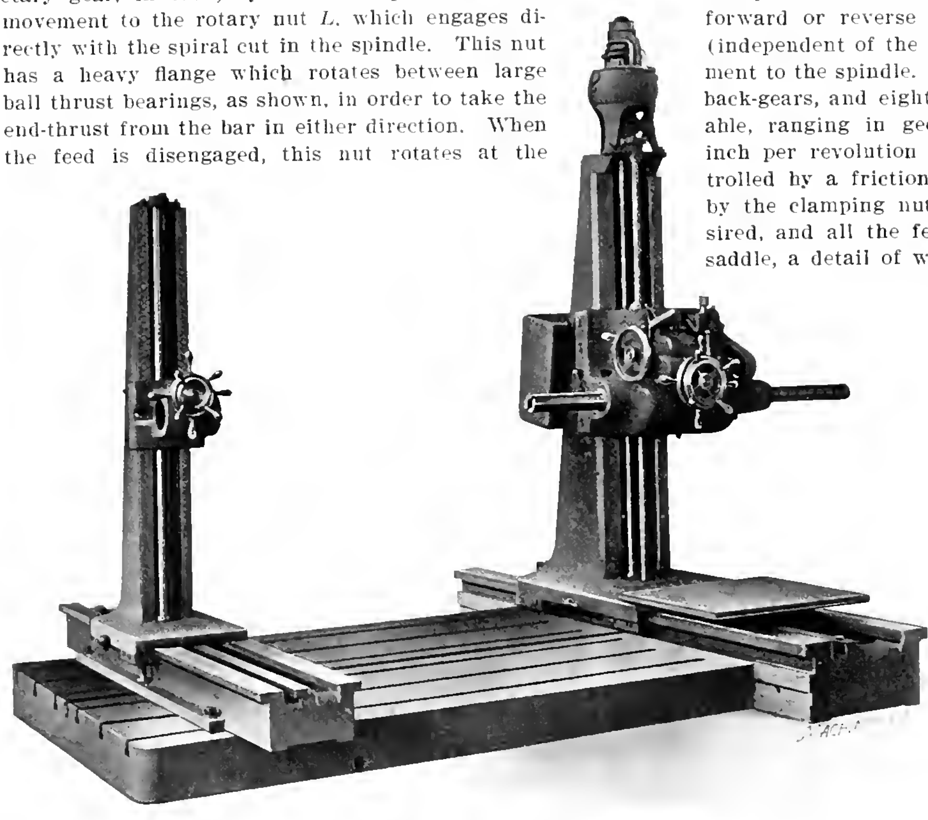

Fig. 1. Rochester Horizontal Boring, Drilling, Tapping and Milling Machine

Milling Feeds for Column and Saddle and Rapid Traverse

On the saddle two concentric pilot wheels *F* and *G* are mounted. The inner wheel *F* is mounted on a hollow shaft, which, through gearing, operates the traverse of the column, and the outer wheel *G* controls the motion of the saddle on the column. The inner wheel, which is free to slide on the hollow shaft, is provided with a double-end clutch so that pulling it outward engages a clutch on the outer handwheel through which power drive is transmitted to a rotating nut on the elevating screw which elevates the saddle. By pushing the wheel *F*, to its inner position, a clutch fixed on the hollow shaft is engaged and the vertical shaft for traversing the column is driven. As these gears connect with the feed change gears (without the back-gears) four feed changes are available in either direction for traversing the saddle or column when milling. Means are also provided for obtaining a positively-driven rapid traverse of 6½ feet per minute for the saddle, column and spindle. Whether the milling feed or the rapid traverse is engaged, depends on the position

of lever *H*. When this lever is moved over to the left, the feed gears are engaged; when it is in the middle or neutral position, as illustrated, the drive is inoperative, and when it is moved to the right, either the column or saddle may be rapidly traversed. The vertical shaft for traversing the column along its bed, transmits the motion by a pinion meshing into a rack in the base slide. This convenient arrangement for traversing the spindle, saddle, and column in any direction, in conjunction with the convenient means for starting, stopping or reversing by the manipulation of lever *J*, greatly facilitates the operation of the machine and effects a great saving in time and labor.

Miscellaneous Features

The saddle is counterbalanced by a weight sliding on the back of the column, and it is guided by large flat bearing surfaces carefully scraped to perfect contact. The bearing on the outboard column for supporting the boring-bar is also traversed by concentrically-arranged handwheels similar to those on the saddle, which are operated by hand only. The saddle column, as well as the outboard support column, has solid wedge gibs and clamping devices for locking them to the bed in any position. The slide base for the main column is provided with a groove on the side for accurately locating the floorplate, and both bases are strongly reinforced by internal ribs. The baseplate of a standard machine of the size illustrated is 6 by 9 feet, but this dimension can be varied to suit individual requirements. This floorplate is of heavy box type construction and it is rigidly attached to the slide base by means of heavy bolts.

The rated horizontal traverse of the column for this size machine is 6 feet, but it can be safely operated laterally over a distance of 7½ feet. One of the noteworthy features of this machine is that the whole length of the spindle can be used for the feed without resetting, thus giving any required range of continuous feed by using the proper length of bar. If desired, two or more bars can be furnished and also special bars in various lengths. The spindle of the machine is bored to receive a No. 5 Morse taper, but different tapers can be provided in the two ends of the bar if desired, and the latter can be readily reversed if necessary. One end of the bar can be threaded for holding milling cutters when this is required. The makers claim that owing to the absence of friction, the feed is so sensitive that small drills can safely be used even on the largest machines. Graduated scales with vernier attachments are provided for the column and base slide, as well as for the outboard support and slide. These scales are, of course, a great convenience for quickly adjusting the machine and for spacing known distances on the work. The spindle feed handwheel is also equipped with a micrometer, by the aid of which adjustments can be made to within 0.001 of an inch. This micrometer reading is very useful in gaging depths in boring, drilling and milling.

The shafts of this machine are all journaled in phosphor-bronze and the sleeves are provided with felt oil pads. A high grade of steel is used for all shafts, and cap-screws, set-screws, nuts, operating levers, etc., are casehardened. The equipment furnished with the machine includes, in addition to the machine itself complete with motor, a floorplate, outboard support, graduated scales and the necessary wrenches, spanners, etc. Special tables, boring-bars, parallels, cutters, etc., will be furnished extra if desired. The company is also prepared to build, in addition to the standard type illustrated herewith, special designs arranged to meet any feasible condition.

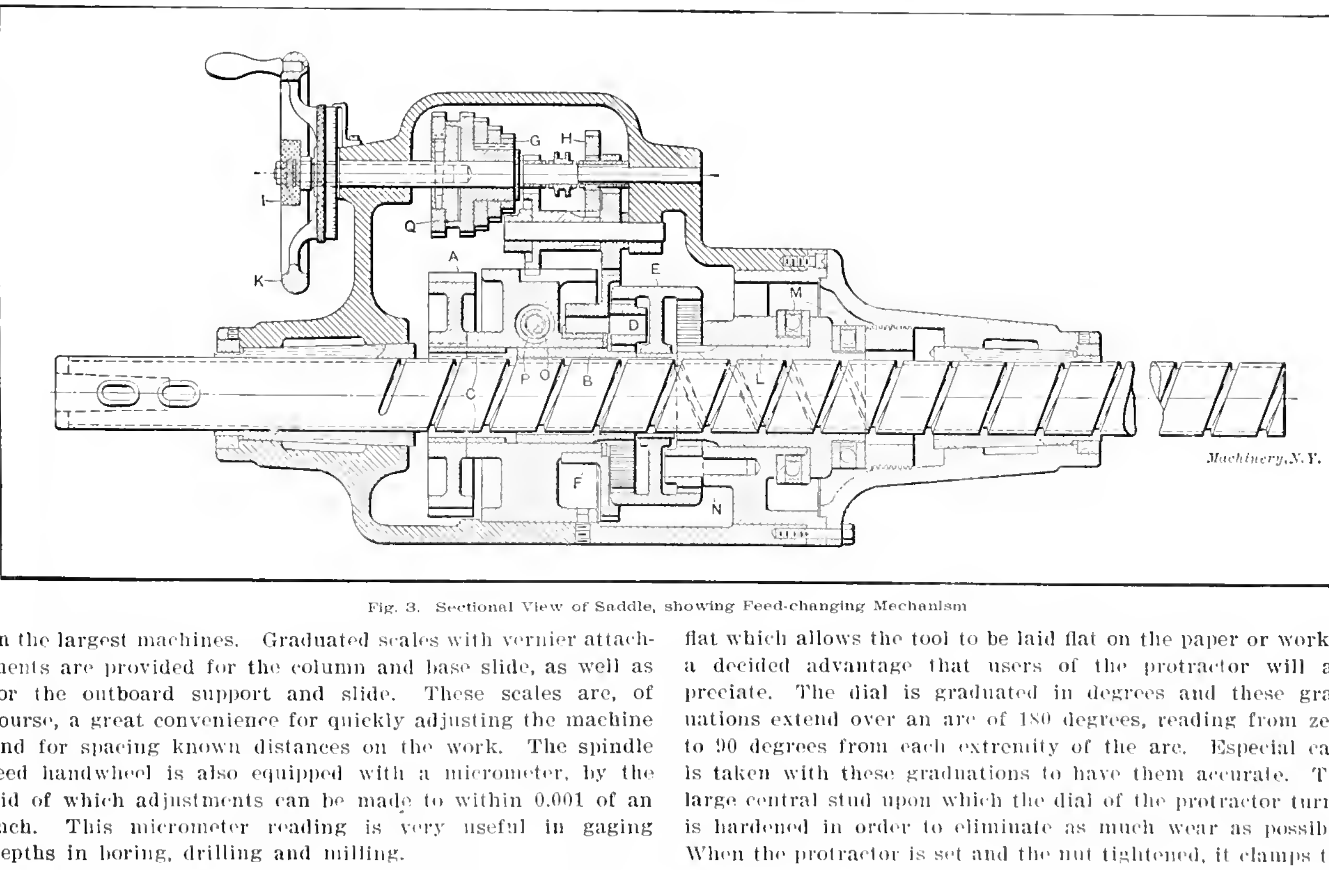

Fig. 3. Sectional View of Saddle, showing Feed-changing Mechanism

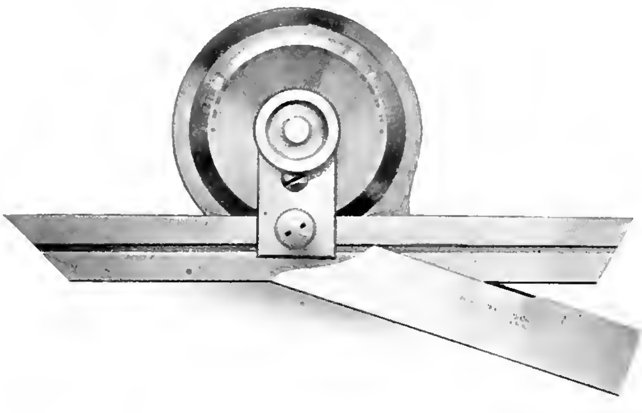
BROWN & SHARPE BEVEL PROTRACTOR

An improved bevel protractor has recently been placed on the market by the Brown & Sharpe Mfg. Co., of Providence, R. I. This protractor, which we illustrate herewith, is an accurate and inexpensive tool that is not only useful to mechanics, but is also of great service to draftsmen.

The design of this tool is simple, and it is similar to the improved universal bevel protractor made by the same company. The principal difference between the two tools is that there is no vernier on the new protractor, so that measurements cannot be made to such a degree of fineness as with the universal protractor; it is intended, however, for work not requiring great precision.

To facilitate the use of the tool, one side of the protractor is flat which allows the tool to be laid flat on the paper or work—a decided advantage that users of the protractor will appreciate. The dial is graduated in degrees and these graduations extend over an arc of 180 degrees, reading from zero to 90 degrees from each extremity of the arc. Especial care is taken with these graduations to have them accurate. The large central stud upon which the dial of the protractor turns, is hardened in order to eliminate as much wear as possible. When the protractor is set and the nut tightened, it clamps the dial rigidly in position so that there is no danger of slipping.

The blade of the protractor is free to move backward and forward for its entire length, independently of the dial, which feature adapts it to a wide range of work. This blade is



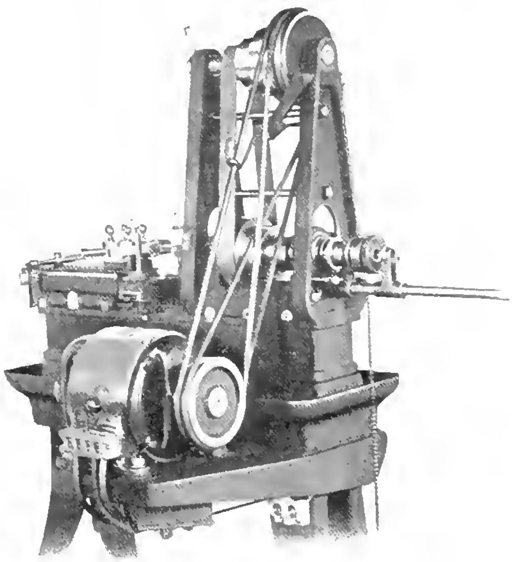
Brown & Sharpe Bevel Protractor for Mechanics and Draftsmen

clamped independently of the dial and is rigidly held in place. Great care has been taken in cuttiug the grooves, etc., so that there is very little chance for dust to accumulate and cause inaccuracies in the measurements.

GARVIN MOTOR-DRIVEN SCREW MACHINE

The standard No. 1 screw machine, which the accompanying engraving illustrates, is the type regularly built by the Garvin Machine Co., Spring and Varick Sts., New York City. This particular view shows the machine equipped with a motor drive, the motor being mounted on a bracket at the rear so as to form an integral part of the machine. The manufacturer's idea in using the regular stock machine for attaching the motor drive is of twofold benefit. In the first place, orders can be executed more promptly, and, in the second, a motor-driven portable machiue, that can be set anywhere in the factory to suit conditions, can be obtained at moderate cost.

The main belt connecting the upper and lower cone pulleys can be made endless, as the eccentric adjustment provided for the upper cone, which runs loose on a shaft, makes it possible to obtain sufficient tension to transmit the required power for operating the machine. As this adjustment is quickly

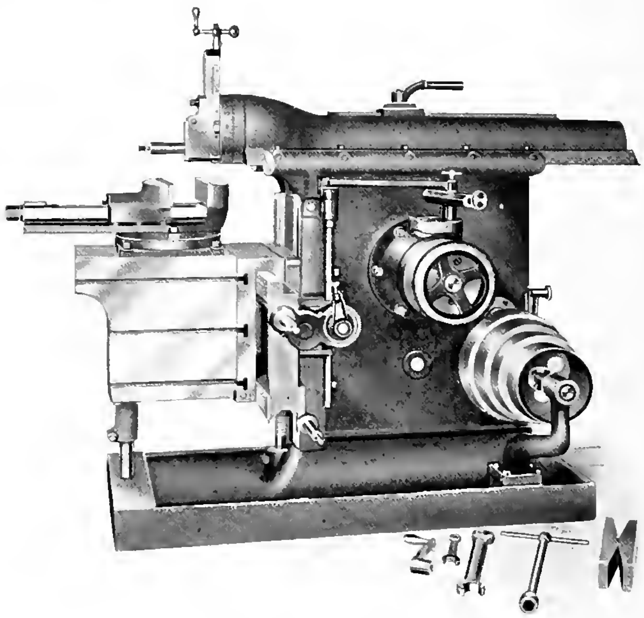


Garvin Screw Machine equipped with Motor Drive

operated, it may be used for slacking the belt prior to shifting it for obtaining speed changes. The straight and crossed belts that are used to connect the motor with the upper cone pulley, are under the control of the shipper handle shown projecting in front of the machine. These belts, which are ½ inch in diameter, run on a system of three grooved pulleys overhead, those on the outside being loose pulleys and the oue in the center, tight. The machine is started aud stopped from the front side, thus making the control convenient to the operator. A half-horsepower motor is used to drive the machine, the motor running at 1600 revolutions per minute. This machine has a capacity for stock up to 5/8 inch in diameter through the spindle, which is equipped with automatic wire feed. The weight complete, when skidded for shipment, is 600 pounds.

IMPROVED MILWAUKEE SHAPER

The shaper illustrated herewith, which is known as the "Milwaukee" shaper, is built by the Lutter & Gies Co., Milwaukee, Wis. It has been the aim of the builders of this machine to secure, both as to general design and workmanship, strength aud simplicity in all the working parts. The base is of the pan design and it is strongly ribbed inside to insure stiffness. It also projects well out from the column and affords a rigid foundation. The column is also of liberal dimensions and rigidly braced. As the engraving shows, the slides overhang at both ends, giving long bearing surfaces to the ram. The ram has a quick return and it is strongly constructed. It is provided with eight speeds, four being obtained by a four-step cone pulley, which number is doubled by the back-gears that are engaged by means of a lever at the back of the machine. The table is slotted on both the top and



Twenty-four inch Shaper built by Lutter & Gies Co.

the sides, and it has a working surface of 18½ by 15 inches on top, and 16½ by 14 inches on the side. By loosening the bolts which fasten the table to the apron, it may be revolved to any position that may be required. This is a valuable feature which adapts the tool particularly for toolmaking and die work. When the table is removed, either the vise or the work itself can be clamped directly to the front of the apron, T-slots being provided in this surface. The vise has a graduated swivel base, and it can be clamped at the side of the table as well as on the top. The tool head is also graduated and it swivels to any angle. The vertical feed is provided with micrometer adjustments. The length of stroke can be changed instantly from the working side of the machine by simply manipulating the large handwheel shown. Just what the stroke is at all times is indicated by a pointer located near the handwheel. The feeding mechanism is simple in construction, the movement being transmitted from a slotted crank to a vertical splined shaft, which is connected through bevel gears to the ratchet shaft. An adjustable table support is provided for eliminating all spring from the table when doing heavy work. All bearings such as those of the ram, apron, and slides are provided with taper gibs to permit the maintenance of the accurate fit originally given to these parts. The cross-rail screw has ball thrust bearings and a micrometer collar reading to thousandths of an inch. The elevating-screw nut for the saddle, is provided with ball bearings to eliminate friction as far as possible. The machine can be conveniently used for keyseating, as there is an opening

under the ram large enough to allow the passage of a shaft 3 inches in diameter. The stroke of this shaper is 24½ inches. The automatic cross traverse is 29½ inches and the downward feed in the tool head, 11 inches. The table has a vertical adjustment of 11¾ inches, and the vise has a maximum opening of 15⅜ inches. The net weight of the machine is about 4000 pounds.

COLBURN 24-INCH HEAVY-DUTY DRILL PRESS

A heavy-duty drill press that is of unusual interest, not only because of its constructional features, but also by reason of the results in the way of rapid drilling which it makes possible, was exhibited at the recent convention of the American Railway Master Mechanics' and Master Car Builders' Associations at Atlantic City. This tool, which is the latest product of the Colburn Machine Tool Co., Franklin, Pa., can be arranged for either belt or electric drive. Fig. 1 illustrates the electrically-driven machine that was used by the Celfor Tool Co., at the convention referred to, for demonstrating its high-speed twist drills, and which will be installed in its plant at Buchanan, Mich., for drill testing.

These machines are built on the unit system, that is the speed changing mechanism is in one separate box, the feed change gears are enclosed in another separate case, and the head is another unit, entirely independent of the other parts. The advantages of this method of construction, not only in the manufacture, but also in connection with repair work, or in the location of any defects that may develop, are well-known.

All gears used on this machine either run in a bath of oil or are made of steel and hardened. This includes the main

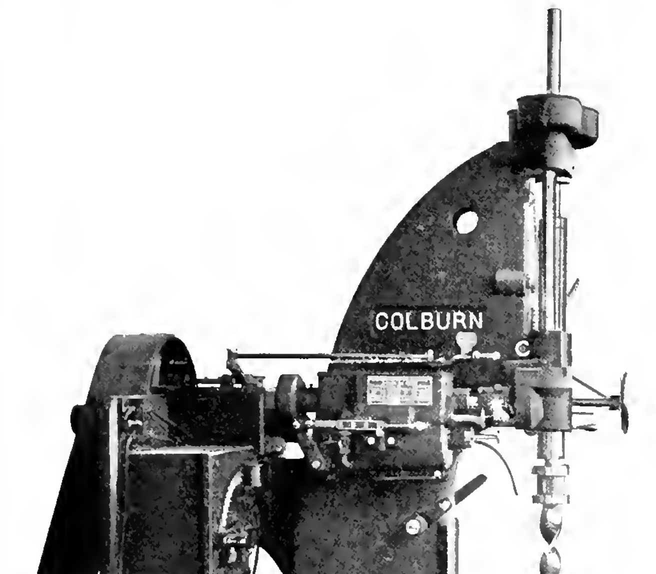


Fig. 1. Colburn 24-inch Heavy-duty Electrically-driven Drill Press

driving gears for the spindle, the bevel gears connecting the vertical intermediate shaft with the horizontal shaft at the side of the column, and the two gears connecting this latter shaft with the speed box. The main driving gears through which power is transmitted to the spindle, are helical gears which are comparatively noiseless in operation. These gears are made of steel and the teeth are ground in to insure smooth running. The gears connecting the speed box with the shaft passing through the feed box at the left side of the column, are also of the helical type and hardened.

The Driving Mechanism

The drive is through a single constant speed pulley, which is equipped with a friction clutch, by means of which the machine is started and stopped. The speed change mechanism is encased in an oil-tight box, which is filled with oil so that all the gears and bearings inside it are perfectly lubricated. All the speed changes, of which there are eight, ranging from

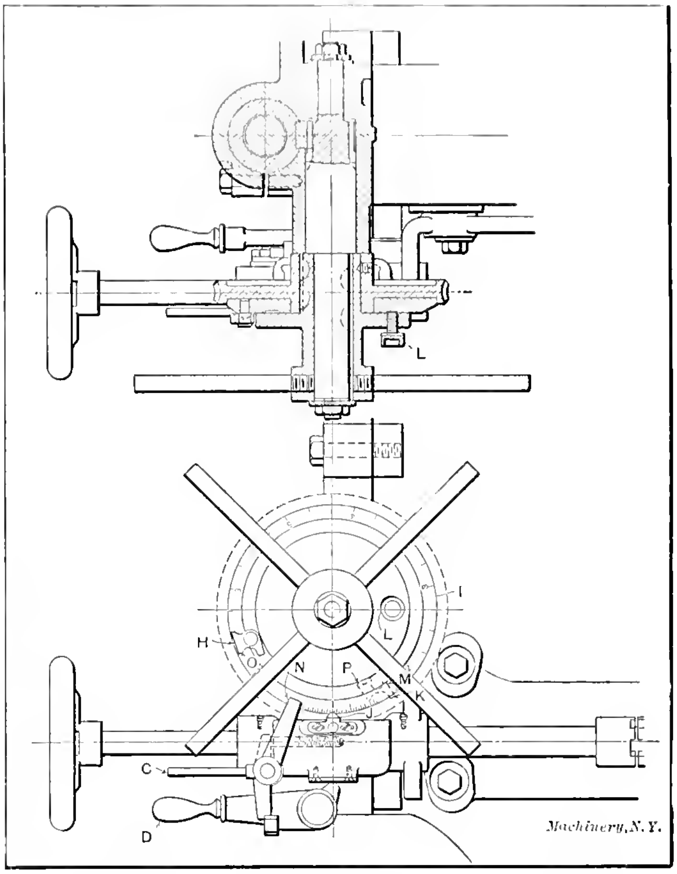

Fig. 2. Section and Elevation showing the Automatic Feed-tripping Mechanism

40 to 440 revolutions per minute, are made by two levers, conveniently located at the front of the machine. Four of these changes are effected by the engagement of a hardened dive-key with different gear combinations, while the remaining four are obtained through back-gears. The gears for the speed changes and also those in the feed box are lined with hardened steel bushings. The drive to the spindle is simple, power being transmitted through short shafts, the bearings of which are close together. The arrangement of the drive is similar to that used in recent vertical milling machine construction.

The Feeding Mechanism

All the feed changes are obtained through positive gears that are also encased and run in a bath of oil. A range of six feeds is available, which vary in geometrical progression from 0.006 to 0.040 inch per revolution of the spindle. These changes are made by means of a dive-key and back-gears. The feeding movement is transmitted to the spindle through a worm-gear of large diameter. This gear has mounted on it a dial graduated in thirty-seconds of an inch, that enables the operator to accurately measure the depth drilled. As these graduations are about ⅛ inch apart, obviously, finer measurements than 1/32 inch may be made by reading between the graduations. This dial, which is adjustable, is provided with a pawl that can be set to trip the feed at any point in 14 inches of the spindle travel, or if desired, the feed may be tripped by hand from the operator's position. A safety shear pin that is placed on the worm shaft protects the feeding mechanism from injury.

The Automatic Trip Mechanism

A detail view of the automatic trip mechanism is shown in section and elevation in Fig. 2, and the method of its operation

is as follows: If the feed is to be tripped automatically in 7 inches or less, pawl *H* is set as indicated by the dotted lines at *K*; if it is desired to trip the feed at a distance greater than 7 inches, pawl *H* is turned to the position shown by the full lines. For example, if it should be required to automatically trip the feed at a depth of 3 inches, the knurled nut *L* would first be loosened and the graduated dial *I* turned until the figure 3 on it was opposite the mark on pointer *J*, after which nut *L* would be tightened. The pawl *H* would then be set in the position shown by the dotted lines, with the result that when the drill had traveled 3 inches, the surface *M* would come in contact with the side *N* of the trip arm and disengage the feed. If, on the other hand, it were required to drill to a depth of 9 inches before the feed was automatically tripped, the dial *I* would be set with figure 2 opposite the mark on pointer *J*, and pawl *H* would be turned to the position shown by the full lines. With the pawl in this position, the contact of surface *O* with lever *N* would not throw out the feed, as the pawl, being loose on its stud, would simply turn and pass the tripping arm without moving it. After the pawl had passed the arm, it would then be in the position shown by the dotted lines, that is with the end *P* in contact with a projecting sleeve, thus preventing further rotary movement, so that when it again came around to the tripping lever, the feed would be disengaged. As one revolution of the dial is equivalent to a depth of 7 inches, it will be seen that by this simple arrangement, the feed is automatically controlled throughout a range of 14 inches. If the knurled nut *L* is loose, the feed cannot be automatically tripped at any point.

Operation of the Machine

The function of the various operating levers will be explained in connection with the elevation shown in Fig. 3. The levers *A* and *B* at each side of the column serve to start and stop the machine through the friction clutch pulley *L*. The lever *Z* mounted just above the feed box, operates the back-gears of the speed change mechanism, while handle *Y* controls the position of the dive-key in the speed box and gives four changes of speed which are indicated by raised letters, A, B, C, and D, which correspond with similar letters on an indicating plate that may be seen in Fig. 1. As before stated, these four speeds are doubled by means of the back-gears. The pull-rod *W* operates the dive-key for the feed changes, and its position is also determined by letters which correspond with those on the indicating plate. The six feeds are obtained by operating this rod in conjunction with pull-rod *X*, which is connected with the back-gears in the feed box. The lever *C* to the right of the machine, may be used to trip the feed by hand, while lever *D* throws the feed in after it has been tripped. The handwheel *E* operates the hand feed, the power feed being disengaged by pulling out this wheel and its shaft which disengages clutch *F*. The capstan handle *G* is for the rapid traverse of the spindle, the worm and gear being first disengaged by means of lever *C*. It will be seen that all the operating levers are conveniently placed; in fact, they are all within a space of 1 foot in height by 2 feet in width.

Miscellaneous Constructional Features

This machine is equipped with a lubricating system, the lubricant being taken from a tank which is located at the side of the machine. The pump is attached directly to the machine frame, and it is driven by a small round belt from the pulley hub. The lubricant, after being forced through the flexible nozzle onto the work, drains back through a strainer into the tank.

The table is of the bracket type and it is provided with extra large bearings on the column. It has a vertical adjustment of 15 inches by means of a large telescope screw that is operated by a crank at the front. This screw has been set off center to permit a boring-bar to pass through the table. The working surface of the table, which is 18 by 24 inches, contains two T-slots, and a large oil pan is provided on both sides and in the front.

The spindle of the machine is of forged high-carbon steel, and the thrust is taken on Hess-Bright ball thrust bearings. The spindle has a travel of 16 inches, and the end is bored to receive a No. 5 Morse taper. The maximum distance from the nose of the spindle to the table is 34 inches, and the distance from the center of the spindle to the face of the column is 12½ inches.

Tests

Tests made with the motor-driven machine illustrated in Fig. 1 which is equipped with a 25-horsepower constant speed, Westinghouse motor that is connected to the clutch pulley of the drill press by an 8-inch belt, showed a capacity for rapid drilling that exceeded the expectations of the designers. For example, in a test conducted by the Colburn Machine Tool Co., a 1½-inch drill was driven at the rate of 31.2 inches per

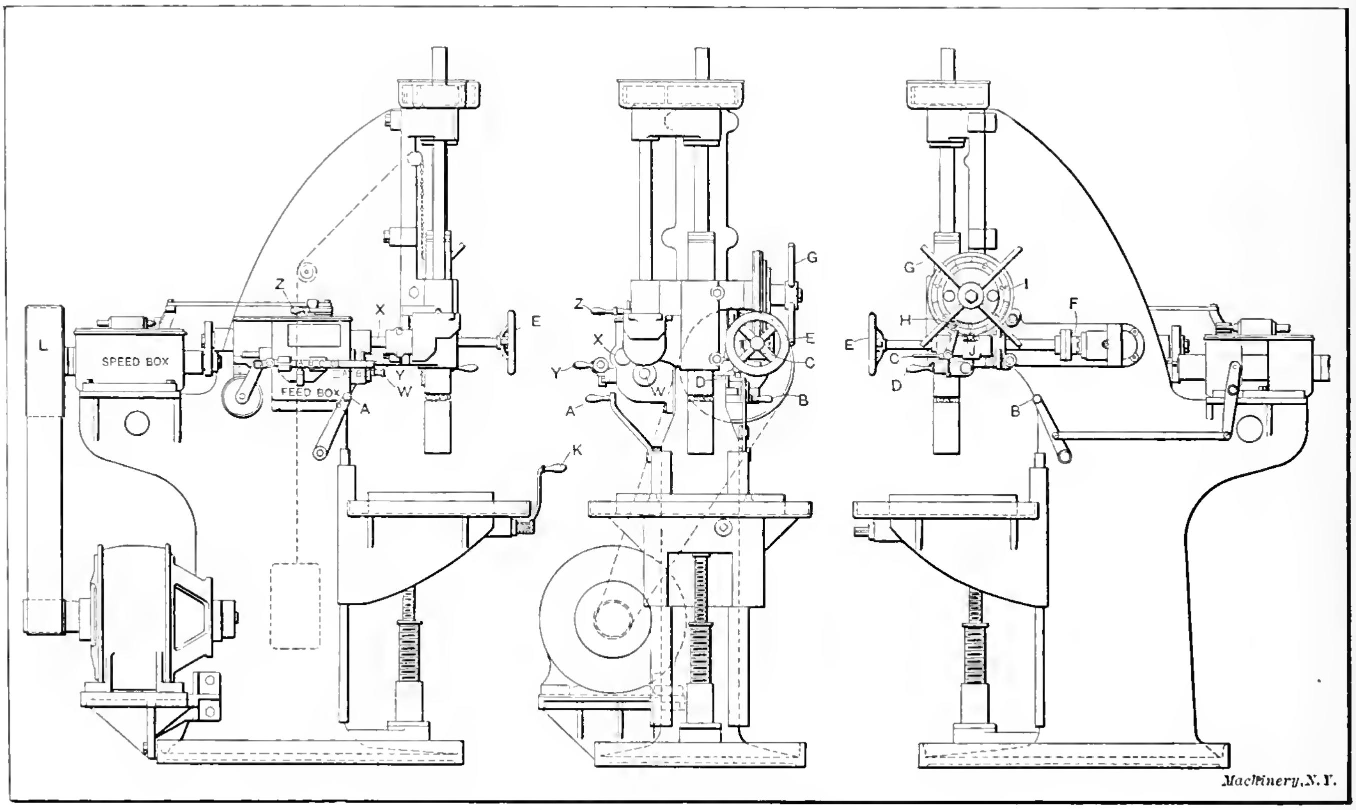

Fig. 3. Elevations of a Motor-driven Machine

minute, without injury to either the machine or drill, which illustrates in a striking way the power and strength of the machine. When, however, an attempt was made to use a little larger drill than this, the drill was burned. The makers believe, though, that it would be practical, when using a 1-inch drill, to drill holes in ordinary cast iron at a feed rate of 31.2 inches per minute. Another interesting experiment was made with a 3-inch drill, which was driven through cast iron at 11.25 inches per minute. The cutting speed was then increased from 147 feet to 262 feet per minute, without changing the feed, which gave a feed rate of 15.7 inches per minute. After the drill had penetrated to a depth of 3 inches, the fuse blew out, at which time the power consumption was 53 horsepower. Of course, this kind of drilling is not advocated, but was simply done to demonstrate the capacity of both machine and drill.

When the machines are electrically driven, the constant speed type of motor is employed. This motor is mounted on an extension of the base at the rear of the machine where it is out of the way. As the motor is located beneath the feed change box, there is practically no increase in floor space required when the motor drive is employed, as is plainly shown by the front elevation, Fig. 3. The manufacturers recommend a belt drive direct from the motor to the driving clutch pulley; this allows the machine to be started and stopped by means of the clutch without stopping the motor. Any make of constant speed motor can be used and the size should range from 5- to 20-horsepower, depending on the work to be performed.

FLICKINGER COMBINATION GAS ENGINE AND AIR COMPRESSOR

A combination gas engine and air compressor for supplying, simultaneously, power and compressed air, is now being manufactured by the Flickinger Iron Works, Bradford, Pa. Both the engine and compressor operate as a combined unit, one end of a single cylinder being used as an explosion chamber for developing the required power, while the other acts as a compressor. The arrangement is such that the machine can be instantly converted into a simple gas engine while running, and the compressor can also be thrown into commission at any time. This feature would be especially applicable to shops requiring power continuously and compressed air intermittently.

Exterior and sectional views of this gas-driven compressor are shown in Figs. 1 and 2, respectively. The gas engine or

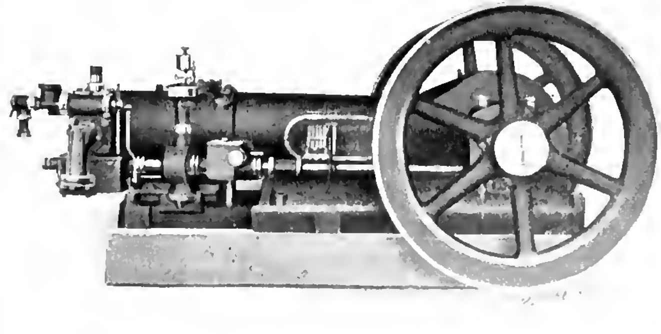

Fig. 1 Gas-driven Compressor which may be used as a Motor and Compressor, simultaneously

power end of the machine works on the four-cycle principle and it is identical in construction with the gas engine manufactured by this company. The special feature of this engine is the valve mechanism which consists of an automatic cut-off valve, controlled by a governor. This governor is of the centrifugal ball type, and the arrangement is such that the charge is throttled in proportion to the load. The ignition system used depends on the requirements, either a Bosch magneto, jump spark, or make-and-break system being employed. When the magneto is installed, it is mounted on the engine frame and driven by a transmission chain, connecting with the secondary shaft so as to make only one revolution for each spark. This spark can be advanced or retarded while the engine is running, and the same intensity of spark is produced when starting as when running at full speed.

The air compressor end of the cylinder is equipped with a mechanically-operated intake valve, which is similar to the Corliss engine valve. This valve, which is plainly shown in the sectional view, is at rest during the entire compression

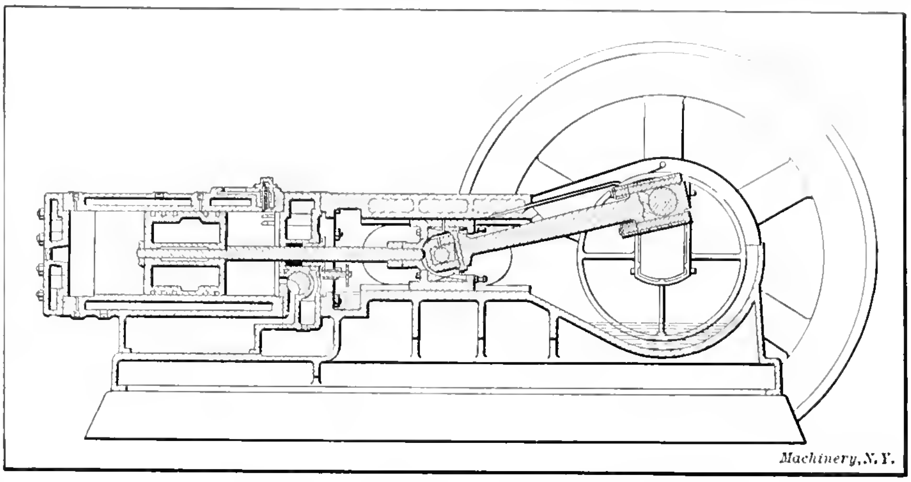

Fig. 2. Sectional View of the Combination Gas Engine and Compressor

stroke, which minimizes the wear. The discharge valves are of the standard poppet type, and have removable guides which can be taken out without breaking any pipe connections. The valves on the motor end of the cylinder are of the mushroom type. The exhaust valve is operated by a cam on the lay-shaft, while the inlet valves are opened by the vacuum created during the suction stroke. These valves, which are provided with dash pots to insure smooth working and easy seating, are so arranged that the incoming charge strikes against and cools the exhaust valves. The cylinder is furnished with a water-jacket throughout its entire length, and the front and back heads are also water-jacketed. The bed is of the bored-guide type and the main bearings are provided with interchangeable bronze liners which can be renewed at any time. The crankshafts are of the center-crank type and the journals are ground true on a special machine. The connecting-rods are forged from solid steel billets and are provided with a screw and wedge take-up on the crosshead end, and solid bronze boxes. The crank end is of the marine type and has steel boxes lined with genuine babbitt metal. All parts are made of high-grade material and the engine is rigidly constructed throughout.

These machines are built with single cylinders in sizes up to 50-horsepower. They are also made in the duplex and tandem types up to 100-horsepower and with the duplex tandem arrangement in larger units. The duplex engine can be furnished with only one side fitted with a compressing cylinder, if the power requirements are greater than those of the air.

ELMORE SENSITIVE DRILL PRESS

A very compact and conveniently-operated sensitive drill has been brought out by the Dwight Slate Machine Co., Hartford, Conn. This machine, while in the "sensitive" class, has been rigidly and substantially constructed to enable it to meet the demand for the higher speeds which the new alloy steel drills now employed have made possible and desirable.

Perhaps the most striking feature of this new design is the form of belt drive employed. This drive is so arranged that several changes of speeds may be quickly obtained while the machine is in motion, without leaving the operating position, or shifting the belt either on cones or in tension. By referring to Figs. 1 and 2, which show, respectively, single and multi-spindle machines, it will be seen that connection from the pulleys on the drive shaft to the pulleys on the spindle, is made by an endless belt. This belt, which is $1\frac{1}{4}$ inch wide and

17 feet long, passes around two driving pulleys of different diameters at the rear, and over suitably arranged idlers to two driven pulleys on the spindle. Between each of these sets of pulleys, friction clutches have been interposed, the clutch for the spindle being operated by the small crank seen near the top of the column, and the clutch for the driving pulleys by a similar crank located on the column just opposite the driving shaft. It is by means of these levers, which are self-locking in all positions, that the speed changes, of which there are four ranging from 500 to 2050 revolutions per minute, are obtained. The lower lever, which operates the clutch between the driving pulleys, also controls the starting and stopping of the machine. This construction, therefore, makes it possible to start and stop any spindle of a multi-spindle machine, independently of the others. This independent feature makes it unnecessary to employ tight and loose pulleys, the machine being equipped with constant speed drive on a single pulley.

An indicating plate, which is attached to the column, shows graphically the relative positions of the upper and lower clutch handles for obtaining the various speeds. For example, when both handles occupy a vertical position both clutches are disengaged; by moving the lower one to the left and the upper one to the right, a speed of 500 revolutions per minute is obtained; by shifting the lower one also to the right, this speed is increased to 800 revolutions per minute, etc.

The pulleys on both the driving shaft and spindle are mounted on stationary hollow quills, which arrangement relieves both the spindle and driving shaft from all belt stress. The proper tension of the belt is obtained simply by turning a knurled nut through which the screw of the idler yoke at the rear passes.

The spindles of these machines are bored with a No. 2 Morse taper hole and each spindle is counterbalanced by a flat coiled spring located in the sliding head. These springs can be adjusted to exactly counterbalance the spindle, or so as to automatically return it to its upper position. The feeding lever may be easily moved in or out for obtaining varying degrees of leverage, and it is automatically retained in any position desired by the same spring which counterbalances the spindle. Positive depth stops are mounted on each spindle quill within easy reach of the operator.

In order to make frequent oiling unnecessary and to eliminate friction as far as possible, ball bearings are used throughout. All cones and raceways are carefully hardened and ground. The clutches employed are of the simple cone type and are of large proportions, considering the duty imposed on them.

As each unit of a multi-spindle machine may be operated independently of the others, a continuous drive shaft connecting all the spindles may be used, in which case they would have the same ratio of speed changes. If it is desirable, however, an independent drive can be provided for each spindle by using varying sizes of pulleys on the lineshaft, so that the spindles can have a different speed ratio. For example, with a three-spindle machine, the speed of two of the spindles could be controlled by one drive shaft, thus providing a suitable ratio of speeds for the drilling operations, while the third spindle could be driven independently and at the proper speed for tapping, counterboring, facing and similar operations. This feature adapts the machine particularly to varied classes of work.

Another good point in the construction of this tool lies in its compactness, a comparatively small amount of floor space being required. The projected floor space for a single-spindle machine is only 20 by 33 inches, while that of one with 6 spindles is 34 by 63½ inches. As it is unnecessary for the operator to make adjustments at the rear, rows of these drills may be set back to back, thus effecting a considerable economy in the matter of floor space.

These tools are built with any number of spindles up to and including six. The distance from the center line of the spindle to the face of the column is 8 inches. The total traverse of the spindle is 13 inches, and the maximum distance from the table to the spindle is 32 inches on the single-spindle type, and 26 inches on the multi-spindle machines, which, as Fig. 2 shows, are equipped with a table-raising device. The approximate net weights of the single- and six-spindle types are 500 and 2150 pounds, respectively. The company is prepared to equip this tool with an electric drive if desired. When this form of drive is employed, the motor is mounted on a separate bracket which is attached to the rear of the column.

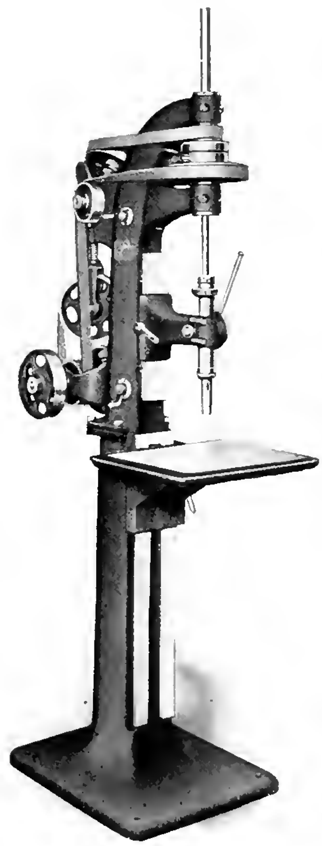

Fig. 1. Single-spindle Sensitive Drill Press, built by Dwight Slate Machine Co.

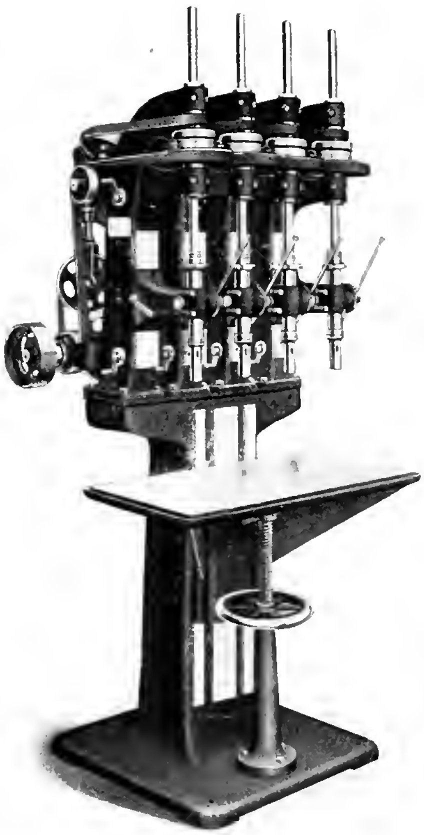

Fig. 2. A Dwight Slate Machine of the Multi-spindle Type

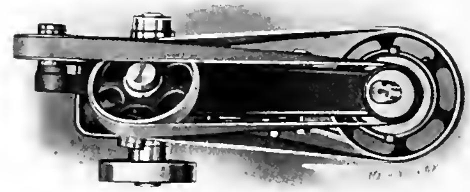

Fig 3. Plan View of the Belt Drive

BAIRD TOOL AND DIE GRINDER

The Baird Machine Co., of Oakville, Conn., is now manufacturing the tool and die grinder illustrated in Fig. 1. This machine is intended as an all-around grinder for the tool-room or for general work, and it can be used for the grinding of punches, dies, automatic machine tools, lathe and planer tools, etc. It consists of a neatly designed column on which is mounted a tool steel spindle carrying an emery wheel on each end. An adjustable tool rest is provided for one wheel to support lathe, planer or similar tools, while beneath the opposite wheel there is a table on which may be supported punches, dies and similar tools while they are being ground. The bracket on which this table is mounted can be easily and quickly adjusted vertically on the column. It is clamped rigidly in the desired position by a cam and lever, and a counterweight connected with the bracket and contained in the pedestal, keeps it from falling when the clamp is released. This counterweight also makes it easier to raise or lower the bracket. In addition to the adjustment of the bracket on the

column, a fine adjustment is provided for the table that is obtained by means of the small handwheel shown in the illustration. This fine adjustment, which has a range of 1 inch, is desirable for the grinding of dies and similar work. The maximum adjustment of the bracket on the column is 12¾ inches. The construction of the spindle and its bearings is shown in Fig. 2. The spindle has ground taper bearings which run in bronze boxes, the composition of which is the same as that required by the United States Government for bearings. These boxes are dustproof and they have simple adjustments for taking up wear, as the engraving indicates. They are provided with ring oiling devices and they can easily be replaced with new ones when this is necessary. The height from the floor to the center of the spindle of this machine is 40 inches, and the distance between the wheels is 15¼ inches. The distance from the top of the table to the center of the spindle with the table and bracket in the lowest position, is 15¾ inches, and the surface of the table is 10 by 18 inches. Two emery wheels, 12 inches in diameter with a 1-inch face, a set of wrenches, water tank, and a countershaft are furnished with this machine. The countershaft is provided with a slotted lever shipper that is operated by simply twisting a rod, and it is locked in either the on or off position.

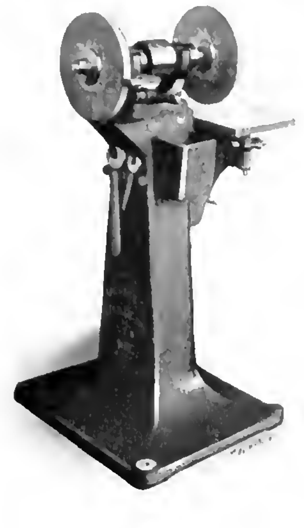

Fig. 1. Baird Tool and Die Grinder

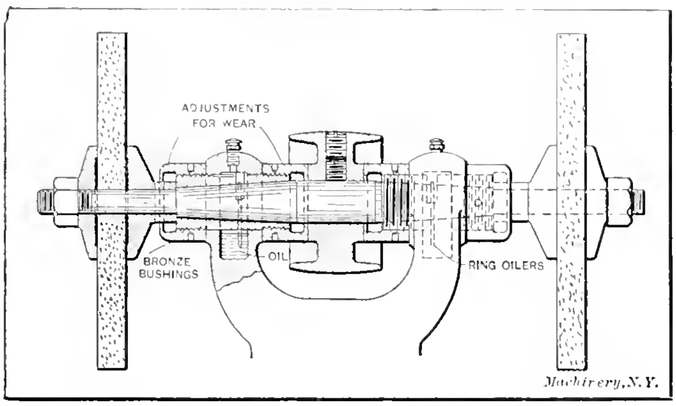

Fig. 2. View showing Construction of Spindle

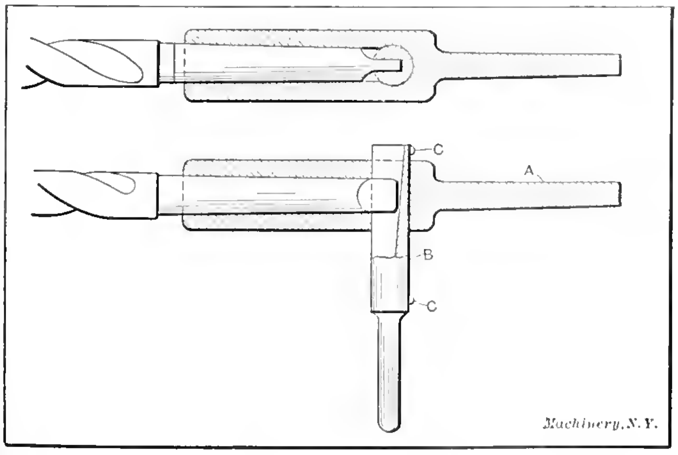
LINSLEY LATHE DRILL HOLDER

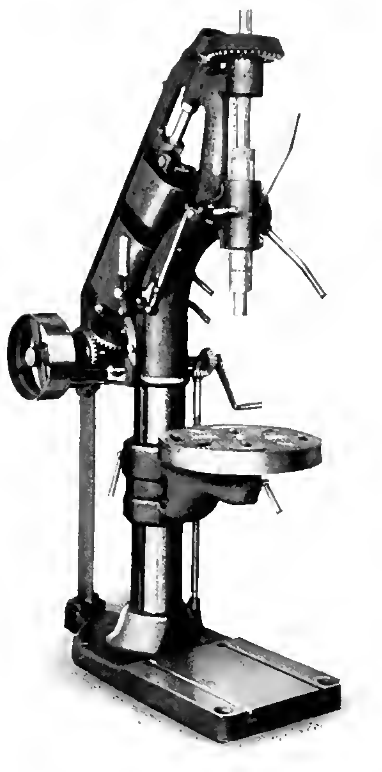
A drill holder for the lathe, which has been brought out by the Linsley Tool Co., 13370 Superior Ave., Cleveland, Ohio, is shown in the accompanying line engraving. The shank *A* of this holder is turned to fit the tailstock spindle, and the outer part or body is bored to fit the drill or tool-shank. A cross-shaft or pin *B* is provided, that slides loosely in a hole bored through the holder. This cross-pin has a groove cut in it, the sides of which extend down over the tang of the drill, thus preventing the latter from turning in the holder. As the bottom of this groove is cut on an incline, the pin *B* is also used to force the drill from the holder. When the holder is in use, the end of pin *B* rests on the lathe tool-rest. The two screw-heads *C* prevent the two parts of the holder from becoming separated when it is not in use.



Drill Holder for the Lathe

BARNES ALL-GEARED TAPPING MACHINE WITH AUTOMATIC REVERSE

In the department of New Machinery and Tools for May, 1908, and November, 1909, we illustrated and described the 20- and 24-inch all-geared drills built by the Barnes Drill Co., 602 S. Main St., Rockford, Ill. This company has now brought out a new design, which, while of the same general construction as those previously described, contains some noteworthy improvements. By referring to the accompanying illustration, it will be seen that this drill, which is of the automatic reversing type, has a single pulley for driving and reversing. A reverse speed of 1¾ to 1 is obtained by means of friction clutch gears which are mounted on the driving end of the machine instead of being on the spindle. The automatic reversing mechanism is a very desirable feature, particularly for depth tapping. It can be set so that the instant the tap reaches the required depth, the spindle will automatically reverse and back the tap out at practically twice the speed at which it entered. This mechanism can also be set so as to trip automatically (or by hand) and stop the spindle instantly without reversing its movement. The spindle may be reversed or stopped at any time by a small trip lever which is conveniently located. This machine has four direct, geared speeds and four back-geared speeds, making eight changes of geared speeds available.



Barnes 20-inch All-geared Tapping Machine with Automatic Reverse

This type is built in 20- and 24-inch sizes, and the makers claim that these machines are the strongest and most powerful upright drills of their swing. The 20-inch machine drives a 1¼-inch U. S. standard tap, running at 125 revolutions per minute into cast iron, without using the back-gears. When the back-gears are thrown in, a 1½ inch U. S. standard tap may be driven into cast iron at a speed of 50 revolutions per minute, while the 24-inch size will drive a tap up to 2 inches in diameter. With the positive power feeds added to these machines, they can be used advantageously for both drilling and tapping.

LODGE & SHIPLEY CRANKSHAFT LATHE

In the department of New Machinery and Tools of the June, 1909, number of MACHINERY, we illustrated and described a lathe manufactured by the Lodge & Shipley Machine Tool Co., Cincinnati, for turning the ends of automobile crankshafts of 2½ inches throw. Recently this firm has built a lathe for

turning much larger crankshafts, a general view of which is shown in Fig. 1. This machine is a standard 36-inch patent head lathe raised in the sand to swing 42 inches over the shear. The special attachment for holding a shaft while it is being turned, is illustrated in Figs. 2 and 3. This attachment can be easily adjusted to bring the crankpin center into alignment with the axis of the lathe spindle, and it also affords a powerful drive and rigidly supports the crank so that there is practically no springing action when taking a cut.

A swiveling chuck *A* attached to the faceplate, carries one end of the crankshaft by securely gripping it in a bearing having a hinged cap. The base upon which the chuck swivels, has a tongue which fits a planed slot passing through the center of the faceplate. This chuck can be placed with its center coincident with the center line of the lathe to turn shaft bearings, or it can be set eccentrically to any desired amount within its range, for turning crankpins. The swiveling base allows the attachment to be adjusted for shafts having pins located at different angles. A steel strip *B* bolted in the slot at one side of the chuck-plate, locates the chuck at just the proper distance off center to give the correct throw for the crankpin to be turned. The weights shown attached to the faceplate opposite the chuck are for counterbalancing both chuck and crankshaft.

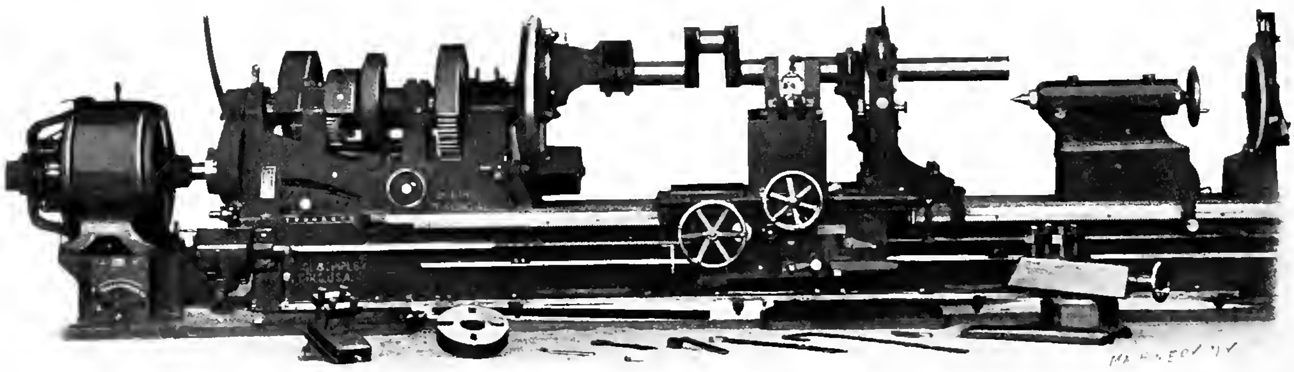


Fig. 1. Large Crankshaft Lathe built by the Lodge & Shipley Machine Tool Co.

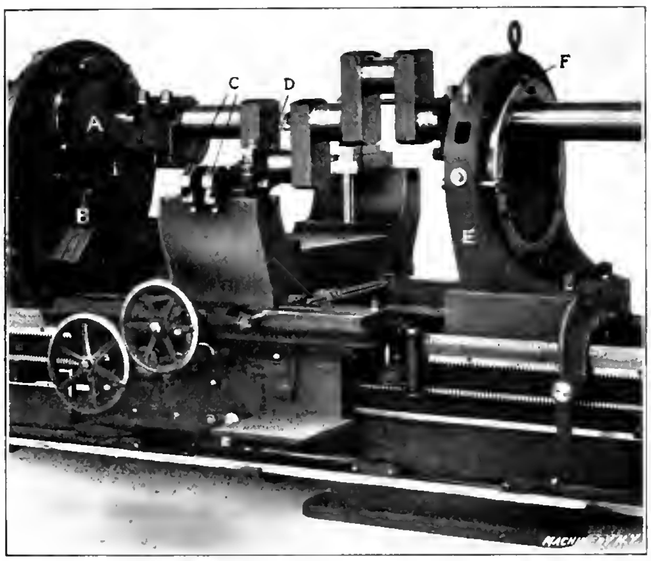

Fig 2. View showing the Crankshaft Turning Attachments

When turning the pins, the outer support *E* holds the tail end of the crankshaft. This outer support is a carrier chuck, but not a driving head, as the drive for the crankshaft is from the faceplate end only. The shaft is held at the proper distance off center by being gripped in the hinged bearing *M* which is attached to the central rotating chuck. There is an annular bearing *F* in the outer support, so that the chuck carrying the eccentrically-located shaft is free to revolve. Thus the clamping bearings of both the swiveling chuck and the outer support, always remain in line as the shaft revolves. This outer support also serves as a steady-rest, by gripping the shaft close to one of the crank webs.

Locking pins *H* and *N* bring the two clamping bearings into exact alignment with each other before the hinged caps are finally tightened to grip the crankshaft. The faceplate locking pin is carried in a bracket attached to the inner ways of the bed. A star knob on the front of the bracket furnishes convenient means for sliding the pin into or out of its seat in the faceplate. The locking pin in the outer support is similarly operated. Before placing the crankshaft in the lathe, the two locking pins are slipped into their seats, which exactly aligns both chucks, so that the shaft can be placed in them and gripped without danger of springing. The locking pins are then withdrawn, leaving the chucks and shaft free to revolve.

Connected front and rear tool-rests are used, both rests being cast in one piece with the long cross-slide that is mounted upon the bridge of the carriage. This slide has power feed as well as hand movement. An upright post gives a firm support to each tool almost out to the cutting point, and prevents excessive overhang. The front block carries three tools. Two of these tools *C* are for facing the cheeks of the shaft and are carried in a hinged holder so that they can be thrown back when not in use; the third tool *D* turns the cylindrical portion of the pin. The rear tool-rest has a holder *K* containing two cutting tools spaced just the proper distance apart to fillet the ends of the pin, and thus determine the length of the portion which is to be turned.

Since the special fixtures are needed only for turning the pins, our description has covered that work only. The turning of the bearings is a separate and previous operation, being straight turning between centers with the outer support removed, the swiveling chuck on the center of the faceplate and the tailstock center supporting the other end of the crankshaft.

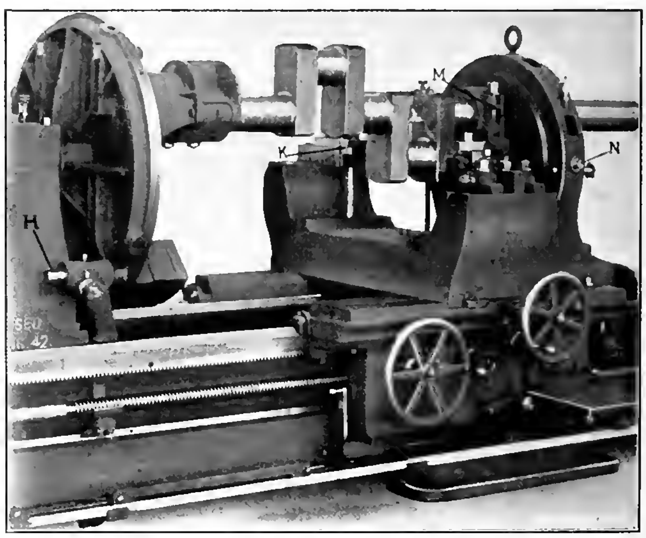

Fig 3. Another View of the Turning Attachments

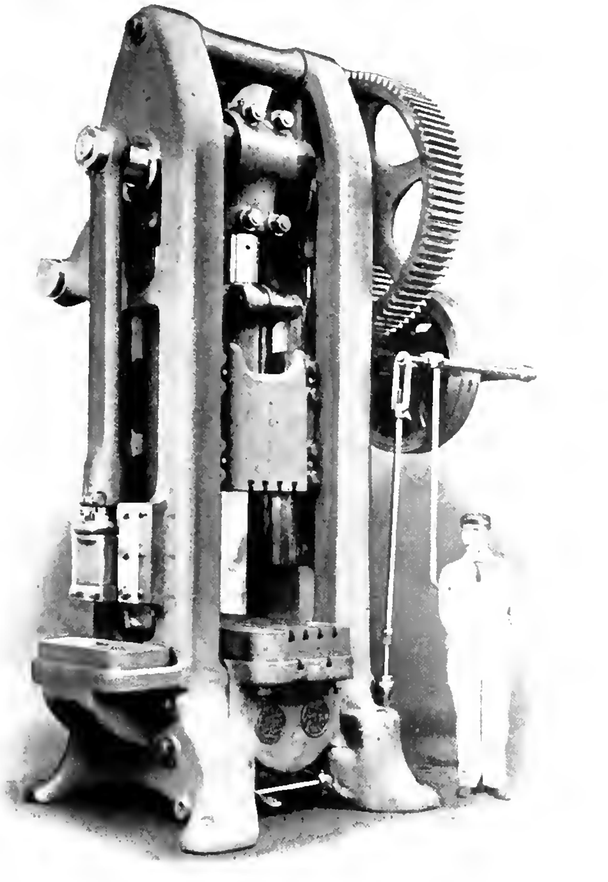
Multiple stops for length and cross feeds are included in the equipment, and greatly increase the output. These stops have already been described in detail in our description of the smaller crankshaft lathe. We will therefore merely mention here that the longitudinal stops positively determine the correct location of the carriage for all fillets and shoulders, and

that the diameter stops locate the cross-slide to give proper finished diameters when either the front or the rear tools are cutting.

Even when the lathe is not used for turning crankshafts, it will be found a valuable manufacturing tool. The equipment also includes the regular engine lathe parts, such as a small faceplate, compound rest, full swing rest, and wrenches. The crankshaft attachment can be quickly removed from the lathe, and the compound rest substituted for the connected front and rear tool-blocks, leaving the machine in shape for handling the full range of work suitable for an engine lathe.

LARGE FERRACUTE TRIMMING PRESS

The Ferracute Machine Co., of Bridgeton, N. J., has recently built from designs of its president, Mr. Oberlin Smith, several heavy trimming presses for use in a prominent locomotive works. Some of these presses are intended for pressures of 300 tons and others for 200 tons, the illustration showing one of the 300-ton presses. This machine contains a side punch for similar work of a lighter character, thus adding considerably to the capacity of the press. The distance between the columns is 32 inches and the bed measures 30 inches across and 50 inches from front to back. As the engraving shows, the bed, bolster, and ram contain T-slots for die-clamps. The bed of the side punch is 15 by 30 inches. The stroke of the

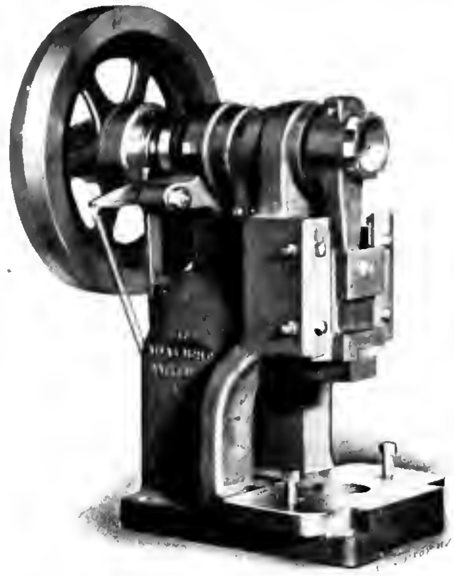


Ferracute Trimming Press of 300-ton Capacity

main press is 12 inches with a 10-inch adjustment, and the side punch has a stroke of 3 inches. The height from the bed to the ram with the latter at the top of its stroke and adjustment, is 34 inches. The drive of the machine is double-geared, the power being transmitted from the flywheel shaft by a pinion and gear to an intermediate shaft at the rear which, in turn, through a second pinion, drives the large gear which is mounted on the main shaft. This arrangement gives a gearing ratio of 50 to 1. The main shaft is a steel forging having a diameter of 9 inches at the journals and 11 inches at the crank. The flywheel is 40 inches in diameter, has a 7-inch face, and weighs 1100 pounds. This press is equipped with a friction clutch which enables the operator to start or stop it at any part of the stroke. The machine occupies a floor space 10 feet by 7 feet 6 inches. Its height is 14 feet, and the weight, approximately 68,500 pounds.

ATLAS BENCH POWER-PRESS

The small bench power-press illustrated herewith has been designed by the Atlas Machine Co., Waterbury, Conn., to meet the demand for a medium weight machine of this type. One of the interesting features of this press is the new one-revolution positive stop clutch which is simple in construction and at

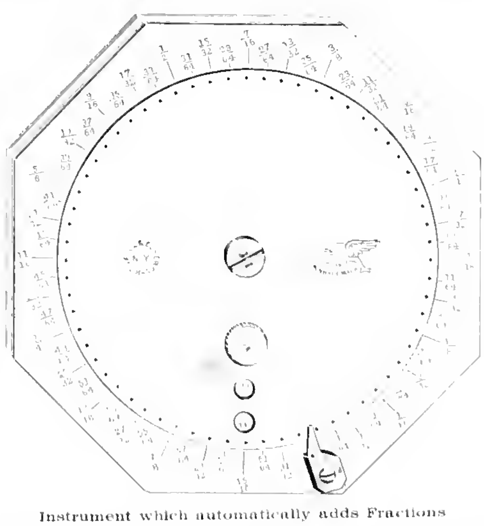


Bench Power Press made by the Atlas Machine Co.

the same time sure in its operation. This clutch, which is operated in the usual manner with a foot-treadle, is released by the striking of a cam point against a knuckle piece, that in its movement slightly raises the pull-down latch and at the same time pushes it off the clutch lever, thus releasing the lever in ample time to engage the driving key which, in turn, pulls out and stops against a positive projection, thus making it impossible for the press to repeat. To arrange the machine for continuous running, it is only necessary to loosen a nut and drop the knuckle piece against which the cam point strikes. In this clutch there are few parts to wear or to become broken, and all the parts are operated by a single spring which is of considerable length, as the engraving indicates. The stroke of this press is 1½ and 2 inches. The height from the bed to the gate (when down) is 7¼ inches, and the die-bed has a surface of 13 by 8 inches. The weight of the press complete is 375 pounds.

KEUFFEL & ESSER FRACTION ADDER

A very simple but practical instrument, by means of which fractions may be quickly added, is illustrated herewith. This fraction adder can be used for adding fractions of 64ths, or



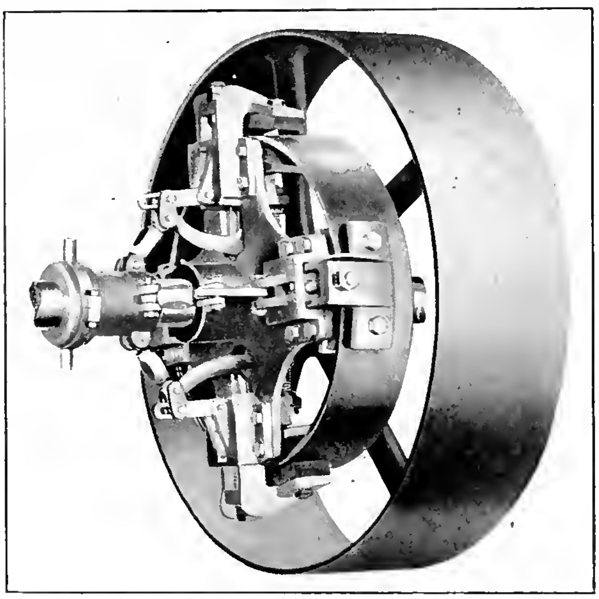
Instrument which automatically adds Fractions

multiples thereof, up to 16 integers. A white xylonite disk which revolves on an octagonal polished wood base covered with white xylonite, has near its circumference sixty-four indentations which correspond in position to the fractional grad-

uations marked on the base. At the lower edge of the base a nickel-plated stop is attached which projects over the disk as shown. If a pointed instrument or pencil point is placed in the small indentation at the circumference of the disk opposite the fraction to be added and the disk is rotated until arrested by the contact of the stop with the pointer, the fraction at which the pointer was originally set will be shown on the counter, providing the latter was set to zero by means of the milled head screw shown, before performing this operation. To add to this fraction any number of fractions, it is simply necessary to place the pointer in the indentation opposite each fraction to be added, and rotate the disk each time until the pointer comes against the stop. The counter will show each successive total through the two windows in the disk, one of these openings giving the integer and the other the fraction. The usefulness of this device will be at once appreciated by those constantly engaged in the checking of drawings or in other computations involving the addition of fractional parts. This instrument is the product of the Keuffel & Esser Co., 127 Fulton St., New York.

LEHIGH RIM FRICTION CLUTCH

A clutch that is especially adapted to high speeds and is suitable for motor-drives or wherever a quick-acting and powerful clutch is required, is illustrated herewith. This clutch, which is made by the Lehigh Clutch Co., Catasauqua, Pa., is of the opposite jaw type, that is, there are two jaws on each arm, making four sets in all, which grip the friction ring both on the outside and inside as the engraving indicates. In operation the outer jaw is drawn toward the center of the clutch and the inner one is forced away from it, the friction ring being gripped between them. A separate positive-acting lever and link are employed to operate each jaw, and connection is made with the spool by special turnbuckles. When the shoes wear, these turnbuckles provide convenient means for adjustment. No springs are used to release the clutch, but the jaws are moved from the rim by positive-acting levers, which are so arranged that the clutch may be engaged or disengaged, it is stated, with less power than is required for any other clutch of equal capacity.



Lehigh Rim Friction Clutch

The construction of this clutch is such that either the inside or the outside jaws may be adjusted independently without disturbing the other member of the pair. The wooden shoes or friction blocks which bear against the rim may be renewed, when necessary, in a very short time, as all that is required is to move the jaws away from the friction ring, loosen the two bolts holding the wooden shoe in place, and slide it along the friction ring until it clears the jaws.

The spider, the spool and the jaws are made of a special mixture of cast iron, while the operating levers and those parts which are subjected to severe strains are made of malleable iron. Each piece of the clutch is finished in jigs, thus making them interchangeable and easy to replace when necessary. This type of clutch is manufactured in all sizes from 12 to 84 inches in diameter and for transmitting from 4 to 1350 horsepower at 100 revolutions per minute.

THE DAVIS EXPANSION BORING TOOL

The Davis Expansion Boring Tool Co., Broadway and Bremen Ave., St. Louis, Mo., has developed a number of improved boring tools, one type of which we illustrate herewith. The particular tool shown, which is known as the style A head, is intended to be screwed onto the end of an ordinary arbor or shank, and it is suitable for use in either the lathe, boring mill, or drill press. One of the points of superiority of this tool over the ordinary cutter used, lies in the ease and quickness with which it can be adjusted to compensate for wear. This feature is, of course, of considerable value when boring to a given size, owing to the fact that it enables the use of higher speeds than would be considered practical with the ordinary non-adjustable tool, as the increased wear of the cutter incident to the higher speeds can be quickly taken up. This tool is adjusted to any size within its range by simply inserting a key wrench in the squared hole of the screw. This screw, which is graduated to give micrometer adjustment, operates a double-expanding tool-steel wedge that comes in contact with the cutters and forces them outward. As the expanding wedge is hardened and accurately ground to obtain a good contact with the cutters, the latter, as far as rigidity is concerned, are practically as one piece. The adjustable feature of this tool is also valuable in connection with grinding the cutters, as grinding to an exact size is immaterial, owing to the possibility of adjustment. Both cutters should, of course, be ground square, to the same length, and have proper clearance for the cutting edges, the same as with the solid type. These tools are made in all styles and in twenty-one sizes to meet the requirements and conditious of every shop.

Davis Expansion Boring Tool

ROCKFORD 14-INCH ENGINE LATHE

The engine lathe shown in the accompanying engraving is of a design that is well adapted to the work of the tool-room, as well as to general manufacturing purposes. This machine is the latest addition to the line of tools manufactured by the Rockford Lathe & Drill Co., Rockford, Ill.

The headstock of this machine is heavily constructed and it is fitted with a 5-step cone with wide face, thus making possible a powerful drive. The bearings are large and they are fitted with the highest grade of babbitt metal obtainable. The spindle has thrust bearings which are also of large proportions and the thrust can easily be taken up or adjusted in a few minutes. The tailstock is of the offset type so that the compound rest can be swung around 90 degrees or parallel with the bed. An eccentric lever is used for clamping the tailstock so that it is possible to quickly adjust it without the use of a wrench. In addition there is an auxiliary locking arrangement for securely fastening it to the bed when doing heavy work.

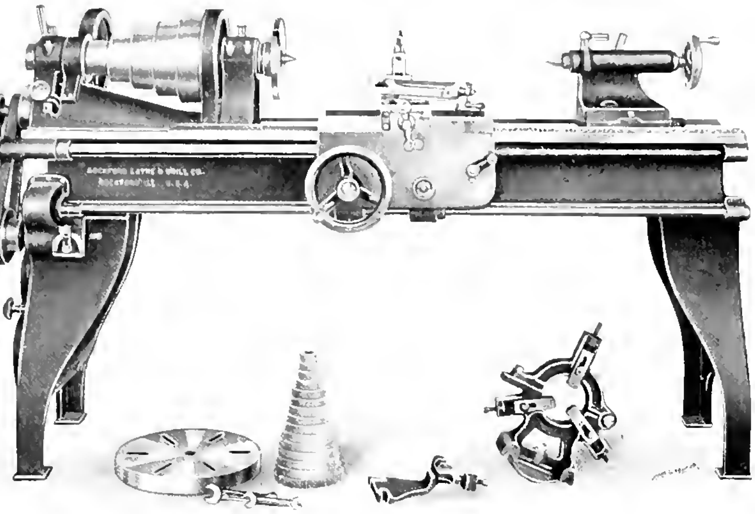
One of the striking features of this machine is the addition of a third bearing in the center of the bed which forms a rigid support for the carriage and insures a steady cut and the elimination of all chatter. This support is provided with a taper block which makes it possible to compensate for wear. The carriage is of a heavy pattern and the carriage-slide is dust-proof, as well as chip-proof, protection being afforded by means of a cover.

All shafts in the apron have double bearings so that the

strains are well taken care of, and the worm runs in oil. The cross-slide has a specially designed locking nut which makes it possible to quickly lock the compound rest or tool-slide at any point along the screw. This is a desirable feature in connection with the use of a taper attachment, as it is only necessary to loosen this nut, and there is no danger of dirt getting down into the screw.

The feed is by belt drive to a gear-box by means of which three changes, controlled instantly by a lever, are obtained. As two-step cones are provided, this number is doubled, making six feeds in all. The width of the feed belt is 1¼ inch, which, combined with the ratio of gearing in the box, gives a powerful drive.

The bed is of the heavy box pattern and it is so arranged that a taper attachment can be applied at any time. The legs supporting the headstock end of the bed contain a cabinet which has shelves enough to accommodate all the change



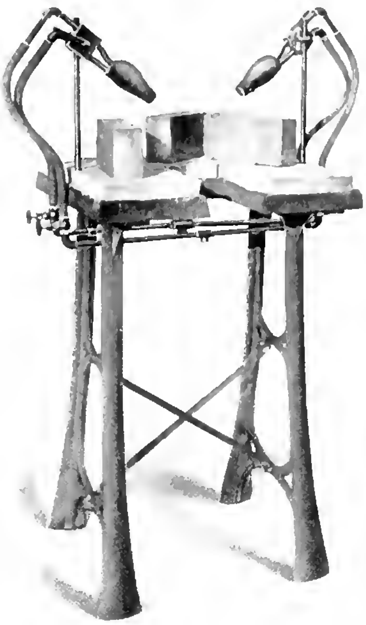
Fourteen-inch Engine Lathe built by the Rockford Lathe and Drill Co.

gears, thus keeping them free from dust and dirt. The central hole of the faceplate furnished with this machine is made just large enough to admit the center thus making it possible to use this extra surface when boring small jigs and similar work, which could not be held on the conventional faceplate owing to the diameter of the central hole.

This lathe is particularly adapted to tool-room work, as it has a thread-cutting capacity ranging from 1 to 92 threads per inch. So far as we know, this is the largest range of threads that can be cut on any lathe. This machine swings 16 inches over the bed and 9¼ inches over the carriage. The diameter and lengths of the front and rear headstock bearings are, respectively, 2½ by 4 and 2⅛ by 3 inches. The length of the bed is 6 feet 6 inches and the maximum distance between the centers, 36 inches. The net weight of the machine is 1900 pounds.

SCOTT BRAZING FURNACE

The brazing furnace shown in the accompanying engraving is a recent design brought out by C. U. Scott, Davenport, Iowa. This furnace may be operated by city gas or gasoline, and it is provided with two burners which are mounted on standards located at each side of the table. The blocks by which the burners are attached to the standards may be adjusted (by loosening a handle nut) in either a vertical or horizontal plane or vertically on the standards, so that the flame from the burners can be brought to bear on any part of the top of the furnace. Connection with the air and gas pipes is made by flexible hose, and valves at the side of the table provide convenient means for proportioning the mixture admitted to the burners. As the engraving shows, the top of the furnace is supported on well-braced legs, and it has a rectangular opening in the center through which long parts can extend. Two important features claimed for this furnace are, that the heat can be taken without scaling work and the burners will not blow out while in operation. As soon as the burners are lighted, a temperature of 1872 degrees is available.



Scott Brazing Furnace with Two Adjustable Burners

HOEFER CONNECTING-ROD DRILLING AND FACING MACHINE

The manufacturers of automobile engines have realized the necessity of performing the various operations on the motors with machines especially adapted to work of this class. Heretofore, considerable motor work has been done on standard machines which required many changes, in order to adapt them to certain operations, which of course affected the output. One of the expensive operations in the manufacture of automobile engines is the connecting-rod, which requires accuracy and perfect alignment, both in drilling the holes and facing the ends. After studying the problem, the Hoefer Mfg. Co., 120 Jackson St., Freeport, Ill., has designed a special machine for this purpose, which drills and faces accurately both ends of the engine connecting-rod without the necessity of changing the rod in the jig, or changing the tools or drills.

The principle of the machine, front and rear views of which are shown in Figs. 1 and 2, is extremely simple and its operation can be readily mastered by comparatively inexperienced men. The attachment and operating devices are so arranged

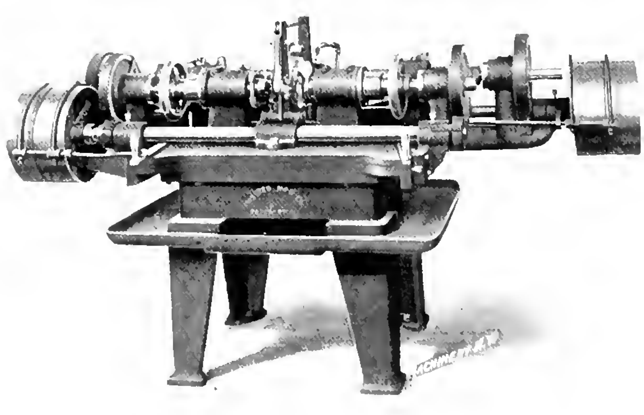


Fig. 1. Front View of Hoefer Connecting-rod Drilling and Facing Machine

that it is almost impossible for the operator to produce defective work. The machine consists principally of two heads, which are adjustable and gibbed to a solid bed. One of these heads carries the drilling spindles for both the large and the small ends of the connecting-rod, and the other head has two spindles in which are placed the facing tools for the ends of the rods. The connecting-rods are placed in a trunnion jig which has hardened steel jaws operated by a quick-releasing screw. The jaws clamp the rod firmly during the operations of both drilling and facing, as but one setting of the rod in the jig is necessary to complete it, which gives the best possible results.

After the rod has been set, an eccentric lever on the two

projecting arms is locked, thus giving additional support to the rod for high-speed drilling. The small end of the connecting-rod is drilled first by throwing in a power feed lever. While the drill is removing the stock, the operator, by means of two handwheels shown in Fig. 1, faces the sides of the large end, and as the cutters face concentric with the holes, a very

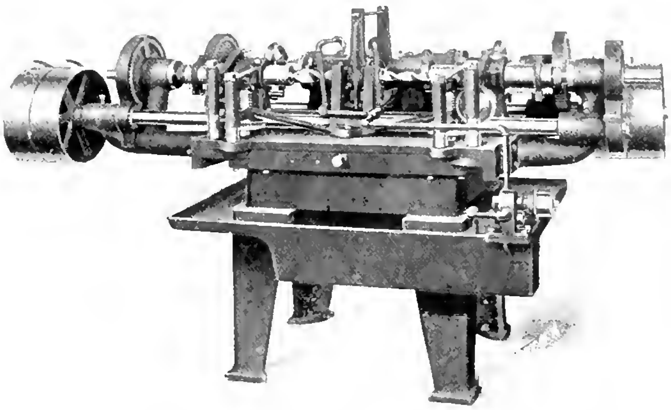

Fig 2. Rear View of Connecting-rod Drilling and Facing Machine

good finish is secured. When these operations are completed, the eccentric lever is opened and the trunnion jig is swung 180 degrees against an adjustable positive stop. After clamping the ends of the rod again by means of the eccentric lever, the power feed of the large drill spindle is thrown in and the large end is drilled while the operator faces the small end. As the spindles are in perfect alignment with the trunnion jig which carries the connecting-rod, absolute accuracy is assured. In each end of the trunnion is placed an adjustable positive stop (steel hardened) for the facing tools, and each end of the rod, as it is swung from one position to another, carries with it its own stops so that when once set, all dimensions are duplicated.

The spindles are made of a crucible steel, carefully ground and run in bronze bushed bearings. They are driven through gearing by wide-faced pulleys which rotate at a high speed, thus insuring ample power. The two drilling spindles are driven by one driving shaft, but the gearing is proportioned to give the proper speeds for the large and the small drills. The two heads carrying the drill and facing spindles are gibbed to a heavy bed and are adjustable for connecting-rods varying in length from 10 to 14 inches.

With ordinary connecting-rods, it requires about five minutes to drill and face both ends; this time includes picking up the rod, fastening it in the trunnion jig, and taking it out of the jig. Even better time than this has been made on a day's run.

As there is but slight variation in the holes of ordinary connecting-rods, the machine was designed for but one speed. The feed also has but one speed, so in neither case can the operator change the speed or feed.

ELECTRICALLY CONTROLLED REVERSING DRIVE FOR POND PLANERS

An electrically controlled reversing mechanism for direct motor-driven planers, characterized by its remarkable simplicity, has recently been applied by the Pond Works of the Niles-Bement-Pond Co., Plainfield, N. J., to the regular line of heavy planers brought out by this company. Some of the advantages of this reversing drive are that the overload on the motor at the time of reversal is reduced to a minimum; that it is possible to obtain very short strokes of the platen without any perceptible shock, and without injury or abnormal wear to the mechanism; and that the platen motion becomes practically positive, the platen stopping at the end of every stroke within a limit of variation of less than one-eighth inch.

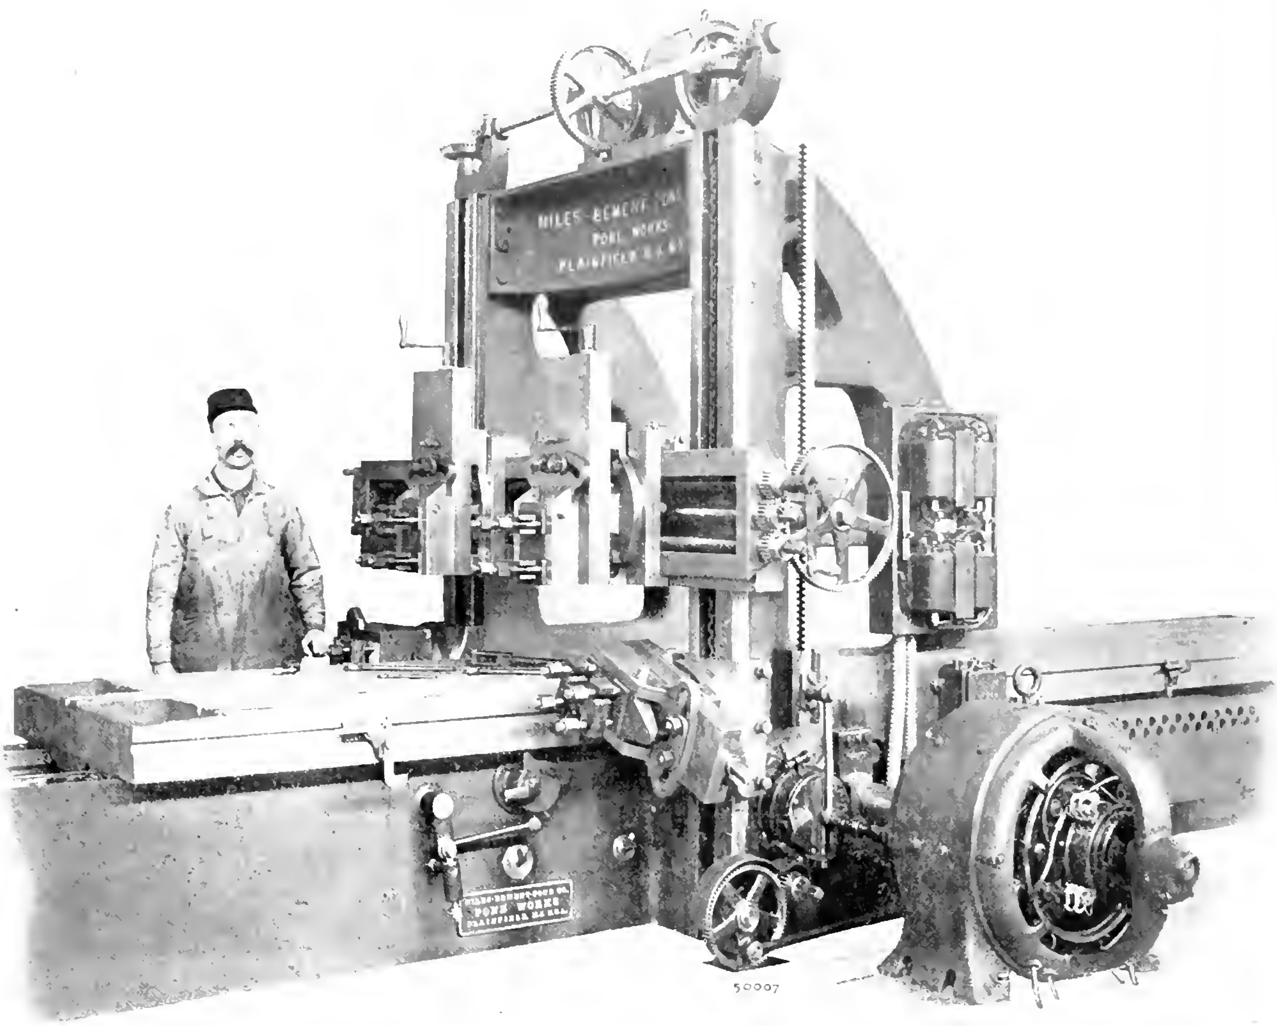

Fig 1 Pond Planer with Electrically Controlled Reversing Mechanism

A planer provided with direct motor-drive and reversing mechanism of this type is shown in Fig. 1. The whole driving and reversing mechanism consists of a motor mounted directly on the pinion shaft, a controller mounted on a marble panel on the side of the planer housing, as shown, and a pilot switch placed in the same position on the planer bed as the hand lever control or rocker lever of the ordinary belt driven machine. This pilot switch is tipped by adjustable dogs on the side of the platen in the same way as is the ordinary rocker lever, and by its movement it electrically operates the controller. It is entirely enclosed and is but six inches in outside diameter.

The controllers are made in two sizes, according to the size of motor for which they are to be used. The controller for motors from 7½ to 30 horsepower is provided with three magnets, while the controller for motors of 35 horsepower and up consists of four magnets or solenoids, on the plungers of which are mounted the electrical contacts. This latter type is the one shown in Fig. 1. The only parts susceptible to wear and replacement in the mechanism are the contacts, but these are all simple in shape, being made of sheet copper or bar stock such as would be found in any average shop. The replacement can be made by any mechanic.

On the controller are mounted two index scales or dials, one controlling the range of cutting speeds and the other the return speeds. These scales will be seen in Fig. 1, one on each side of the magnets. Each scale is provided with thirteen graduations or divisions by means of which the same number of different motor speeds are obtainable by simply sliding a knob on the scale. The cutting speeds obtainable on the standard type of planers vary from 25 to 40 feet, and the return speeds from 60 to 100 feet; but these speeds can, of course, be changed to suit individual requirements. The cutting and return speeds are entirely independent of each other, so that it is, for example, possible to use the slowest cutting speed and the highest return speed, or *vice versa* should this for any reason be deemed desirable. The reversible electric motor used is built by special specifications and it is shunt wound with a speed range of 4 to 1, the revolutions per minute varying from about 250 to 1000.

As will be seen from the illustration Fig. 1, the pilot switch is provided with a handle so that it may be operated by hand instead of by the reversing dogs, thus giving the operator immediate control of the machine. By a slight movement of the switch it may be placed in a neutral position which will immediately stop the platen. A valuable feature of the planer is that, owing to this direct hand control, it is possible for the operator to control the speed at any time during the cutting or return strokes. For example, in working castings with hard spots, thin walls, etc., or working a line of castings mounted on the platen, when one or more castings are harder than the others, the operator would set his index for the cutting speed most suitable for the average of the softer castings, and when the tool is about to enter the harder metal or the thin walls, he can, by simply moving the pilot switch by hand, obtain a reduction of cutting speed which will be maintained until the pilot switch is returned to its former position. Thus the platen is under the absolute control of the operator, even when in motion, and it is possible to stop the table within a limit of ⅛ inch by throwing the pilot switch to the neutral or "off" position.

On account of the controller's automatic action it is impossible to reverse the motor's direction of rotation until its speed is very low. This feature not only reduces the power required for reversal by nearly 100 per cent at the instant the direction of motion changes, but it also saves the feed line from any voltage surge or pumping action. At the moment of reversal the motor acts as a generator and tends to stop itself. The length of time of this action is automatically taken care of by the ingenious design of the controller. The variable speed of the motor is dependent entirely on shunt field regulation, and no armature resistance is used. Another important feature is that at the instant of starting, the motor has full field strength, giving it the maximum torque at a time when it is most required.

In Figs. 2 and 3 are shown two charts giving the load curves of a planer operated by this reversing drive, and showing that even at the time of reversal the motor is not subjected to excessive load, and hence in no way to excessive heating; it can, therefore, stand up to the requirements of modern service for any length of time.

The most noteworthy of the advantages of this drive may be briefly summarized as follows: The elimination of any frictional drive mechanism, such as is introduced by belts, friction clutches, etc., tends to give a more positive stroke and eliminates the shocks incident to reversal. There are no replacements necessary on account of the wear of friction surfaces, the only wearing parts being the contacts, as mentioned,

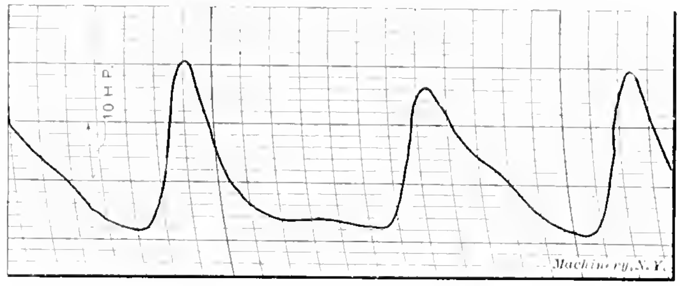

Fig. 2. Curves for Power Consumption, 84-inch Pond Planer with 35-horsepower Motor, Stroke of Table 71.2 inches, Cutting Speed 30 feet, Return Speed 65 feet

which may be easily and quickly replaced. The speed range is greater than that possible with any other drive, and cutting and return speeds are independent of each other. The shock at the time of reversal is almost entirely eliminated, due to the elimination of the rapidly revolving belt driving pulleys. It has been ascertained by experiments that 85 per cent of the momentum of a planer at the time of reversal is due to the rapidly revolving driving pulleys. The possibility of obtaining a short stroke—from 3 to 4½ inches on 36- to 96-inch planers—is also a feature well worth mentioning; and the ease of operation, the platen being at all times under the absolute control of the operator; the possibility of changing the cutting speed during any part of the stroke; and the elimination of a great number of driving members liable to wear and damage are features of high importance. The small space occupied by the controller is also an advantage. The controller used for motors up to 30 horsepower occupies a space of only 17½ by 19¼ inches, and is 4½ inches thick. Considerable economy is also obtained by the method of absorbing the inertia of the motor, due to the fact that at the instant of reversal the motor acts as a generator and produces the power which stops it.

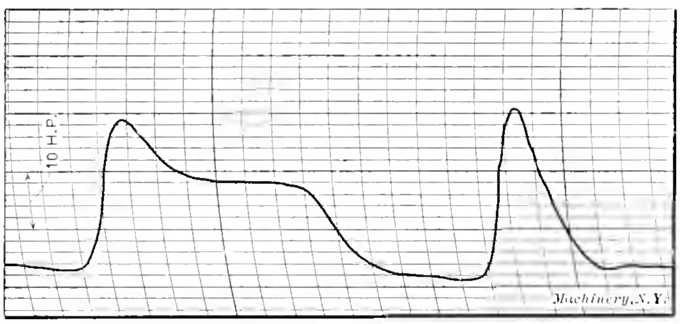

Fig. 3. Curves for Power Consumption, 84-inch Pond Planer, with 35-horsepower Motor, Stroke of Table 12 inches, Cutting Speed 30 feet, Return Speed 110 feet

The builders are prepared to equip their full regular line of planers with this drive, and will also attach it to their belt-driven type of planers in which case the motor is connected directly to the driving shafts on which the belt pulleys ordinarily are mounted.

* * *

The following is from a paper by J. B. Doan of the American Tool Works Company on the tariff, read at the Rochester meeting of the National Machine Tool Builders' Association: "As an example of the varying import duties upon machine tools when shipped into some of the leading countries, I quote the following approximate figures, applying to the shipment of a 14-inch or 16-inch lathe, weighing approximately 1,800 pounds: Into Germany, $15.61; France, $38.02; Denmark, $24.10; Austria-Hungary, $40; Italy, $14.28; Russia, $107.84."

NEW MACHINERY AND TOOLS NOTES

Engine Lathe: South Bend Machine Tool Co., South Bend, Ind. Lathe that may be operated by the foot or with power as desired. It swings 13 inches over the bed and has a maximum distance of 33 inches between the centers.

Tumbling Barrel: E. C. Bliss Mfg. Co., 91 Sabin St., Providence, R. I. Small double tumbler designed for bench use. The finishing and burnishing is accomplished by the use of steel balls which have proved efficient for this work.

Oilless Roller Bearing: Troy Roller Bearing Co., Troy, N. Y. Bearing that is designed to run without oil, a small amount of dry graphite being the only lubricant used. Bearings of this type are made for practically all purposes.

Pipe Die Stock: Borden Co., Warren, O. Die stock equipped with narrow dies which recede to form the pipe taper. The dies may be adjusted by simply shifting a cam, so that pipe from 1 to 2 inches in diameter may be threaded. The dies cut easily, and it is stated that a 2-inch pipe may be threaded by one man without difficulty.

Shop Truck: Gannett Electrical Co., 55 Pine St., Providence, R. I. Small, heavily-constructed two-wheeled truck for moving heavy machinery or parts. By connecting two of these trucks in line with a heavy timber, a narrow truck of any length can be made, and by attaching two such trucks with cross-pieces, the width can be extended as required. Each of these trucks weighs about 30 pounds.

Lathe Tool-holder: Kearney Foundry, Machine & Automobile Co., Kearney, Neb. Tool-holder in which the blade is clamped between two wedge-shaped washers by a slotted bolt through which the blade passes. This method of clamping and holding the tool permits adjusting it vertically or swinging it to the right or left. It is also possible to tilt a thread-tool to the angle of either a left- or right-hand thread.

Core Machine: Falls Rivet & Machine Co., Cuyahoga Falls, O. Vertical jar-ramming core machine, which forms the core in a vertical shell or core-box, that is given a jarring motion by two ratchets which alternately lift and drop the core-box in order to compact the sand. For making ordinary straight cores, the core tube itself may be used, but for irregular work, special dies or core-boxes are inserted in this vertical tube.

Low Knife Bar Shear: Thomas Carlin's Sons Co., Henry W. Oliver Building, Pittsburg, Pa. A shear designed for cutting muck bars or other material within its capacity. It will sever soft steel stock up to 1¾ inch square. As the shear arm is connected directly with the crankshaft by a pitman, it has a speed of from 60 to 80 working strokes per minute, thus making it possible to handle large quantities of material in a given time.

"Changeezy" I-Beam Trolley: New Jersey Foundry & Machine Co., 90 West St., New York City. Trolley that is so constructed that it may be converted from a plain to a geared one or *vice versa*, thus making it possible to rack the trolley along the track when handling heavy loads or to pull it along at comparatively high speed when light, by disengaging the gears. This change is made by the hand-chain, which is also used to move the trolley by the rack and pinion.

Right-angle Drilling Attachment: Lowndes & Butler, Norristown, Pa. Compact attachment intended for drilling in places where lack of room precludes the use of an ordinary power drill. The driving shank has a Morse taper and is connected with the drill socket by hardened steel spiral gears provided with ball thrust bearings. This attachment is made in four sizes with drill capacities ranging from 9/16 to 2 inches, and corresponding weight variations of from 2¼ to 10 pounds.

Pneumatic Chuck: Bashlin Tool Works, Grove City, Pa. Pneumatically-operated chuck for small lathes that is intended for the rapid handling of castings of irregular shapes These chucks are made with jaws of two styles, the alligator and the four-hinged, either of which may be attached to the master collet used. The four-hinged chuck is intended for round or hexagonal work, etc., while the alligator jaws are for holding irregular parts, such as valve bodies, air and gas cocks, and similar pieces.

Friction Clutch: F. C. Sanford Mfg. Co., Bridgeport, Conn. Clutch that transmits power by friction alone until the speed and resulting centrifugal force is great enough to swing out pivoted locking dogs, which engage with pins and form a positive drive. The design is such that the work of the friction surface is confined to starting and accelerating to normal speed, thus lengthening the life of the clutch. The locking dogs and the pins with which they engage, are of hardened nickel steel and the clutch itself is bronze-bushed.

Double-Head Traverse Drill: National Machine Co., Hartford, Conn. Two-spindle drill which differs from previous designs in having a hand feed instead of an automatic feed, both spindles being fed simultaneously by a pilot wheel at the front of the machine. The heads are adjustable along the bed giving a maximum distance of 20 inches between the spindles. The spindles have a travel of 5⅜ inches, and the distance from the spindle centers to the bed is 7 inches. The machine will drill holes up to 9/16 inch in diameter.

Pipe Wrench: Brosnihan Wrench Co., 31 Hermon St., Worcester, Mass. Pipe wrench designed along the lines of an ordinary monkey wrench and equipped with hardened and tempered tool steel jaw faces which are serrated for gripping pipe or other round parts. The face of the sliding jaw is wedge shaped and it is free to slide on a correspondingly inclined surface on the jaw so that work is gripped tightly by the wedge action when pressure is applied to the handle. Extra jaw faces can be furnished when desired. These wrenches are made in four sizes, ranging from 8 to 18 inches.

Special Drilling Machine: Buckeye Machine Co., 2617 East 76 St., Cleveland, O. Special machine for drilling cross holes in bolts, etc., for cotter pins or other retaining devices. The machine has five drilling spindles and the work is clamped by quickly operated levers so that the holes are drilled centrally and the correct distance from the bolt ends. Each spindle with its drill is automatically fed by cams which are mounted on a horizontal shaft extending across the machine. The drive is through a single pulley mounted on the central spindle which transmits the movement to the remaining spindles by spur gears.

Mono-rail Trolley Hoist: Heyl & Patterson, Inc., Pittsburg, Pa. Mono-rail trolley hoist, the frame of which is hung from two cast-steel trucks by steel straps which rest on ball bearings. With this construction, the trucks are independent of each other so that they will operate on comparatively small curves. Each truck has four 10-inch cast-steel wheels, which are set at such an angle as to be perpendicular to the slope of the I-beam flange on which they run, thus reducing the wear on both the flange and wheels. This trolley is provided with an operator's cab and is driven by an 11 horsepower Westinghouse motor.

Auxiliary Planing Head: Cincinnati Planer Co., Cincinnati, O. An auxiliary floor planing head intended to handle work usually done on the open side planer. It consists of a column with a swiveling head which has a vertical travel above the planer table of 42 inches. The face of the column is pivoted in the center so that by swinging it around, the planing head may be used on either side of the planer. Power feed is taken from the double combination friction on the planer itself, connection being made to the feeding mechanism of the column by a suitable rod. The feeds are controlled by a small lever at the top of the tool-head, and the amount of feed may be varied by means of a slotted crank.

Improvements in Surface Grinder: Walker Grinder Co., Worcester, Mass. The Walker "single-stroke" rotary surface grinder, which was illustrated and described in the February, 1910, number of MACHINERY, has recently been equipped with a number of improvements. The spindle is now driven with an independent belt drive, the belt transmitting the power direct from the countershaft at the rear to the spindle by a quarter-turn belt, thus giving a more powerful drive than formerly obtained. The quarter-turn belt in the column which transmits power from the countershaft to the table speed-change mechanism, has been provided with an improved take-up device for varying the belt tension. This design is also equipped with a new belt shifter, which may be easily operated and which is conveniently located.

Heavily Designed Radial Drills: Mueller Machine Tool Co., Cincinnati, O. Heavily designed 4- and 4½-foot radial drills brought out to meet the requirements of modern practice. The column is heavily constructed, and the arm is of hollow rectangular section and has been increased considerably in weight. The arm can be locked to the column by one handle and it can be lowered at twice the elevating speed. The back-gears are located in the head and they may be engaged or disengaged without shock and while the machine is in motion, by a conveniently located lever. A tapping mechanism is provided, and the spindle is equipped with a depth gage and automatic stop. A speed box of the geared friction type gives twelve changes of speed, which is doubled by the back-gears, making twenty-four speeds in all available for the spindle. By means of a combination positive and friction feed, eight changes to each change of spindle speed may be obtained without stopping the machine.

Electric Controllers: General Electric Co., Schenectady, N. Y. Controllers for use on electrically-driven machine tools and wherever the starting service is frequent or of a severe nature. They are of the drum type and have embodied in their construction a number of special features to adapt them to the conditions of modern practice. Among these may be mentioned substantial removable barriers between the fingers wherever required; magnetic blow-outs for all equipments for 500-volt service or for large currents at lower voltages; special screws to hold the segments with heads slightly countersunk below the surface so as to prevent their wearing with the segments, and tapered at such an angle as to prevent their loosening; sheet iron covers lined with asbestos to protect live parts from dust and mechanical injury, and eliminate the danger of shock from accidental contact; terminals and other parts readily accessible; and field control with adjustable fingers similar in design to the fingers for the armature circuit.

Fourteen-inch Engine Lathe: Young Machine & Tool Co., Worcester, Mass. Engine lathe of the plain type that is intended for repair and general machine shop work. The feed-rod of this machine is so arranged that either a belt or direct gear drive may be obtained. This positive drive for the feed-rod, makes possible the taking of heavy cuts for rapid reduction. The construction of the apron is such that it is impossible to throw in both feeds at once, thus eliminating the danger of stripped gears and spoiled work. All the bearings of this lathe are cast iron and like those on the bed, they are hand-scraped. This lathe is built with either a 6- or 8-foot bed It will swing 16 inches over the bed and 11 inches over the carriage. A four-step cone pulley is provided, thus giving, by means of the back-gears which have a ratio of 10 to 1, eight speed changes. Change gears are provided for cutting any pitch of thread, ranging from 4 to 36 per inch, inclusive. The maximum distance between the centers with the 6-foot bed is 36 inches. The net weight of the machine is 1470 pounds.

Improved Upright and Radial Drills: Prentice Bros. Co., Worcester, Mass. The radial drills manufactured by this company have been re-designed to adapt them more thoroughly to modern needs. The base has been made more massive beneath the column and the arm is heavily ribbed to resist torsional strains. A feed dial has been conveniently located on the head, which, by the movement of a crank, gives four speed changes, which number may be doubled by a second adjustment. A dial depth gage is also provided which is so arranged that it can be set to zero for any position of the drill. The spindle, through the quick speed change box, has sixteen changes. The machine is equipped with a tapping attachment, a quick return mechanism and an automatic stop motion. The upright machine also contains a number of important changes. The back gears are so arranged that the spindle may be changed from high to low speed or *vice versa* without stopping the machine and simply by the operation of a back-gear lever. Eight spindle speeds are available, and the machine is equipped with the Prentice quick-return and stop motions.

Automatic Nut Tapper: Acme Machinery Co., Cleveland, Ohio. Automatic non-reversing nut tapping machine which taps the nuts straight through as with hand tapping, thus insuring an accurate thread. The nuts to be tapped are placed in a hopper at the top of the machine from which they are fed automatically to a chute that leads down to the tap. At the bottom of this chute there is a reciprocating mechanism that feeds the nuts onto the revolving tap. The machine is provided with three taps which are indexed successively to the tapping position. When the shank of one of these taps is filled with tapped nuts, the tap-carrying mechanism revolves automatically, thus bringing another tap into position, which is then filled as before. The number of nuts that are fed onto the tap is automatically regulated by their thickness. After a tap is filled with nuts, it is indexed from the working position; it then stops automatically, thus enabling the operator to remove it and the tapped nuts. These machines are made in three sizes, designated as Nos. 1, 2 and 3. The first has a capacity for nuts up to ¼ inch, the second to ½ inch, and the third up to 1 inch in diameter. The machine is very rapid as two or three nuts are tapped at a time, and the mechanism is simple and durable.

Four-head Drilling and Facing Machine: Garvin Machine Co., Spring and Varick Sts., New York City. Machine with four heads that is particularly adapted for drilling or reaming four holes simultaneously in such parts as universal joint rings, bevel gear differential spiders, etc. The four heads are located 90 degrees apart on a cross-shaped bed, and the drive is taken from a four-way, right-angle countershaft, there being a separate belt for each spindle. In the center of the bed, and coincident with the axes of the four-spindles, there is a plate to which fixtures may be clamped The heads have a power feed of 4 inches and a tripping mechanism is provided. The heads are returned to their outward position by a handwheel, and the feeding mechanism is so arranged that they may be adjusted independently if desired. The spindles have threaded ends to permit the use of round box tools, and each has on the inside a drill spindle provided with a Morse taper hole for receiving drills or reamers. The machine is provided with a lubricating system for the cutters, oil being contained in a reservoir in the base. The maximum distance between the ends of the spindles is 10 inches, and the largest size drill that can be used in steel is 7/8 inch. The machine weighs 2800 pounds.

Pipe Threading Machine: Stoever Foundry & Mfg. Co., Myerstown, Pa. Pipe threading machine with capacity for threading pipe from 4 to 12 inches in diameter. By means of a gear-box, in conjunction with a double train of outside gears, ten speeds may be obtained. All the gears are made of carbon-steel castings fitted with bronze bushings, and they run in oil. The speed changes can be made without stopping the machine, and the control of the latter is by means of a clutch operated from the working side of the tool. The headstock is made in one casting similar to that of the lathe, and contains all the principal bearings, thus insuring permanent alignment. The diameter of the spindle on the inside is such that the largest fittings within the machine's capacity can be passed through. The pipe is held by powerful chucks equipped with three independent steel jaws faced with hardened plates. The die-head is of the sliding or floating type that allows for any eccentricity in the pipe. By moving the die-head to one side, the pipe can be cut off within 3 inches of the face of the chuck. The machine is provided with an oil pump for supplying lubricant to the dies, and all bearings have deep receptacles for holding lubricating wool and oil for insuring good lubrication.

All-wrought Steel Pulley: American Pulley Co., Philadelphia, Pa. Improved design of all-wrought steel pulley which is now being manufactured in large sizes ranging from 44 to 60 inches in diameter. These pulleys have eight arms which are built up of two steel plates that are riveted to an annular rim flange and to the flange of an annular hub ring, the rivets passing through both sections of the arm. The hub shell is riveted to a horizontal leg of the same ring, thus giving a very strong construction. The bore of the hubs is standard while the lengths vary. One bushing is furnished with each pulley and extra sizes are carried in stock so that the pulleys may be fitted to shafting of ordinary dimensions. These pulleys are of the parting type which enables them to be put on the shaft without taking it down. The faces are either flat or crowned and pulleys of considerable width are equipped with a double set of arms. A groove is cut in the center of the pulley face, which allows the air to escape from under the belt as the pulley revolves, which results, it is stated, in increasing the horsepower transmitted by at least one-third over that transmitted by a pulley with a plain face. Tests made with this type of pulley show that one 30 inches in diameter with an 8-inch face, will stand a pull of 250 pounds per inch of belt width without slipping.

BRISTOL-DURAND RADII AVERAGING INSTRUMENT FOR CIRCULAR CHART RECORDS

The extensive use of automatic instruments for recording pressures, temperatures, and electrical units has created a demand for a simple device to quickly determine the average of the records made on such charts, and the integral value for the whole twenty-four hours or whatever time is covered by the record. This demand has been filled by the instrument illustrated herewith, the operation of which is based upon a fundamental plan worked out and patented by Professor W. F. Durand of Stanford University, and constructed in accordance with a novel design developed by William H. Bristol, president of the Bristol Co., Waterbury, Conn.

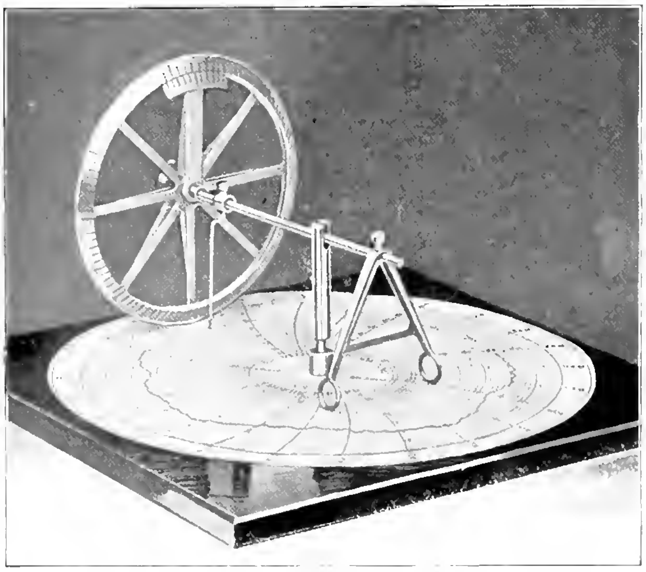
The instrument can be applied for averaging records of any kind on circular charts having uniform graduations, as, for instance, records of watts, amperes, temperature, pressure, etc. Recording instruments equipped with circular charts are therefore made available for a number of applications for which it was previously thought necessary to use the instruments recording on straight lines, or strip record charts. Recording differential pressure gages are coming into use for measuring velocities and volumes of liquids, air or gas flowing in mains, and this integrating device will prove of value for quickly obtaining total volumes of flow for any given period of time.

The simple construction of the instrument is shown by the accompanying illustration. A wooden base with a metal socket is provided for supporting and centering the chart. This socket holds a rotatable pin with a vertical slot at the top to receive the bar which carries the integrating tracer point and triangular support. The vertical groove in the rotatable pin allows the integrating wheel to roll on the chart with uniform pressure due to its own weight. The integrating wheel is six inches in diameter and the rim is graduated into one hundred numbered equal spaces and is fitted with a vernier which makes it possible to easily read with the naked eye to one-tenth of one division on the integrating wheel. The wheel is of such large size it is not necessary to supply any counting device for the number of revolutions. In fact the number of complete revolutions cannot be more than two, even for a record of maximum size on large 12-inch charts.

To operate the instrument, the thumb and forefinger of one hand are applied to the base of the triangular support, which is moved radially, so as to cause the tracer point to continually follow the record curve, while the chart is turned with the other hand. By referring to a line plotted on a sheet of cross-section paper furnished with the instrument, for the par-

ticular record curve that is to be measured, the total reading for the entire twenty-four hours may be taken off directly.

A full explanation of the theory upon which the operation of the instrument depends has been given by Professor Durand, in a paper presented at the New York meeting of the American Society of Mechanical Engineers in 1908. This may be briefly summarized as follows: In applying the instrument, it is necessary to have a uniform radial scale, from which it follows that equal increments in the length of the radius correspond to equal increments in the watts, amperes, temperature or whatever quantity is measured. The integrating wheel, being carried at right angles to the shaft passing through the center, does not turn and give a reading when the tracing point is moved on a straight radial line, but if the tracing point is made to follow a record, the integrating wheel will revolve and the amount of the revolution will correspond to the total of the circumferential elemental components of the record curve, the radial elemental components of the record having no turning effect on the integrating wheel. As the lengths



Instrument for determining the Average Record on Charts of Automatic Recording Gages

of the arcs of concentric circles for given angles or for the entire circumference are proportional to their radii, it is evident that the amount of turning of the integrating wheel, and the reading obtained thereon, will be proportional to the average radius of the record traced.

The instrument is adapted for integrating charts with either straight or curved radial time arcs. The correction necessary for radial time arcs which are curved, may be made after completely tracing the record, by returning the tracing point to a point on the chart having the same radius as the starting point, the movement of the tracing point being along an arc corresponding to the curved radial time arcs.

SEMI-ANNUAL CONVENTION NATIONAL GAS AND GASOLINE ENGINE TRADES ASSOCIATION

The most successful semi-annual convention in the history of the National Gas and Gasoline Engine Trades Association, was held at the Sinton Hotel, Cincinnati, Ohio, June 13-16 inclusive. About two hundred members and visitors registered and over thirty dealers and manufacturers had products on exhibition. Racine, Wisconsin, was chosen for the next meeting, which will be held some time in December. Several interesting papers were read by prominent authorities, and a number of social events were features of the evenings.

Election does not occur until the next meeting, and the officers whose terms do not expire until then are: President, M. A. Loeb, Cincinnati, Ohio; vice-president, C. D. Hamilton, Elyria, Ohio; treasurer, Otto M. Knoblock, South Bend, Indiana, and secretary, Albert Stritmatter, Cincinnati, Ohio.

* * *

According to statistics quoted by *Page's Weekly*, there are at present about 85,000 private automobiles in use in Great Britain, about 15,000 motor cars used for industrial purposes, and nearly 9000 public service cars.

DON'TS FOR DRAFTSMEN

By H. E. WOOD

Don't use a loose-jointed T-square.

Don't use a triangle that is too thick.

Don't use instruments with dull points.

Don't make unnecessary lines on a drawing.

Don't use an extremely soft drawing board.

Don't draw with the sun shining on your work.

Don't push a pen or pencil when you can draw them.

Don't design odd or special sized bolts or screws.

Don't use ink that is thick and stringy; new ink is cheaper.

Don't forget that a comprehensive drawing is a valuable asset.

Don't make fancy flourishes and leave off necessary information.

Don't keep a watch lying on your board, open and face toward you.

Don't refuse to listen to what a "jackleg" machinist wants to say.

Don't put perspective drawings and plan drawings on the same sheet.

Don't turn in a drawing until you are sure there are no mistakes on it.

Don't let scales and triangles get dirty, as they will soil your paper.

Don't miss an opportunity to do a little job of machine or bench work.

Don't keep any more instruments lying on the board than you are using.

Don't forget that bicarbonate of soda and water will bleach blue-prints.

Don't put all the patternmaker's dimensions on the machine shop drawings.

Don't use different T-squares and triangles on a complicated drawing.

Don't use too much pounce on tracing cloth, and clear off what you do put on.

Don't leave blue-prints when you are printing them, as they are easily spoiled.

Don't fail to sign all drawings which you make, as it often saves controversy.

Don't forget to backline letters and figures when they are pasted on a tracing.

Don't think that it is always necessary to make machine shop drawings right up to scale.

Don't design curves in machinery when you can make straight flat surfaces answer as well.

Don't forget that oxalate of potash dissolved in water will make a white ink for blue-prints.

Don't let a tracing stand in the sun between the time you start tracing it and the time you finish it.

Don't indicate an oil hole and channel in such a manner that the oil will form an air trap for itself.

Don't fail to mark very distinctly the bearings that should be tight, from the ones that should be loose.

Don't forget that the draftsman can save his employer more money with less exertion, than a machinist can.

Don't let the chief measure anything for you, but if he gives you a measurement, then work faithfully to it.

Don't forget that in some cases a loose bearing is better and much more economical than a tight one.

Don't fail to indicate where oil holes and channels should go, as they are vital points in the design of a machine.

Don't forget that washing soda, gum arabic and water makes a good writing fluid for fine lines on blue-prints.

Don't be reluctant about consulting with both the patternmaker and molder sometimes regarding framework and large castings.

Don't forget that very often a little note of explanation in the corner of a drawing will save the foreman many annoyances.

Don't forget that bread crumbs rubbed thoroughly over a drawing after it is completed will take off the majority of the dirt, and will not disturb the pencil lines perceptibly.

* Address: 182 North 4th St., Newark, N. J.

WELDING A LARGE CRANKSHAFT WITH THERMIT

A large three-throw engine crankshaft with a broken web was recently successfully repaired at the plant of the Goldschmidt Thermit Co., in Jersey City, N. J., by the thermit welding process. Owing to the large size of the shaft, which was 9 inches in diameter and 16 feet in length, and the accuracy of alignment necessary after the broken parts had been welded,

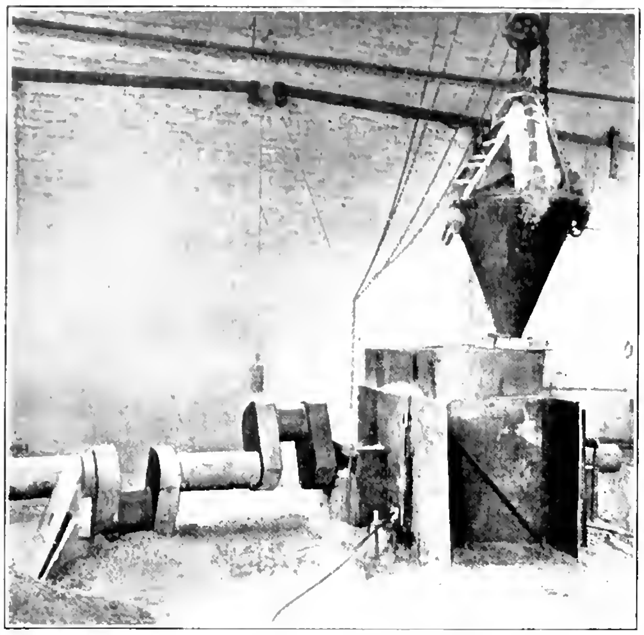

Fig. 1. Large Crankshaft ready to be welded by the Thermit Process

this job is of unusual interest and shows in a rather forcible way the possibilities of the thermit process.

As those familiar with the use of thermit know, it is necessary when making a weld to provide room between the broken ends for the thermit steel. In this instance, an oxy-gas torch was used very effectively for this purpose, and a space two inches wide was quickly cut in the web which had a section of 5 by 15 inches. The crack which made the weld necessary, extended clear across the web between the shaft and crankpin, and penetrated to a depth of 4 inches. The two shaft sections were aligned, prior to welding, by mounting them in V-blocks of the same height that rested on a large surface-plate,

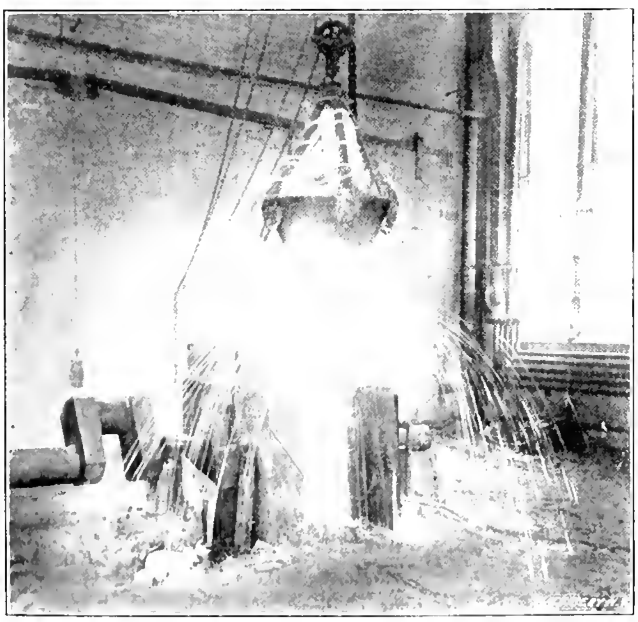

Fig 2 View showing the Thermit Steel running from the Crucible into the Mold built around the Fractured Web

two blocks being used for each section. After the webs of the broken crank had been set in the proper relation with each other, and the sections were securely clamped, the opening at the break was filled in with a yellow wax matrix after which the mold was built up around the crank. This mold was formed of a sheet iron shell, containing a mixture composed of one-third fire sand, one-third fire clay, and one-third ground fire brick. This mixture forms a very refractory material, which is absolutely necessary owing to the intense heat of the thermit steel. Openings were, of course, left in the mold for a gate and riser, and as parts to be welded by thermit must be pre-heated to prevent them from exerting a chilling effect on the steel, additional openings were made at the bottom of the mold for the insertion of gasoline blow torches. The solid web was pre-heated, as well as the broken one, in order that the expansion on both sides of the crank would be equalized. After the parts had been sufficiently pre-heated, which, of course, also melted the wax previously inserted, thus forming a pocket in the mold, the space surrounding the solid web was filled in with dry sand to prevent any possibility of the molten steel breaking through, and the openings for the torches were also closed. A large inverted cone-shaped crucible, containing 450 pounds of thermit, was then swung by a crane over the gate of the mold as illustrated in Fig. 1. The thermit, which is a mixture of ground aluminum and iron-oxide, was then ignited by means of a special powder which generates the intense heat necessary to start the thermit reaction. In forty-five seconds after a match had been applied to the starting powder, the pre-heated thermit steel was tapped into the mold. Owing to the large amount of thermit used, the chemical reaction was unusually violent

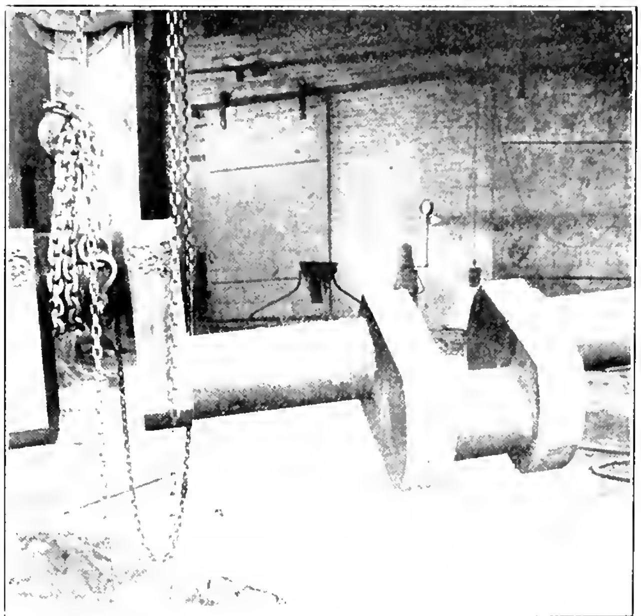

Fig 3 The Shaft after the Fractured Web (seen to the extreme right) had been welded

and produced showers of brilliant and scintillating sparks which formed a very spectacular pyrotechnical display.

During this reaction, the oxygen of the iron is taken up by the aluminum, which has a strong affinity for it, producing aluminum-oxide (or slag) and superheated thermit steel. Immediately after the reaction ceases, the steel which sinks to the bottom of the crucible is tapped into the mold where it comes into contact with the broken sections and because of its intense heat, which is as high as 5400 degrees Fahrenheit, amalgamates with them to form a homogeneous weld. Fig. 2 shows the steel running from the crucible into the mold, while Fig. 3 is a view showing the welded part of the web.

Of course, thermit has been used on larger and more difficult jobs than the one illustrated, but nevertheless, the successful welding of a section of this size in the comparatively short time required, is an interesting mechanical achievement

* * *

ADDITIONS TO MEMBERSHIP OF NATIONAL MACHINE TOOL BUILDERS ASSOCIATION

In addition to the list given in the June number, the following concerns have acquired membership in the National Machine Tool Builders' Association: Fay Machine Tool Co., Philadelphia, Pa.; Ohio Machine Tool Co., Kenton, Ohio; Superior Machine Tool Co., Kokomo, Ind. These make 24 new members, and a total of 119.

SPRING MEETING OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS

The attendance of the spring meeting of the American Society of Mechanical Engineers, held at Atlantic City, N. J., May 31 to June 3 was not as large as that of some of the meetings held heretofore, the registration of members and guests being about 250. The coming joint meeting of the society with the Institution of Mechanical Engineers in England, no doubt caused many who will attend that meeting to forego attending the regular spring session.

A good program was presented, some of the papers being of unusual interest to the engineering profession. A case in point was the paper of Mr. H. J. Freyn, "Some Operating Experiences With Blast Furnace Gas Power Plants." It was conceded to be by far the best exposition of modern gas power practice from the operating standpoint that has been made public. About twenty members took part in the discussion.

The paper by Prof. Walter Rautenstrauch, "A Comparison of Lathe Headstock Characteristics" was a masterly analysis of lathe headstock construction, its object being to show a rational means of working out speed torque combinations and avoiding those combinations which are found in many lathes to be of no practical value. The paper is one that should have the careful attention of machine tool designers generally. In the discussion of the paper, Mr. Carl G. Barth said that certain fundamental formulas deduced on this side of the Atlantic were better than those derived by Dr. Nicholson. For example, the formula $V = \frac{1}{a} + 15$ was valueless for slow cutting speeds as it contained the constant 15. The paper was highly commended by Mr. Taylor, who was disposed to overlook what he considered were comparatively minor faults pointed out by Mr. Barth, and gave the author much credit for the constructive work so valuable to the designers and users of machine tools.

The paper on "Stresses in Curved Machine Members," by Prof. A. L. Jenkins, was followed by a spirited discussion in which conflicting ideas were set forth with more or less convincing force. The thought was expressed that small models freshly cast, containing severe shrinkage stresses, were not safely comparable with full-sized shear frames. Mr. Henry Hess pointed out that the determination of the yield point was all important, and stated that an instrument consisting of a delicate pyrometer and gold-leaf electroscope galvanometer had been developed abroad by which it was possible to test the stresses existing in any part of a machine frame.

The paper by Mr. Wilfred Lewis, "A Shockless Jarring Machine," described a type of molding machine built by the Tabor Manufacturing Company, Philadelphia, Pa., in which the anvil and platen are spring supported. The advantages of the construction claimed are freedom from shocks so destructive to other molds on the molding floor, and the production of homogeneous molds because of avoiding the common causes of flaws and rifts in the sand. The discussion of the paper was characterized by an attack by a competitor which led Mr. F. W. Taylor to deprecate the admission of commercial papers in general. He expressed the thought that unless discussion could be fair and free from trade jealousies, all papers describing commercial machines should be barred from the society's proceedings.

The paper by Prof. Edward C. Schmidt "The Resistance of Freight Trains" dealt with the results of tests made upon the Illinios Central by the railway engineering department of the University of Illinois. The trains tested varied in weight up to 3000 tons. The tests were made on tracks laid with 85-pound rails.

Space will not permit the giving of a full review of the discussion of these or other papers presented. An addition to the list of papers published in the program in the June number was that by Mr. C. K. Lassiter, entitled: "Improved Methods of Finishing Staybolts and Straight and Taper Bolts for Locomotives."

The social event of the meeting was the reception Thursday evening at which honorary membership was conferred on Rear Admiral Melville, U. S. N., retired. Rear-Admiral Melville delivered an address, "The Engineer's Duty as a Citizen."

M. C. B. AND A. R. M. M. ASSOCIATIONS CONVENTIONS

The forty-fourth annual convention of the Master Car Builders' Association and the forty-third annual convention of the American Railway Master Mechanics' Association were held at Atlantic City, N. J., June 15-22, inclusive. Following the custom of alternating the conventions in the matter of priority the Master Car Builders' Association convention was held June 15, 16 and 17, and the Master Mechanics' Association convention June 20, 21 and 22. The Railway Supply Manufacturers' Association held an exposition of railway supplies and apparatus, machine tools, etc., on Young's New Pier simultaneously, as has been the custom for many years. This exhibition of railway supplies is one of the most important annually held in the United States and is growing in importance. Last year the exhibit space was about 65,000 square feet and the year before about 58,000 square feet. This year it was over 71,000 square feet, and still more space would have been used had it been available. Between thirty and forty concerns were turned away that desired to exhibit but could not be accommodated because space was lacking.

The general technical program of the Master Car Builders' Association convention was made up in the usual manner, consisting of topical discussions and papers as follows:

June 15.—Discussion of reports on: "Revision of Standard and Recommended Practice"; "Train Brake and Signal Equipment"; "Brake Shoe Tests"; "Rules for Loading Materials."

June 16.—Discussion of reports on: "Rules of Interchange"; "Coupler and Draft Equipment"; "Car Wheels"; "Safety Appliances"; "Freight Car Trucks"; "Splicing Underframes"; "Car Framing, Roofs and Doors"; "Tank Cars"; "Train Pipe and Connections for Steam Heat."

June 17.—Discussion of reports on: "Consolidation of Master Car Builders and Master Mechanics' Associations"; "Classes of Cars"; "Salt Water Drippings from Refrigerator Cars"; "Mounting Pressures on Wheels and Axles."

Individual paper: "Design of Axle to Carry 50,000 Pounds," by E. D. Nelson, Engineer of Tests, Pennsylvania Railroad.

Discussion: "Springs for Freight Car Trucks."

Discussion of reports on: "Train Lighting and Equipment"; "Lumber Specifications."

The following officers were elected for the M. C. B. Association:

President, T. H. Curtis, L. & N. R. R.
First vice-president, A. Stewart, Southern Ry.
Second vice-president, C. E. Fuller, Union Pacific Ry.
Third vice-president, D. F. Crawford, Pennsylvania Lines.
Treasurer, John S. Lentz, Lehigh Valley R. R.
Executive Committee: J. D. Harris, B. & O. R. R.; C. E. Fuller, U. P. Ry.; and C. A. Seley, C. R. I. & P. Ry.

The technical program of the Master Mechanics' Association was as follows:

June 20.—Discussion of reports on: "Mechanical Stokers"; "Revision of Standards."

Individual paper by W. S. Hayes, Supt. Loco. Operation, Erie R. R.: "Fuel Economies."

Topical Discussions: 1—"Self-dumping Ash Cans," by H. T. Bentley, A. S. M. P., C. & N. W. 2—"Apprenticeship Education," by F. W. Thomas, Supervisor of Apprentices, A., T. & S. F.

Discussion of report on: "Motive Power Development."

June 21.—Discussion of reports on: "Widening Gage on Curves"; "Steel Tires"; "Safety Appliances"; "Superheaters."

Individual paper: "Locomotive Performance under Different Degrees of Superheat," by Prof. C. H. Benjamin, Purdue University.

Individual paper: "Locomotive Frame Construction," by H. T. Bentley, A. S. M. P., C. & N. W. Ry.

Report of Committee on Safety Valves.

Report of Committee on Lumber Specifications.

June 22.—Discussion of report on: "Train Brake and Signal Equipment."

Individual paper: "Freight Train Resistance," by Prof. E. C. Schmidt, University of Illinois.

Discussion of reports on: "Locomotive and Shop Operating Costs"; "Design, Construction and Inspection of Locomotive Boilers"; "Consolidation of Master Mechanics' and Master Car Builders' Associations."

The following officers were elected for the A. R. M. M. Association:

President, C. E. Fuller, Union Pacific Ry.
First vice-president, H. T. Bentley, Chicago & Northwestern.
Second vice-president, D. F. Crawford, Pennsylvania Lines.
Third vice-president, T. Rumney, Erie R. R.
Treasurer, Dr. Angus Sinclair.
Executive Committee members: T. H. Curtis, L. & N. R. R.; F. F. Gaines, Central of Georgia; and G. W. Wildin, N. Y., N. H. & H. R. R.

For several years consolidation of the Master Car Builders' Association and the American Railway Master Mechanics' Association has been discussed without arriving at definite action, but now consolidation seems practically assured. The committee on consolidation presented a report in which it recommended that in view of the fact that neither association would agree to be absorbed by the other, an amalgamated association be formed under the name "The American Railway Mechanical Association." The object of the association shall be the advancement of knowledge concerning the construction and maintenance of cars, locomotives and other railway mechanical appliances by investigation through committees and discussion at conventions. There shall be four classes of members, *i. e.*, active, representative, associate and life. The motion to consolidate has been deferred until another year when investigation of the legal and other aspects of necessary consideration will have been made.

The proportion of machine tool builders exhibiting was not as large as last year. Then out of a total of 228 exhibitors about 50 concerns building machine tools, machinists hand tools and other accessories of the machine shop exhibited. This year there were 42 concerns exhibiting machine tools, accessories and closely allied products out of a total of 255, which number included all exhibitors listed.

Exhibitors of Metal-Working Machines, Accessories and Allied Products

American Vanadium Co., Pittsburg, Pa. Vanadium alloy locomotive parts, including 9-inch locomotive axle bent double under 14,000-ton press pressure to show its remarkable homogeneity and elasticity; 2 x 14-inch vanadium steel eye-bar for new Quebec bridge, the largest eye-bar ever made.

Armstrong-Blum Mfg. Co., Chicago, Ill. Portable grinders for lathes and planers; hand lever punches and shears; "Marvel" power hack-saw machine.

Armstrong Bros. Tool Co., Chicago, Ill. Drop forged lathe and planer tool-holders and other machine shop specialties.

Besly & Co., Charles H., Chicago, Ill. Besly spiral disk grinders (see MACHINERY, May, 1910, for description); spiral circles; forged taps, etc.

Buck Boring Bar Co., Huntington, W. Va. Roughing and finishing expansible cutter boring bar for car wheels.

Celfor Tool Co., Chicago, Ill. Celfor high-speed drills, three-lip drills, flat drills, reamers, countersinks, etc.; tests of Celfor drills on Colburn high-duty drill.

Chicago Pneumatic Tool Co., Chicago, Ill. Belt-driven air compressor for pneumatic drills.

Chisholm & Moore Mfg. Co., Cleveland, Ohio. Cyclone high-speed chain hoists from ½ ton to 30-ton capacity; I-beam trolleys, etc.

Colburn Machine Tool Co., Franklin, Pa. Motor-driven high-duty drilling machine in operation.

Cooper Hewitt Electric Co., New York. Mercury vapor lamps and mercury arc rectifiers for operating same with electric current.

Davis-Bournonville Co., New York. Repaired locomotive parts welded by the oxy-acetylene autogenous process.

Disston & Sons, Inc., Henry, Philadelphia, Pa. Hack saws; regular and superfine files; hand saws and other carpenter's tools.

Dixon Crucible Co., Joseph, Jersey City, N. J. Graphite products for locomotives and cars.

Duff Mfg. Co., Pittsburg, Pa. Hydraulic jacks, ball bearing jacks, etc.

Faessler Mfg. Co., J., Moberly, Mo. Improved sectional tube expanders, etc.

Fairbanks-Morse & Co., Chicago, Ill. Hydraulic and screw jacks; track drills, etc.

Foster, Walter H., New York. Lassiter locomotive bolt turning machine; staybolt threading and reducing machine; Potter & Johnston chucking lathe; staybolt threading machine; automatic nut tapping machine; die chaser grinder, etc.

General Electric Co., Schenectady, N. Y. Electric tool hardening furnace; motor-driven machine tools, Curtiss turbo-generator, etc.

Goldschmidt Thermit Co., New York. Apparatus illustrating the Thermit welding process; metals free from carbon produced by the Thermit process, etc.

Greene, Tweed & Co., New York. Reversible ratchet wrenches; packing.

Hammett, H. G., Troy, N. Y. Locomotive link grinder, etc.

Harrington, Edwin, Son & Co., Inc., Philadelphia, Pa. Chain hoists; I-beam trolleys, etc.

Independent Pneumatic Tool Co., Chicago, Ill. Piston air drills; pneumatic chipping, riveting, calking and flue beading hammers, etc.

Keystone Drop Forge Works, Chester, Pa. Drop forgings, including machine handles, etc.

Landis Machine Co., Waynesboro, Pa. Self-opening Landis die for turret lathes; semi-automatic die head for pipe threading machines; and double-head motor-driven bolt threading machine; single spindle ½-inch bolt threading machine.

Landis Tool Co., Waynesboro, Pa. Cylindrical gap grinding machine, 16 x 72 inches, in operation, especially designed for railroad work; universal cylindrical grinder.

Manning, Maxwell & Moore, Inc., New York. 24-inch F. E. Reed motor-driven engine lathe; 24-inch high-duty Foote-Burt drill; 36-inch Foote-Burt high-duty drill; 26 by 8 by 8-foot single-head motor-driven shaper; 4½-inch Gridley single spindle motor-driven turret lathe; 1¼-inch Gridley four-spindle turret lathe; No. 4 Hendey motor-driven knee-type milling machine; 16-inch Hendey geared head engine lathe; Dreses motor-driven full universal radial drill; 1½-inch National wedge grip heading and forging machine; National motor-driven double head bolt cutter; National die chaser sharpener; Elmore (Dwight Slate Co.) high-duty ball bearing single-spindle sensitive drill press, etc.

National-Acme Mfg. Co., Cleveland, Ohio. Multiple-spindle automatic screw machine in operation.

Niles-Bement-Pond Co., New York. 20-inch LeBlond engine lathe with all-geared heads; three-step cone pulley; LeBlond double back-geared lathe head; LeBlond universal milling machine; pneumatic clamp tool-post for locomotive driving wheel lathes and car wheel lathes; Pratt & Whitney small tools, etc.

Norton Co., Worcester, Mass. Alundum grinding wheels and other alundum abrasive products.

Revolute Machine Co., New York. Continuous electric blue-printing machine.

Sellers, William, & Co., Inc., Philadelphia, Pa. Turret tool-post for 42-inch car wheel lathe; turret tool-post for high-duty locomotive driving wheel lathe; set of three drivers for 42-inch car wheel lathe, etc.

Stoever Foundry & Mfg. Co., Myerstown, Pa. Automatic pipe bending machine; pipe threading and cutting-off machine.

Taylor Mfg. Co., James L., Bloomfield, N. J. Machinists' patternmakers' and boilermakers' clamps.

Tindel-Morris Co., Eddystone, Pa. Cold sawing machine and inserted tooth cold saws; grinders, etc.

Toledo Pipe Threading Machine Co., Toledo, Ohio. Hand-operated pipe threading tools, etc.

Underwood & Co., H. B., Philadelphia, Pa. Portable cylinder boring bar; portable crank-pin turning machine; portable machine for facing off riveting on crank-pins; locomotive pedestal facing machine.

Union Mfg. Co., New Britain, Conn. Lathe, planer, drill, valve, boring mill and car-wheel chucks.

Walworth Mfg. Co., Boston, Mass. Stillson wrenches; Miller ratchet stocks and dies, etc.

Watson-Stillman Co., New York. Hydraulic jacks; centrifugal pumps, etc.

Westinghouse Air Brake Co., Pittsburg, Pa. Air brakes, seven-car passenger train rack equipped with PC equipment, etc.

Westinghouse Machine Co., Pittsburg, Pa. LeBlanc steam condenser and LeBlanc vacuum pump, turbine driven.

Yale & Towne Mfg. Co., New York. Electric hoists, I-beam trolleys, chain blocks, etc.

* * *

DRY HIGH-SPEED TOOL GRINDING

Fine surface cracks are often found on high-speed steel tools after grinding, especially when grinding with a wet wheel. A class of work that is particularly troublesome in this respect is hardened disks such as slitting saws, washers, etc., ground on the side. The cracks develop radially, and although of microscopic depth and really not injurious in most work, they give it a defective appearance and cause rejections and losses. It is pretty well settled now that these cracks are caused by momentary overheating of the steel which results in local expansion sufficient to exceed the elastic limit of the metal. The cracks grow with each revolution of the work, radially to the edge of the disk. The remedy is to use a soft wheel and grind *dry*. When work is ground dry with a soft wheel the pressure is reduced as compared with wet grinding, and thus local overheating is also reduced. Many have the idea that if tools are ground wet there is no danger of overheating. This is a mistake; water cannot be forced to the exact point of contact of the wheel and work, and its local cooling effect is comparatively slight. The effect of the water in wet grinding is to keep down the temperature of the wheel and work generally, but not locally.

On account of the tendency to exceed the safe pressure and ruin tools by overheating when grinding with a wet wheel, some tool experts now recommend dry wheels for all high-speed steel tool grinding. If water is used, it should be used only with the idea of keeping down dust and washing the wheel and tool, and not as a cooling medium of much efficiency.

PERSONALS

Robert S. Alter, secretary of the American Tool Works Co., Cincinnati, Ohio, was married June 25 to Margaret Carel Maury.

George S. De Laney, superintendent of the Stevens-Duryea Automobile Co., Chicopee Falls, Mass., has been promoted to the position of manager.

Alex. Luchars, publisher of MACHINERY, sailed with his family on the *Oceanic* June 15 for a three month's tour in Europe, principally by automobile.

R. D. Reed, for several years with the H. B. Smith Co., Westfield, Mass., has been made manager of the Springfield Foundry Co.'s new plant in Springfield, Mass.

Wilson P. Hunt, of the Moline Tool Co., Moline Ill., recently took an extended eastern trip, including Toronto, Buffalo, National Machine Tool Builders' Association convention at Rochester, Pittsburg and Cincinnati.

F. H. Wilder has been promoted from the position of foreman of the "J and L" department to the position of foreman of the chassis assembling department of the automobile section of the New Departure Mfg. Co., Bristol, Conn.

W. S. Rogers, president of the Bantam Anti-Friction Co., Bantam, Conn., is now on his annual trip to Germany visiting his company's allied German companies, manufacturing balls and ball bearings, and arranging for the coming year's contracts. Mr. Rogers expects to attend the meeting of the American Society of Mechanical Engineers in joint convention with the British Institute of Mechanical Engineers in Manchester and London in July.

C. H. Kingsbury, for the past twelve years manager of the Niles-Bement-Pond Co.'s Boston office, will take a vacation of several months on account of ill-health. Previous to his departure the managers and heads of departments of the Hill-Clarke & Co., Inc., Chandler & Farquhar Co., Prentiss Tool & Supply Co., and Manning, Maxwell & Moore called upon Mr. Kingsbury and extended their best wishes for rapid return of health. They presented him with a Masonic charm, suitably engraved as a token of friendship. Mr. M. Estabrook of the New York office will have charge of the Boston office during Mr. Kingsbury's absence.

Louis I. Wightman, for the past six years advertising manager for the Ingersoll-Rand Co., 11 Broadway, New York, has resigned his position, the resignation taking effect August 1, and will open an office in New York City as an independent specialist in machinery advertising, handling the accounts of manufacturers of machinery and engineering products. Mr. Wightman is well fitted for this line of work by his wide experience in managing one of the largest advertising departments in the machinery field, which was preceded by some years' experience in practical mechanical and electrical engineering, construction work, machine design and manufacture and machinery selling. Mr. Wightman is a graduate engineer, the author of a text-book on compressed air, and an authority on compressed air subjects.

* * *

OBITUARIES

James Wilson, master mechanic of No. 5 machine shop, Ludlow Mfg. Associates, Ludlow, Mass., died at his home in Ludlow, June 5, aged forty-four years.

W. P. Bettendorf, president of the Bettendorf Steel Car Co., Davenport, Iowa, died at his home in Davenport, June 3, in the fifty-third year of his age. Mr. Bettendorf organized the company of which he was president and built the works which cover thirty acres of ground. A recent addition is 2100 feet long. He was the inventor of several improvements in agricultural machinery and railway cars.

John H. Whittemore, a pioneer in the malleable iron industry, died at his home in Naugatuck, Conn., May 28 after a short illness. Mr. Whittemore began in the malleable iron business in 1858, the firm name being Tuttle & Whittemore. After several years the concern was reorganized and the name changed to the Naugatuck Malleable Iron Co. Mr. Whittemore was interested in the malleable iron industry in Cleveland, Chicago, Indianapolis, Toledo, Bridgeport and New Britain.

Charles E. Bailey, a veteran armorer, who retired fifteen years ago after thirty-one years of service as foreman in the Water Shops, United States Armory, Springfield, Mass., and a total of forty-five years in the government shops, died at his home in Springfield, Mass., May 10, aged eighty-three years. Mr. Bailey devised and perfected many valuable fixtures and tools. Col. Benton during his term as commandant recommended to the government that Mr. Bailey receive liberal extra pay for valuable service, but the grant was never made. At the time the Rock Island, Ill. shops were being planned, Mr. Bailey was sent there to prepare plans for the lay-out of machinery. He had charge of the armory exhibit at the Chicago World's Fair in 1903. He was a native of South Berwick, Me.

William P. Davis

D. Wheeler Swift, inventor of printing and automatic machinery used in the manufacture of envelopes, died of paralysis at his home in Worcester, Mass., June 14, aged seventy years. Mr. Swift went to Worcester in 1864 and entered the employ of David Whitcomb who was just starting in the envelope business. He worked twenty years as superintendent for the Whitcomb Envelope Co., during which period he and his brother produced and perfected new machinery which would successfully fold and gum envelopes. In 1884 the Logan, Swift & Brigham Envelope Co. was organized and Mr. Swift was made president. His inventions of new machinery were largely responsible for the success of the company. The United States Envelope Co. was founded in 1898 and Mr. Swift was elected director and mechanical superintendent, which position he filled during the remainder of his life.

John M. Rogers, of the John M. Rogers Works, Inc., Gloucester City, N. J., died in the Cooper Hospital, Camden, N. J., June 4, following an operation, aged sixty-eight years. He was born in Key West, Fla., and his early life was spent as purser on the side-wheel steamer *Golden Rule*, running between New York and the Isthmus of Panama. After the wreck of this vessel off Roncador Reef, he spent a few years in the employ of his uncle, the late Francis Morris. After his marriage he resided in Wilmington, Del., where he entered the printing business, having full charge of the John M. Rogers Press for several years. In later years he became actively engaged in the machine business, being one of the pioneers in the manufacture of measuring tools. Mr. Rogers developed the John M. Rogers Works, Inc., Gloucester City, N. J., of which he was president at the time of his death. He leaves a widow and two sons, J. Morris Rogers and Francis C. Rogers.

William P. Davis, president of the W. P. Davis Machine Co., Rochester, N. Y., died at his home in that city May 30, aged sixty years. Mr. Davis was born in Lima, N. Y., in 1850 and was educated in the public schools of Honeoye Falls. Early in life he manifested a strong mechanical bent, and entered a machine shop at Auburn when only fourteen years old. Eight years later Mr. Davis started a machine shop of his own in North Bloomfield, N. Y., and later removed to Canandaigua, N. Y., where he remained three years. In 1890 he moved to Rochester, where quarters were occupied in the Borseline building at the foot of Commercial St. In 1894 he organized the W. P. Davis Machine Co., and in 1897 the present large brick plant in which about 200 men are employed was erected on St. Paul St. near the New York Central station. Mr. Davis was a charter member of the National Machine Tool Builders' Association and was prominently identified with it from the time of its organization, having always filled an official position. He was treasurer of the association at the time of his death, which office he had held since 1906. It was largely through his efforts that the last meeting of the association was held in Rochester but his last illness prevented him taking part. He leaves a widow, one daughter, an aged father and brother, Charles F. Davis, secretary and treasurer of the W. P. Davis Machine Co.

* * *

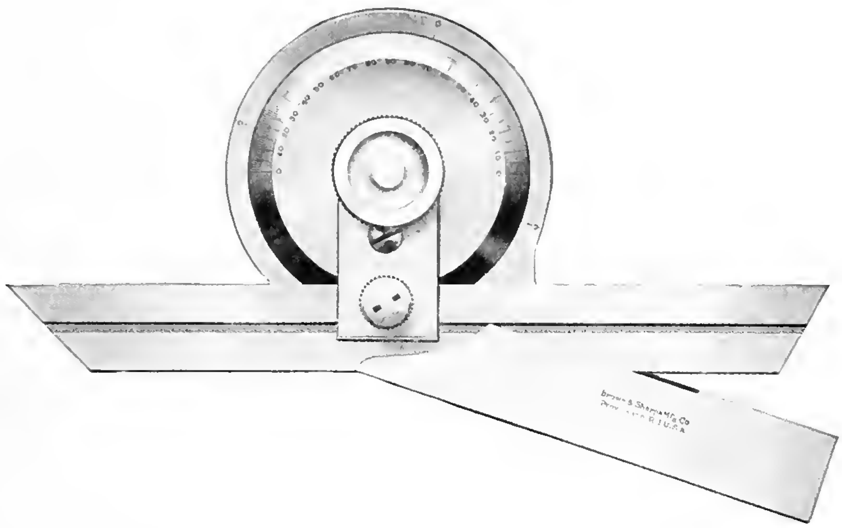
There have been many attempts to formulate an explanation of a steam turbine's operation which will be understandable by the non-technical man. One of the simplest we have seen is given by the *Daily Star* of Lincoln, Neb.:

"The turbine stands about 6 feet high and is about 6 feet through. It is cylindrical. The turbine wheels inside are used to keep the acids and zinc stirred so as to generate electricity rapidly."

This was contained in a comment on an accident to a turbo-generator. No wonder it blew up!—*Engineering News.*

Here is a new tool, accurate and inexpensive, for laying out or establishing angles.

B. & S. IMPROVED BEVEL PROTRACTOR



The protractor is made with one side flat so that it can be laid flat on the work or paper—a feature that adds greatly to the utility of the tool.

The blade can be moved separately from the dial and can be moved back and forth its entire length. It is clamped independently of the dial and this adapts the tool for work where other protractors cannot be used.

DIAL GRADUATED TO DEGREES

All graduations on the dial are accurately made, the graduations reading to degrees. These graduations extend over an arc of 180°, reading from 0 to 90° from each extremity of the arc. The tool is intended for work that does not require a Vernier, a point wherein it differs from the Universal Bevel Protractor. The dial turns on a large central stud which is hardened to prevent wear. When the dial is set, this clamp nut holds it rigidly in place, doing away with all danger of slipping and consequent inaccuracies in the measurements.

The Protractors are made in two sizes, with 6" or 12" blades.

Send for new folder.

BROWN & SHARPE MFG. CO.

PROVIDENCE, R. I., U. S. A.

COMING EVENTS

June 20-July 6.—Detroit Industrial Exposition, Detroit, Mich., under the auspices of the Detroit Board of Commerce to accelerate the city's industry and commerce. The exposition grounds will be on the Detroit River where a large exposition building is being erected to be used in conjunction with the Wayne Pavilion. W. G. Rose, manager, Detroit Board of Commerce, Detroit, Mich.

July 26-29.—Joint meeting of the American Society of Mechanical Engineers and the British Institute of Mechanical Engineers in Birmingham and London, England.

July 28-30.—Convention of the Society of Automobile Engineers, Detroit, Mich. Subjects for discussion: "Gears," "Commercial Vehicles," "The Electric Vehicle," "Gasoline Motors," "Metals and Treatment," "Wheel Rims, Tires, etc.," "Bearings," "Driver's Seat on Left-hand or Right-hand," "Final Drive," "Factory Systems," "Contests," etc. Howard E. Coffin, president, 1451 Broadway, New York.

August 16-19.—Annual convention of Traveling Engineers' Association, Clifton Hotel, Niagara Falls, Canada. Subjects to be discussed are: "Fuel Economy," "Superheating," "Education of Firemen," "Development of Air Brake Equipment," "Locomotive Lubrication," and "New Valve Gears." W. A. Thompson, secretary, N. Y. C. Car Shops, East Buffalo, New York.

October 10-14.—Annual convention of the American Street and Interurban Railway Association, Atlantic City, N. J. A. C. Donecker, secretary and treasurer, 29 West 39th St., New York.

SOCIETIES AND COLLEGES

Bulletin of Syracuse University, April, 1910.
General catalogue and catalogue of the summer session which is held July 5 to August 16. Address the University of Syracuse, Syracuse, N. Y.

Society of Automobile Engineers, 1451 Broadway, New York, has taken over the work of the Association of Licensed Automobile Manufacturers' mechanical branch and will broaden the activity of the association in its relation to the motor car industry. Its object is to collect, scientifically arrange, and disseminate motor car engineering data and information.

NEW BOOKS AND PAMPHLETS

Concrete from Sand Molds, by A. A. Houghton. 145 pages, 5½ by 7½ inches, 12 illustrations. Published by Norman W. Henley & Son, 132 Nassau St., New York. Price, $2.

This interesting book describes the processes of molding concrete, especially ornamental forms, in sand molds, the practice being similar to molding for metal castings. It is a revived art, there being evidence to show that it was practiced by the Romans. The work describes the process of preparing and mixing the sand for hardened sand molds, how to make sand molds from wood and metal patterns, construction of sand molds from clay, plaster, concrete, or other patterns, method of making cores, how to combine molds to mold large monolithic work, molding concrete brick with sand molds, facing molds with crushed granite, marble flour or any other material, etc.

The Polytechnic Engineer. 144 pages, 6 x 9 inches. Illustrated. Published by the Polytechnic Institute of Brooklyn, New York.

This work is published annually by the undergraduates of the Polytechnic Institute. Volume X contains the roster of the corporation, officers, officers of instruction, Polytechnic Institute engineering societies, board of editors, and among others the following technical articles: "Negative Track-Feeders," by Samuel Sheldon; "Some Experiments on the Casehardening of Steel by Gases," by John C. Olsen, John R. Brierley, and John S. Weiffenback; "Train Resistance Formulas and Speed-Time Relations," by William D. Ennis; "Deflections of Beams with Variable Moments of Inertia," by C. W. Hudson; "Gyration Stresses in Shafts," by D. D. Barlow; "Automobile Transmissions," by Edward O. Ericson; "Continuous Indicator Diagrams," by M. G. Farrell.

CATALOGUES AND CIRCULARS

Sprague Electric Co., 527 West 34th St., New York. Catalogue of electric hoists.

General Electric Co., Schenectady, N. Y. 18th Annual report to the stock-holders.

Ingersoll-Rand Co., 11 Broadway, New York. Bulletin No. 3017 on gas compressors.

Sprague Electric Co., 527 West 34th St., New York. Catalogue of flexible steel armored hose for compressed air or steam.

Emerson Electric & Mfg. Co., St. Louis, Mo. Bulletin No. 3707 of electric buffing lathes for alternating and direct currents.

Graton & Knight Mfg. Co., Worcester, Mass. Circular entitled "What Mr. Denniston Says," advertising G. & K. leather belting.

National Brake & Electric Co., Milwaukee, Wis. Bulletin No. 389 on types of National emergency and variable release brake valves.

Turner-Fricke Mfg. Co., Sharon, Pa. Catalogue of Turner-Fricke gas engines, illustrating and describing the construction in detail.

Westinghouse Machine Co., East Pittsburg, Pa. Circular W-M 501 on the Westinghouse-Le Blanc condensers for steam power plants.

Reynolds Machinery Co., Moline, Ill. Circular of Reynolds gear hobbing machine illustrated and described in the April, 1909, issue of Machinery.

Ingersoll-Rand Co., 111 Broadway, New York. Bulletins Nos. 306 and 3023 on Class O duplex steam-driven air compressors, and Class OC duplex Corliss driven air compressors.

Miami Valley Machine Tool Co., Dayton, Ohio. Blotter advertising 13-inch and 16-inch lathes; plain, cutter and reamer grinders; universal tool and cutter grinders; 12-inch and 14-inch drills, etc.

General Electric Co., Schenectady, N. Y. Bulletin No. 4737, illustrating and describing electric hardening furnaces designed for the hardening and tempering of tool steel. (See Machinery, November, 1909.)

Union Mfg. Co., New Britain, Conn. Circular advertising economical iron castings which in quality and net cost should give the highest satisfaction. The company has specialized on the work for forty years.

Carb-Ox Co., Rogers Park, Chicago, Ill. Catalogue of gas analysis instruments and allied specialties, used in the determination of boiler efficiencies, gas producers, etc., whether the fuel be coal, oil, gas or refuse.

National Brake & Electric Co., Milwaukee, Wis., Bulletin No. 388, "Types of National Motorman's Air Brake Valves." These air brake valves are designed for street railway urban and interurban service.

Chicago Bearing Metal Co., Chicago, Ill. *The Graphose Age* being the second number of a publication devoted to graphose-bronze, white brass, brass castings, babbitt metals, solder and other products of the company.

Crescent Machine Co., Leetonia, Ohio. Catalogue of Crescent wood-working machinery comprising band saws, universal saw tables, shapers, jointers, variety wood-workers, planers, planers and matchers, swing cut-off saw, disk grinders, etc.

Aerial Navigation Co. of America, Girard, Kans. Circular illustrating and describing the Call aviation engine built in two sizes—45 horsepower and 90 horsepower, weight 135 and 225 pounds respectively, price $700 and $1,200.

Negretti & Zambra, 38 Holborn Viaduct, London, E. C., England. Revised price list and instructions for acrometer, an instrument giving direct readings of the maximum cylinder pressure of internal combustion engines, compression, vacuum, etc.

Risdon Tool & Machine Co., 63 Canal St., Waterbury, Conn. Circular giving official organization and statement of its activities. The company designs and makes dies, models, tools, sub-press dies, light machinery, and does all kinds of light manufacturing.

Union Mfg. Co., New Britain, Conn. Catalogue of combination, universal, independent, geared scroll, scroll combination, planer, boring mill, car wheel, grinding machine, box body, round body and drill chucks. The company also builds special chucks of every description to order.

General Electric Co., Schenectady, N. Y. Bulletin No. 4732, containing upwards of fifty illustrations of installations of Curtiss steam turbine generators of various classes. The bulletin should interest central station managers and others concerned with the production of large powers.

W. F. & John Barnes Co., Rockford, Ill. Catalogue of the various styles and sizes of Barnes upright drills, horizontal radial drills, gang drills, drill press attachments and other machine tools. This catalogue is attractively arranged, and contains much that is of interest relating to drilling machinery.

Pawling & Harnischfeger, Milwaukee, Wis. Bulletin No. 18, illustrating and describing traveling electric hoists. Besides showing the various types of hoists made, the bulletin illustrates a number of interesting installations. It will interest the plant engineer, superintendent and other responsible men desirous of saving costs in handling material.

Cling-Surface Co., Buffalo, N. Y. Report of an interesting experience in the treating of a painted ten-inch heavy canvas belt which had been treated with "Cling-Surface" after having been condemned as being no good. After being treated with the "Cling-Surface," the belt ran at 850 R. P. M. and transmitted 85 H. P. without sign of slip, although the sag was 23 inches between pulleys.

Tate Jones & Co., Inc., Pittsburg, Pa. Circular No. 129 on fuel oil burning equipment for open-hearth furnaces. The Kirkwood oil burner is illustrated and described; also reversing valve stand, pumping, heating and regulating systems, etc. Views are shown of installations of the apparatus in foundries and steel works, and a piping diagram of oil fuel installation in an open-hearth steel plant is included.

L. A. Williamson Co., 79 Milk St., Boston, Mass. Booklet describing Williamson's electric "Flexilyte," which is a portable electric light extension containing a cord that can be unwound to any desired length and which is held fast by a sliding catch. The fixture is neat in appearance and convenient to use, there being no extra length of cord hanging in loops, the excess length being coiled within the fixture.

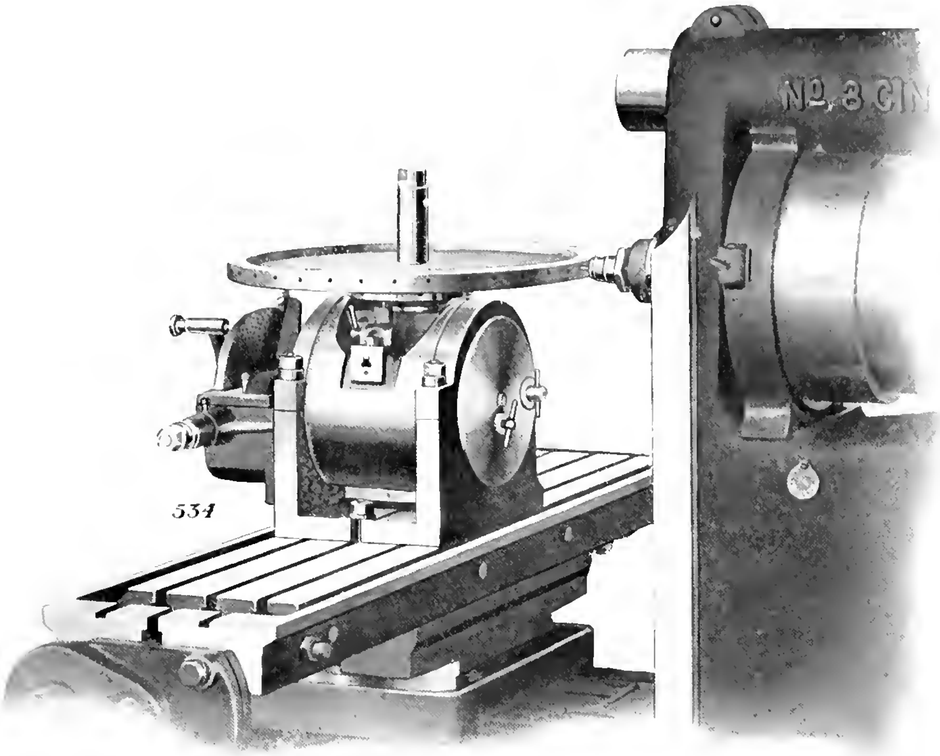
De Laval Steam Turbine Co., Trenton, N. J. Treatise on De Laval centrifugal pumps, giving the results of tests and illustrations and descriptions of various types of centrifugal pumps for all classes of service. The characteristic curves of several sizes of pumps designed to meet the requirements of representative classes of service are reproduced, and testing apparatus illustrated. The construction of pumps is shown disassembled, and much matter of engineering interest is included. The treatise is recommended to the attention of all interested in the possible use and operation of centrifugal pumps.

National-Acme Mfg. Co., Cleveland, Ohio. Parts and tools catalogue for the Acme automatic multiple-spindle screw machine. It illustrates the component parts of head, spindles in head, spindles in slide, main slide, cut-off and forming cross-slides, top slides, feed mechanism, spindle stopping mechanism, power transmission—drive, power transmission—control, power transmission—back gears, power transmission—housing, countershaft, frame, oil system, stock carriage, cams, chucks, box-tools, tools for top slides, tools for cross-slides, dies and drill-holders, etc. The book is intended particularly for men in charge of automatics and automatic screw machine departments. Copies are sent free upon request.

Green Fuel Economizer Co., Matteawan, N. Y. Pamphlet entitled "Foundry Heating System," containing detailed descriptions of two novel installations recently made by the company. In one of these installations, a foundry of 515,000 cubic feet capacity and having walls made up entirely of glass was successfully heated by a small four-section "Positivflo" heater. The pamphlet also describes a novel arrangement of ducts whereby the heat is supplied just where needed by the workmen, at the same time furnishing them with fresh air, and forcing the smoke and gases out of the building through the skylight. By using the right number of heater sections, and regulating the volume of air delivered, it is also possible to maintain the foundry at such temperature at night that cores and molds will be prevented from freezing.

Ward Leonard Electric Co., Bronxville, N. Y., recently published a pamphlet describing a new generator and storage battery outfit for automobile lighting. The ingenious feature of the device is the provision of an electrically controlled magnetic clutch between the engine and the generator. This control connects the generator with the power whenever the gear shifting lever is moved from the neutral position. When the engine and generator have speeded up so that the voltage induced becomes slightly greater than that of the storage battery, an automatic electric switch connection is closed between them, charging the battery. Whenever the voltage of the generator falls below that of the cells, this switch automatically opens, preventing an improper discharge of the battery. When the engine and generator speeds become so high that the charging amperes reach a predetermined amount, an automatic electric switch breaks the circuit to the clutch, thus slowing down the dynamo armature. When this again has been reduced below the critical point, the clutch circuit is thrown in again, accelerating the dynamo. It will thus be seen that the dynamo speed is kept within predetermined speed limits, no matter how high the engine speed attained. Two storage batteries are provided, either of which may be used for the lighting service, and the other for ignition. The storage feature provides for both light and ignition over periods when the engine has been stopped for some time.

CINCINNATI UNIVERSAL TOOL ROOM MILLERS



Thirty-six holes ¼″ diameter are spaced on the periphery of a 19″ disk rigidly held on a 12″ Index Head. They are first drilled, then bored a trifle under size, and finally reamed to a plug gauge fit with a specially ground ¼″ end mill. The error between holes is less than one thousandth (—.001″). To get such results requires a miller that is accurate all over.

This is a good illustration of the best method of handling work of larger diameter than the index centers will swing. The swivel trunnions on our Dividing Head are large in diameter and fully protected in all positions, insuring permanency of alignment at any angle to which the spindle may be set.

Cincinnati Millers are as famous for their accuracy as for their productive capacity.

The Cincinnati Milling Machine Company

CINCINNATI, OHIO, U. S. A.

European Agents—Schuchardt & Schutte, Berlin, Stockholm, St. Petersburg and Copenhagen. Alfred H. Schutte, Cologne, Brussels, Milan, Paris, Barcelona and Bilbao. Donauwerk Ernst Krause & Co., Vienna, Budapest and Prague. Chas. Churchill & Co., London, Birmingham, Manchester, Newcastle-on-Tyne and Glasgow.

Canadian Agent—H. W. Petrie, Limited, Toronto, Montreal and Vancouver.

Australian Agents—Thos. McPherson & Son, Melbourne.

CONTENTS FOR JULY

The first column of page numbers applies to the Engineering and Railway Editions; the Second to the Shop Edition

This whole mechanism would seem to be as well adapted for development into a railroad car lighting apparatus, as for automobile use.

International Harvester Co., Chicago, Ill. Circular describing plan of industrial accident department of the International Harvester Co. and associated companies, comprising International Harvester Co. of Canada, Ltd., International Flax & Twine Co., Wisconsin Steel Co., Illinois Northern Ry., Chicago & West Pullman & Southern Ry., Owasco River Ry., and Deering Southwestern Ry. The scale of compensation provided is as follows: In case of death there will be paid three years' average wages, but not less than $1,500 nor more than $4,000. In case of the loss of a hand or foot, one and one-half years' wages, but in no event less than $500 nor more than $2,000. For the loss of both hands or both feet, or one hand and one foot, four years' wages, but in no event less than $2,000. In case of other injuries, one-fourth wages during the first thirty days of disability; if disability continues beyond thirty days, one-half wages during the continuance thereof, but not for more than two years from the date of the accident. Thereafter, if total disability continues, a pension will be paid. Provision is made so that the employes may increase the benefits to be paid during the first thirty days of disability to an amount equal to half-wages. This is accomplished by the creation of a benefit fund, to be paid by the company, be sufficient to provide half-pay for all injured which employes earning $50 per month or less will contribute 6 cents a month, employes earning more than $50 and less than $100, 8 cents These small contributions will, together with the one-fourth wages a month, and employes earning more than $100, 10 cents per month. employes during the first thirty days of disability.

TRADE NOTES

Bausch Machine Tool Co., 200 Wason Ave., Springfield, Mass., has made plans for building a three-story addition, 50 by 100 feet.

Lees-Bradner Co., Cleveland, Ohio, manufacturer of gear generating machines, is building an addition, 30 x 50 feet, to its factory.

Deane Steam Pump Co., Holyoke, Mass., branch of the International Steam Pump Co., will build a new foundry plant 290 feet long, 150 feet wide.

C. W. Hunt Co., New York, builder of coal handling, conveying and hoisting machinery, has appointed C. T. Anderson manager of the Chicago office, 1616 Fisher Bldg.

Sebastian Lathe Co., Covington, Ky., has just completed a 45 x 80 foot single story, concrete floor, trussed roof addition to its shop, and reports orders ahead for the next three months.

Knox Automobile Co., Springfield, Mass., is building an addition to its plant, 66 x 125 feet, six stories and basement. The addition will increase the company's manufacturing space about 25 per cent.

Wisconsin Engine Co., Corliss, Wis., has appointed George B. Foster its Chicago sales manager. His office will be located in the Fisher Building, Chicago. Mr. Foster represents the company in the Chicago district.

Springfield Foundry Co., Springfield, Mass., has bought a large tract of land on the main line of the Boston & Albany R. R. and will at once build a large plant to meet the requirements of its increasing business.

Cutler-Hammer Mfg. Co., Milwaukee, Wis., maker of electric controlling devices will hereafter manufacture the Kohler system automatic push button control for printing presses, motor-driven tools, etc. This system was developed by Kohler Bros. of Chicago.

Globe Stove & Range Co., Kokomo, Ind., has largely increased its plant. It has installed a Newten cupola of 14 tons hourly capacity and an outfit of ladles and trucks for an industrial railway, all furnished by the Northern Engineering Works, of Detroit, Mich.

Ready Tool Co., Bridgeport, Conn., has engaged Mr. G. C. Parker to act as its sales manager. Mr. Parker has been for the past three years connected with the William J. Smith Co., New Haven, Conn., and has had successful experience marketing machine shop accessories.

Westinghouse Machine Co., East Pittsburg, Pa., held its annual meeting of stockholders June 21. The orders received for shop products during the fiscal year ending March 31 aggregated $5,123,612.23, an increase of $2,322,536.88 as compared with the previous fiscal year.

C. W. Hunt Co., New York, builder of coal handling, conveying and hoisting machinery, has opened offices in State Bank Bldg., Richmond, Va., and also at 607 Rhodes Building, Atlanta, Ga., with Mr. W. F. Lee, for several years preliminary engineer to the company, in supervision.

Peerless Automatic Machine Co., Cleveland, Ohio, manufacturer of automatic screw machines, was recently burned out, the loss being $15,000, partly insured. The company will erect a new plant immediately, and expects to be ready to handle business again in about ninety days.

Penberthy Injector Co., Detroit, Mich., numbered its 600,000 Penberthy automatic injector on March 29, 1910. It is estimated that 600,000 size G G injectors would handle about one-third the amount of water flowing over Niagara Falls, or approximately 2,520,000,000 gallons per hour.

Crocker-Wheeler Co., Ampere, N. J., at a recent meeting of directors, elected the following officers: President, Schuyler Skaats Wheeler; first vice-president, Gano Dunn; third vice-president, Arthur L. Doremus; chief engineer, Gano Dunn; secretary, Rodman Gilder; treasurer, W. L. Brownell.

LaSalle Machine & Tool Co., LaSalle, Ill., manufacturer of surface grinders and foot presses, has contracted for an addition to its plant, 48 x 95 feet, which will practically double the capacity of its shop built only a little more than two years ago. The construction calls for the completion of the new addition August 1.

G. M. Yost Mfg. Co., Meadville, Pa., has purchased the plant and equipment of the Williamson Vise Co., Bradford, Pa. The entire outfit of the Williamson Vise Co. will be moved to Meadville and the G. M. Yost Mfg. Co. will make a complete line of vises for machinists, patternmakers, wood-workers, jewelers, blacksmiths, and toolmakers.

M. L. Andrew & Co., Cincinnati, Ohio, manufacturer of wood-working machinery and multiple-spindle drills for metal drilling is now located in its new factory, corner of Colerain Ave. and Alabama St. The new location gives the company excellent facilities. The plant has been thoroughly equipped with modern tools and the output will be greatly increased.

Jacobs Mfg. Co., Hartford, Conn., chuck maker, has posted a notice to the effect that its factory will be closed the first week in August, and its employes who have worked nearly as full time as possible up to August 1 will be given a vacation for a week with full pay, paid in advance. In order to fill orders, it will be necessary for the plant to run Saturday afternoons until August 1.

Cooper-Hewitt Electric Co., New York, has recently purchased the substantial structure located on the corner of Grand and 8th Sts., Hoboken, N. J., for the manufacture of Cooper-Hewitt electric lamps. The new factory will be fully equipped with modern machinery and devices for the manufacture of the lamps. The plant is four-story and basement, the total space being 60,000 square feet.

Reliance Electric & Engineering Co., Cleveland, Ohio, announces that its armature shifting type of variable speed motor will be known as the Reliance adjustable speed motor instead of the Lincoln variable speed motor as formerly. This change is made necessary in order to better describe the type of motor in accordance with the present standard terms adopted by the American Association of Electric Motor Manufacturers.

International Acheson Graphite Co., Niagara Falls, N. Y., has adopted the name "Gredag" for its graphite grease in order to distinguish it from other grease products which contain impure natural graphite. The graphite blended with high-grade grease is an electric furnace product, exceedingly pure. The graphite is soft and unctuous and is a perfect lubricant in itself. It is claimed that in "Gredag" all the merits of graphite and grease are combined, making a lubricant of high quality and value.

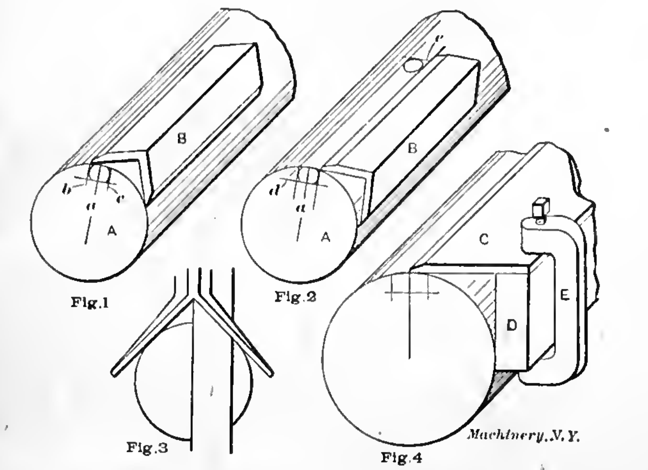
Cincinnati Planer Co., Cincinnati, Ohio, has completed the removal of machinery to its new building at Oakley, a suburb of Cincinnati.

Supplement to MACHINERY, August, 1910

Operations for the Article in this number entitled "Machine Shop Practice—Key Fitting"

SHOP OPERATION SHEET NO. 142.

Oscar E. Perrigo MACHINERY, August, 1910



Laying Out a Shaft Keyway

NOTE.—It is assumed that it is necessary to keyseat the shape *A* by hand, either because of its size or position which makes the use of a planer or milling machine impracticable.

1. Rub moistened sulphate of copper, (blue stone) over the outer surface and end of the shaft where the keyway is to be laid out.

2. Scribe a center line *a* from the center of the shaft to the point where the center of the keyway is to be. This line may be quickly drawn by the use of a center square as illustrated in Fig. 3, or the center of the shaft may be located and a line drawn through it and the keyway center.

3. Lay off arcs on either side of the center line, by the use of dividers set to one-half of the width of the keyway, and scribe lines *b* and *c* tangent to these arcs and parallel to the center line *a*.

4. Apply the keyseat rule *B* to the shaft, as shown in Fig. 1, with its upper edge set to coincide with the line *b* which represents one side of the keyway. Hold both blades of the keyseat rule firmly against the shaft and with a scriber, draw a line as long, or somewhat longer than the keyway to be cut.

5. Shift the keyseat rule to the position shown in Fig. 2; that is so that its edge coincides with line *c*, and scribe a second line.

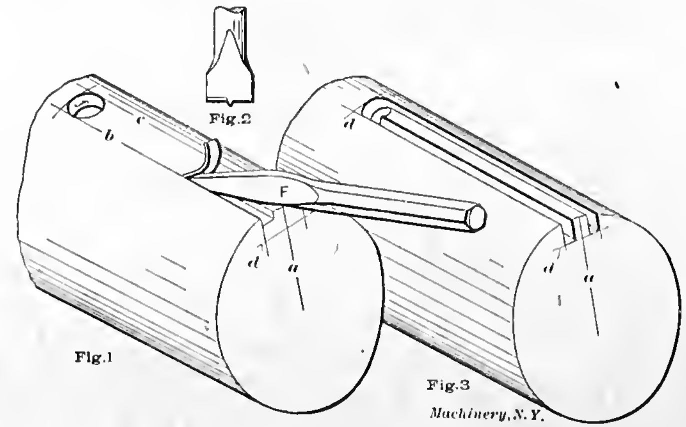
6. Across these lines, draw a line *e* indicating the end of the keyway. Just within this line and tangent to the side lines, scribe a circle with dividers.

7. Upon the end of the shaft, draw the depth line *d* at right angles to the center line.

NOTE.—Should the shaft be so large in diameter that the keyseat rule shown in Figs. 1 and 2, will not embrace it sufficiently to insure parallel lines, a practical device for the purpose may be improvised as shown in Fig. 4, by using a broad straightedge or plate *C*, and a parallel strip *D*, attached to each other by two screw clamps at the ends.

SHOP OPERATION SHEET NO. 143.

Oscar E. Perrigo MACHINERY August, 1910



To Chip a Keyway in a Shaft

NOTE.—The keyway to be cut is supposed to have been laid out with lines on the curved surface indicating the width and length of the cut, and on the end indicating the width and depth.

1. Make a deep punch mark in the center of the circle previously laid out at the end of the keyway, and with this mark as a starting point, drill a hole *f* slightly deeper than the depth of the keyway, using a teat drill such as is illustrated in Fig. 2. This type of drill, as its shape indicates, leaves the bottom of the hole flat. A hole at the end of the keyseat is not, of course, absolutely necessary when the latter is to be cut by hand, but when the work is done by planing, such a hole provides clearance for the tool at the end of the stroke.

2. With a stout cape chisel *F*, somewhat less than one-third the width of the keyway, and held in the position shown, begin a light cut at the end of the shaft and slightly inside of the side line. Carry it steadily and at an even depth, back to the end hole *f*. Repeat the cut as many times as is necessary to cut nearly down to the depth line *d*.

NOTE.—There is no fixed rule for determining the depth or width of a keyway, but a good general rule which corresponds closely to average practice is to make the width equal to one-fifth the diameter of the bore and the depth to one-half the width, measuring at the side.

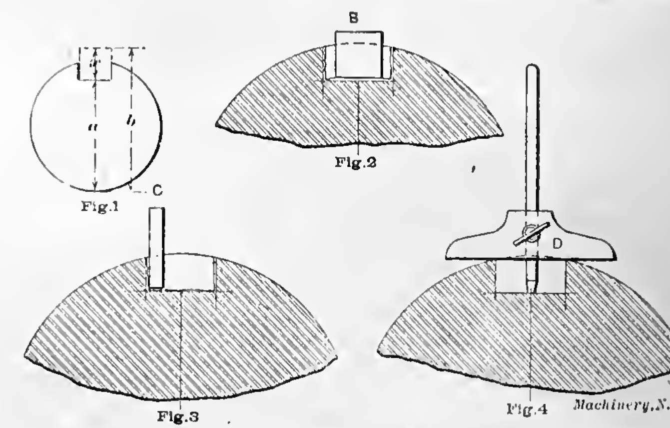
3. Proceed in the manner described in Step 2, to chip another channel at the opposite side of the keyway and slightly inside the scribed line. When this channel has also been cut to depth, the work will appear as shown in Fig. 3.

4. With a wider chisel, proceed to cut out the central rib between the two channels, making as many cuts as necessary and carrying them down nearly to the depth line *d*.

NOTE.—In chipping a long groove, it is necessary that an equal depth be maintained through its entire length, otherwise the proper depth will be more difficult to hold with each successive chip. There will also be more difficulty in keeping the cut straight laterally. The chisel should be slightly wider at the cutting edge than farther back, to provide clearance.

SHOP OPERATION SHEET NO. 144.

Oscar E. Perrigo MACHINERY, August, 1910



To Finish a Keyway by Filing

NOTE.—After the keyway has been cut as close to the line as is practicable by chipping, as described on the preceding sheet, it is finished to the correct width and depth by filing.

1. Select a second-cut square file of the blunt type, if possible; that is one whose sides are parallel throughout its length. Use this as at *B*, Fig. 2, to file the bottom of the keyway and straighten, somewhat, any unevenness there may be at the sides. Hold the point down firmly with the left hand to prevent any rocking motion, and be careful not to mar or misshape the corners of the keyway at the end of the shaft.

2. Set the depth gage *D*, Fig. 4, to the required depth and apply this in the position shown, and at different points to insure a uniform depth throughout the length of the keyway. Before using this gage, all burrs should be carefully removed from the edges on each side.

3. There will be a short portion of the keyway next to the end hole that is not conveniently reached with the file. Chip this out carefully with a light, thin cold chisel and square out the end of the keyway in the same manner.

4. Select a second-cut "hand file" with one "safe edge," and holding the file as indicated at *C*, Fig. 3, with the safe edge down, file the left side of the keyway exactly to the line. With the end of a scale, test the angle to see that the side is square with the bottom.

NOTE.—The edge or side of a file is said to be "safe" when it is without teeth and finished smooth. The advantage in having one of the sides smooth is that it can be placed next to a finished surface, which would be spoiled or marred if subjected to additional filing.

5. File the right side as described in Step 4. Test the width of the keyway with the key to be used. It should crowd tightly down to the bottom of the keyway at all points in its length.

NOTE.—When keyseats are being machined in a number of shafts and hubs, much keyfitting can be eliminated by taking measurements as indicated at *a* and *b*, Fig. 1, as then slight variations in the diameter of the shaft or hub will not affect the dimensions *x*.

HIGH-PRESSURE CYLINDER DIAMETERS FOR AIR COMPRESSORS—I

Method of Using the Accompanying Charts.

The diameters of high-pressure cylinders for compound air compressors are found instantly from the accompanying charts for varying pressures and altitudes, when the low-pressure cylinder diameter and the stroke have first been computed with reference to the required piston displacement. The dotted lines and arrows in the diagrams indicate the procedure when the diameter of the low-pressure cylinder is 20 inches and the air compressed to 200 pounds gage pressure. The ratio between the cylinder diameters so found divides the load equally between the two stages, provided the intercooler abstracts all the heat due to compression in the first stage.

The ratios of cylinder areas in the charts are obtained from the absolute ratio of compression.

Example: Compression of 150 pounds gage pressure required.

Absolute pressure = 150 + 14.7 = 164.7 pounds.

Absolute ratio of compression = 164.7 ÷ 14.7 = 11.2.

The square root of this ratio is the ratio of the low-pressure piston area to the high-pressure piston area, or

$$\sqrt{11.2} = 3.35 = \text{ratio of cylinder areas.}$$

A table of absolute ratios of compression for various pressures and altitudes is given below:

Table of Absolute Ratios of Compression.

Gage Pressure, Pounds	Absolute Ratio of Compression		
	Sea Level	5000 feet	10000 feet
80	6.44	7.55	8.92
100	7.80	9.20	10.90
125	9.50	11.25	13.40
150	11.20	13.30	15.90
200	14.60	17.40	20.80
250	18.00	21.50	25.80
300	21.40	25.60	30.70

The general formula for determining the high-pressure cylinder diameter is:

$$d = \sqrt{\frac{D^2}{\sqrt{\frac{P_1 + P_2}{P_1}}}}$$

in which d = *diameter of high-pressure cylinder,*
D = *diameter of low-pressure cylinder,*
P_1 = *initial pressure,*
P_2 = *terminal gage pressure.*

THE ELLIS ADDING TYPEWRITER

THE PRINCIPLE OF THE ADDING MECHANISM, AND ITS APPLICATION TO A NEW TYPE OF MACHINE

By RALPH E. FLANDERS

THE commercial adding machine is so fearfully and wonderfully made, that it might well seem a reckless undertaking to describe it in a general way for the general mechanical reader. The temptation is strong, however, in the case of the machine here illustrated, for three reasons. The first of these is the courtesy of the makers, the Ellis Adding Typewriter Co. of Newark, N. J., who went beyond the usual bounds in giving explanations and offering facilities for investigation. The second is the fact that the machine, while very highly developed, is yet so arranged that the principles involved can be easily and clearly illustrated. The third reason is the fact that the whole mechanism is full of suggestion to the designer of automatic machines in other lines, on the score of the particular movements employed, as well as on the score of the general orderliness of the design.

Fig. 2. Sample of Double-column Work done by the Machine

With this preamble, and with the assurance that the mechanism will be described in its larger features only, it is hoped that the reader will have the courage to follow the explanation through.

The Work of the Adding Typewriter

First let it be briefly stated what this machine is and what it will do; we can then pass on to a discussion of the way in which it performs its work. It is a combination of two completely developed machines—a visible typewriter and an adding machine, both writing on the same line on the same piece of paper, in plain sight of the operator, and each designed to possess all the advantages with which the best separate machines of its class are provided.

An example of the work of which the machine is capable is shown in Fig. 2, which illustrates a statement, including both debit and credit accounts written down indiscriminately, with each set of items added up and printed in a total at the bottom. The writing is done with the typewriter in regular typewriter fashion, and the figures are set up and printed in regular adding-machine fashion, on the same line and at the same time that the reading matter is written. This evidently requires two adding mechanisms, or two "accumulators" as they are called, one for the debit and the other for the credit column. This provision of two accumulators with the accompanying adjustments for their convenient use in relation to each other, is a novel feature in adding-machine construction.

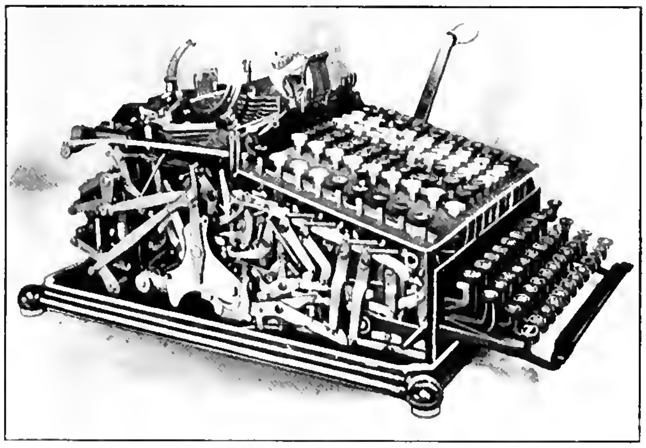

Fig. 3. Front and Left-hand View of the Machine with the Case Removed

Besides this, the machine is adapted to perform numerous other "stunts" such as the printing of items in a series of vertical columns, and the adding of these columns into totals both horizontally and vertically. Finally these totals, both horizontal and vertical, may be added together in a grand total. This operation is useful for such work as cost sheets, etc. Discounts may also be reckoned, amounts may be subtracted from each other, and so on, enabling the machine to do a wide range of commercial work.

Perhaps this recital of the intricate processes of which the machine is capable sounds rather confusing, but it will be made plain by the following description of the action of the adding mechanism.

The Principle of Action of the Adding Machine

Figs. 5, 6, 7 and 8 illustrate the principle on which the machine works. Figs. 1 and 10 show that the adding keyboard is composed of nine vertical rows of nine keys each. The lower key of each row is numbered 1, the next 2, and so on up to 9. Of the nine vertical rows the first one on the right is for

units and the next for tens, etc.; or, since the punctuation is usually set for reckoning in dollars and cents, the first is for cents, the next for dimes, and the succeeding rows for dollars.

Figs. 5 and 6 show digrammatic sections through the machine along the line of any one of these vertical rows of adding keys, say the first or cents column for instance. The keys are shown at *G*. Other important parts of the mechanism are the rack *A*, the type sector *F* by means of which the

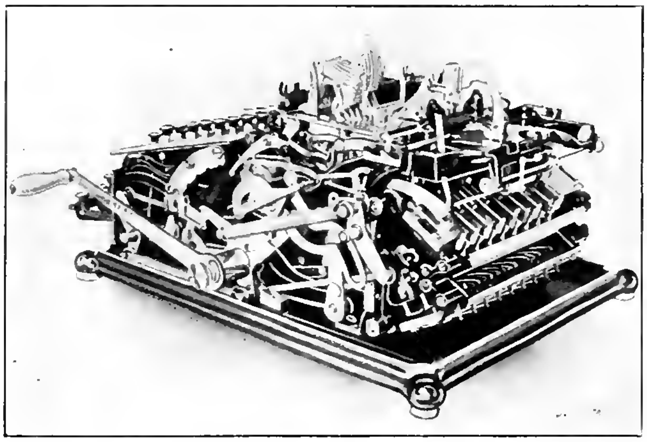

Fig 4 Rear and Right-hand View with Case Removed, showing Operating Mechanism and Accumulators

numbers are printed on paper carried by roller *K* and the accumulator wheels *B*, by which the addition is performed. All these, as well as the other moving mechanism shown in Figs. 5 and 6 are duplicated for each one of the nine rows of keys, there being nine racks, nine type bars, nine sets of accumulator wheels, etc., in all.

The adding mechanism is operated by the movement of rack *A*. This movement takes place under the influence of spring *O* whenever stop *N* is swung back as shown in Fig. 6 by the operation of the handle of the machine. The length of the movement which spring *O* thus gives to rack *A* is determined by keys *G*. If the figure $476.34 is set up on the keyboard, for instance, key "4" will be depressed in the cents column, and when the movement of the rack takes place, the rack teeth beneath the accumulator wheel will have moved four spaces.

This is more clearly seen in Fig. 5 where each of the keys *G* is shown to be mounted on a stem which carries a stop *H* at the lower end. When the keys are depressed, these stops come into line with corresponding steps formed at the left-hand end of the rack *A*. These steps are so proportioned that when key 1 is depressed, for instance, the rack is allowed to move one tooth before striking its abutment. When key 2 is depressed it moves two teeth and so on as shown by the dimensions at the bottom of Fig. 5. When no key is depressed, indicating zero, then a stop is interposed which prevents any movement of the rack. When key 9 is depressed, the rack takes the full movement of nine teeth allowed by the striking of the lips on the under side of the rack against supporting bar *J*.

Each rack *A* has cut in it a slot engaging pin *C* in sector *D*. Each sector is in turn connected by link *E* with the type bar *F*, carrying characters from 0 to 9. Whenever, as shown in Fig. 6, a key (key 4, for instance,) is depressed and the rack is allowed to move four teeth backward under the influence of spring *O*, the type bar *F* is thereby set at the corresponding figure. The throwing forward of lever *L* to which the type bar is pivoted then prints this figure "4" on paper wrapped about roll *K* as shown in Fig. 6. It is important to remember that rack *A* and type bar *F* are positively connected under all conditions. It should, perhaps, be mentioned that the teeth in sector *D* simply provide for more accurate alignment of the type in printing than would otherwise be possible. Just before the printing stroke takes place arm *W* swings up, carrying a plate which enters the corresponding tooth space in each one of the nine sectors *D*, aligning all the figures on type bars *F* and giving a good, evenly printed number on paper.

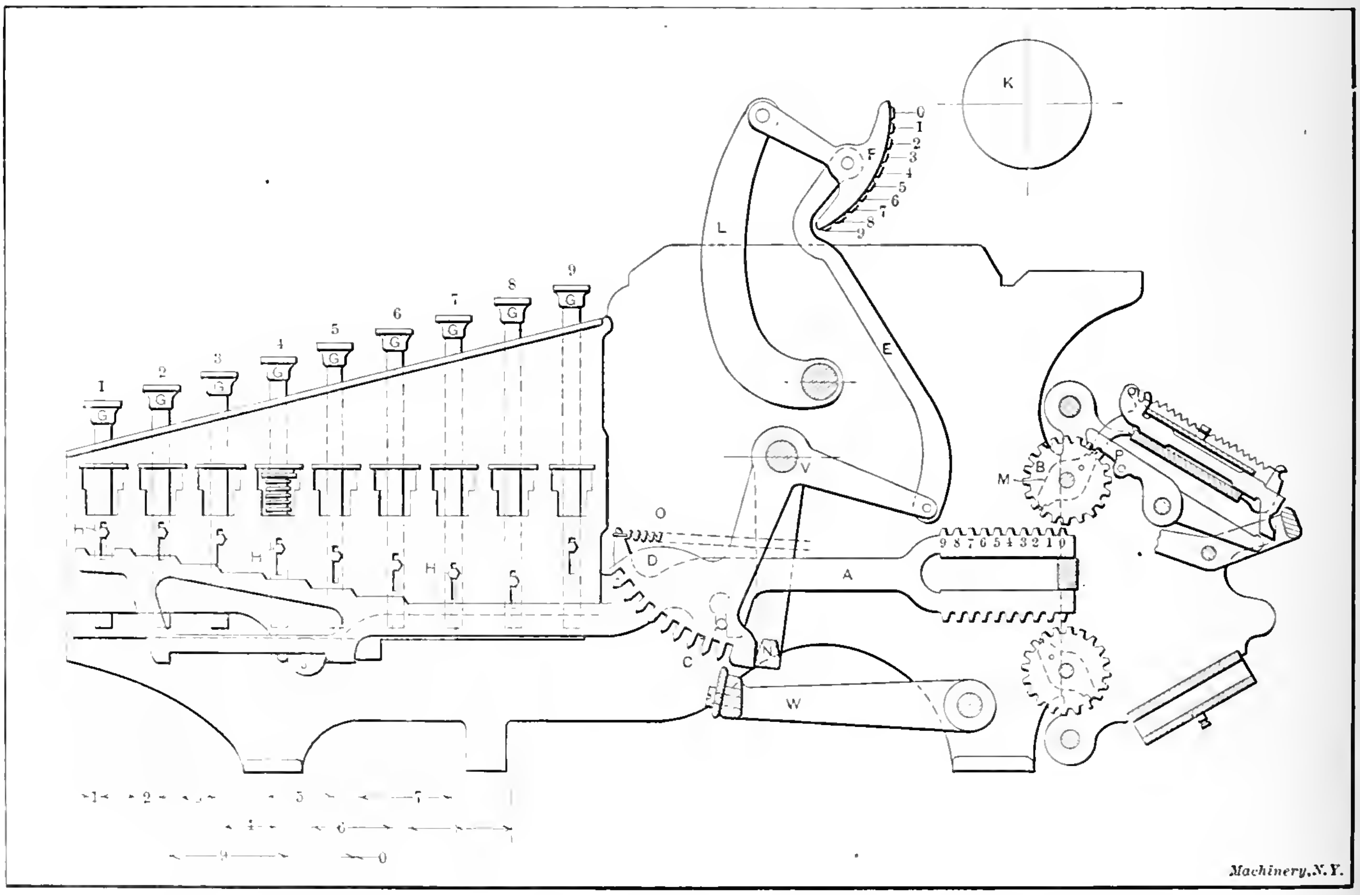

Fig 5 Diagrammatic Cross-section of the Machine showing Relation of Keys, Racks, Accumulators and Printing Mechanism

Now we come to the accumulator mechanism in which the adding is done. There are ordinarily, as explained, nine accumulator wheels for each of the nine racks. Here, however, there are two sets of these nine wheels, one above rack *A* and the other below. The upper one is the debit accumulator for addition in the debit column and the other is the credit accumulator for the credit column. A general view of the

mechanism is shown later in Fig. 9. We will, for the time being, consider only the upper or debit accumulator.

This set of nine accumulator wheels, of which only one is shown at *B* in Figs. 5 and 6, may be swung into and out of engagement with the teeth of racks *A* at will. These accumulator wheels have 20 teeth each. They might as well have ten, except for the fact that it would make them inconveniently small. Each wheel is provided with a two-tooth ratchet *M* positively pinned to it. This ratchet therefore spans ten of the wheel teeth between its points. Pawl *P* is adapted to engage the teeth of ratchet *M*, and is connected with mechanism by means of which the tens are carried from one column to another (that is, from one accumulator wheel to another) as will be later described. With this rapid review of the mechanism, we can turn to Fig. 7, which shows in diagrammatic form the method of procedure followed in the simple problem of adding 4 to 9, and getting the sum 13.

The Order of Operations for Adding

At *A* in Fig. 7 the machine is shown "clear," that is with the accumulator wheels at zero, which means that one tooth of the two-tooth ratchet is up against the hook of the pawl. Key 4, corresponding to the number we wish to add into the accumulator wheel, is now depressed and the operating handle of the machine is pulled over. The first thing that takes place is that the rack is allowed to move four teeth to the right as shown at *B* (see also Fig. 6). In this position the number "4" is printed. Next (as shown at *C* in Fig. 7) the mechanism automatically throws the accumulator wheel down into engagement with the rack. Then as the operator allows the handle to return, the next thing that takes place is the return of the rack to the zero position again as shown at *D*, carrying the accumulator wheel with it a space of 4 teeth from its zero position. The mechanism then disengages the accumulator wheel, leaving the machine ready for the next operation with the 4 added into the accumulator, as shown at *E*.

We now wish to add 9 to the 4. Key 9 is depressed and the operator pulls the handle. This results in a movement of nine teeth of the rack as shown at *F* in Fig. 7. The figure "9" is then printed. The accumulator wheel is next engaged, as at *G*. Then the rack is returned to the zero position as at *H*, and the accumulator wheel is disengaged as at *I*. This evidently moves the accumulator wheel 9 + 4 = 13 teeth as shown at *H*. In doing this, one of the teeth of the two-tooth ratchet as it passes under the pawl raises it, as shown by the full and dotted lines at *H*. This raising of the pawl operates a spring-loaded mechanism, which shifts the next accumulator wheel (that for the tens column) one tooth, when the wheels are returned from engagement in operation *I*. This operation exactly corresponds to that of "carrying" when adding with pencil and paper. This is here done automatically. It is not thought advisable to describe this carrying mechanism in detail as the parts are small and rather complicated, though the action is simple enough.

(The mechanism may be understood a little more clearly, however, if the reader follows the actions of the wheels when every one of them in the accumulator, from cents up to the millions of dollars is set at 9—that is to say, when they are set up for 9,999,999.99. Now suppose that one cent is added in, so that the first wheel is moved beyond 9—that is, to 0. The tooth of the ratchet *M* will then pass under the first pawl, raising it. Now when the accumulator wheels return from engagement, this raising of the first pawl releases a spring-loaded mechanism which moves the next wheel from 9 to 0. This, in turn, moves the next wheel from 9 to 0 and so on until each one of the row has been advanced one tooth, setting the whole row at 0,000,000.00. This operation, of course, takes place in a flash. It is done so rapidly that neither the eye nor the ear can take in the successive operations, but each one is dependent on the preceding one. So much for the carrying mechanism.)

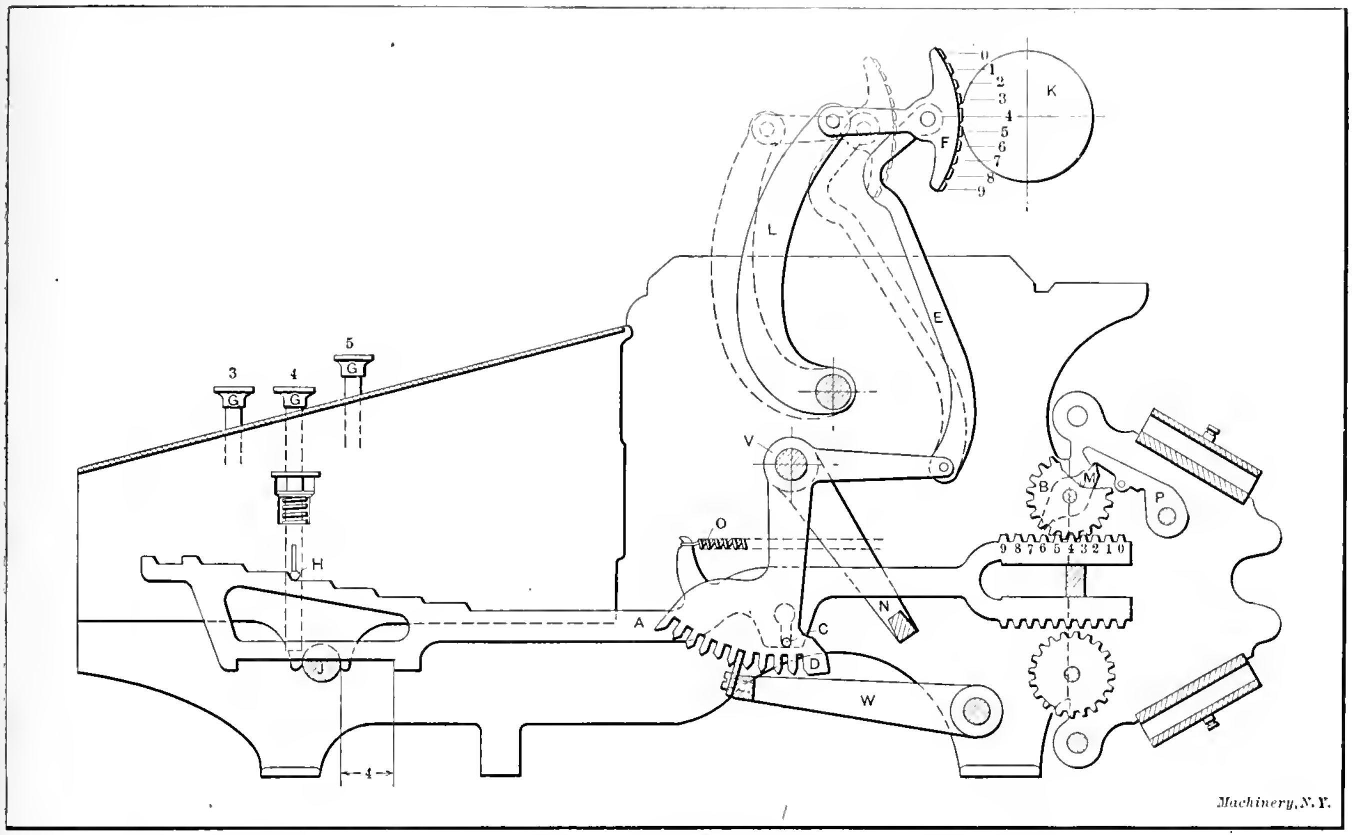

Fig. 6. Diagrammatic Cross-section showing the Machine set up for Printing the Number 4 and Adding it into the Accumulator

We have now added 9 and 4 into the accumulator wheel. Of course, this process can be carried on indefinitely, adding in any number of different numbers. Suppose that we now are through with the addition and wish to take a total. How is this done? The operations required are shown at *J*, *K*, *L*, and *M* in Fig. 7.

Finding the Total

The first thing the operator does is to depress the "credit total" key at the left of the key-board, the sum having been added into the upper or credit accumulator. He then pulls the operating handle, and the next thing that takes place, as shown at *J*, is the throwing of the accumulator wheels into engagement with the racks. The next operation is the release of the racks so that the springs move them toward the right. There are in this case no keys depressed in the keyboard, so that the racks would move the full distance of nine

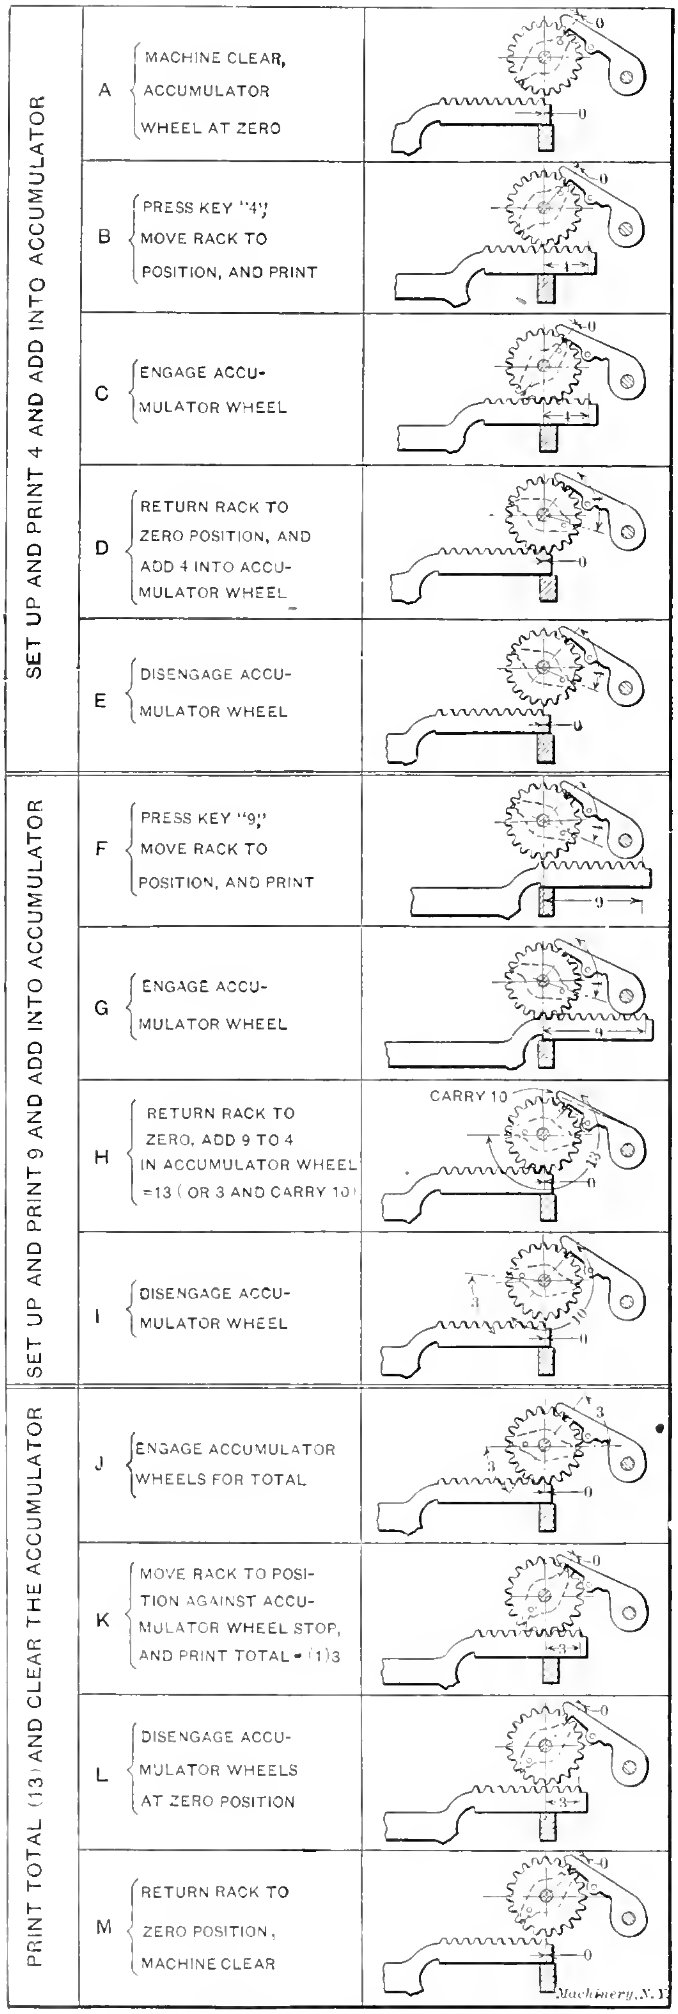

Fig. 7. Diagram Illustrating the Principle of Action of the Ellis Adding Typewriter

teeth, were it not for the fact that they have to carry the accumulator wheels with them, and the ratchets on these wheels come in contact with the pawls, thus arresting their movement and stopping the movement of the racks.

Now in the operation *I*, adding 9 into the 4 already in the wheel had set the units wheel 3 teeth beyond the point of the ratchet, and the tens wheel 1 tooth beyond the point of the ratchet. It is evident, then, that in operation *K* the units rack will be allowed to move 3 teeth and the tens rack 1 tooth. This, as shown in Fig. 6, will evidently set up the unit type bar at "3" and the tens type bar at "1." On the return of the handle the printing mechanism is operated, transferring the total "13" to the paper. The accumulator wheel will then be released, and the rack will be allowed to return to the zero position as shown at *M*. This leaves all the accumulator wheels back in the zero position, with the teeth of the ratchets back against the pawls, leaving the machine "clear" as at *A*, ready for the next operation.

Taking Sub-totals, etc.

It might have been desired to print a sub-total instead of a total. That is to say, it might have been desired to print a total for the addition as far as it had proceeded, but not to clear the machine, thus permitting more figures to be set up and printed and added into the same sum. Sub-totals can be printed at any point in the adding up of a line of figures, as required, by a simple change in the operation shown at *J*, *K*, *L* and *M* in Fig. 7. This consists simply in allowing the wheels to remain in engagement at *L*, so that the racks, when they return in operation *M*, will bring the wheels to the same position as they had in *J*, thus leaving the totals still set up in the accumulator.

Since there are two independent accumulators, it is evident that a number can be added into either one or both of them; or a total or sub-total can be taken from one of them and added into the other—all depending on the manipulation of the keys and the time of throwing the accumulator wheels into and out of action.

The order of the operations followed in printing without adding, in printing and adding, taking sub-totals, and taking totals to clear the machine, are all given in tabular form in Fig. 8. A study of Figs. 5, 6, 7 and 8, should serve to give a clear idea of the principle underlying the operation of the mechanism. It should be stated that this principle is not original with this particular machine, but was invented many years ago and has been adopted by all commercial adding machines of this type. It is worked out differently here, however, than in other machines, and in a way that offers a number of advantages.

The Various Sections of the Machine in Detail—The Accumulator

One of the fundamental features in the design of this machine is the fact that it is arranged to be built in sections. There are fourteen of these sections, each of which takes care of some particular function of the whole machine. The first of these to be described is the double accumulator, two views of which are shown in Fig. 9. This forms a self-contained unit. The accumulator wheels and the two-tooth ratchets shown in the previous diagrams will be readily seen in the engraving. The springs seen on the accumulator at the left, actuate the device for carrying the tens from one wheel to the next, to which reference has already been made. The upper accumulator is for the debit totals and the lower for the credit totals. Either set of wheels may be thrown in by the operation of the levers (marked *Q*), shown at the end of the accumulator at the right of the engraving. These levers, one of which is shown in Fig. 17, are operated by a mechanism at the left-hand side of the machine, to be explained later. The only connections this compact mechanism has with the rest of the machine are through the racks, as already described, and through the action of these levers *Q*.

The Flexible Keyboard

The keyboard section of the adding machine is shown in two views in Fig. 10. It is built up entirely of screw machine and presswork parts, showing much ingenuity in its design. It forms a rigid, self-contained unit, which may be inserted in

the complete machine without difficulty. Although it is comparatively simple in construction, it has a wide variety of duties to perform. One of the most interesting points of the construction relates to the method by which the "flexible keyboard" effect is produced. A "flexible keyboard" is one so arranged that when a key has been depressed, it will stay down; but the pressing down of another in the same vertical column

Operation	No	Rack	Accumulator Wheel	Type
To Print without Adding	1	Back to Key		
	2			Print
	3	Forward to Zero		
To Print and Add	1	Back to Key		
	2		Engage

	2	Back to Wheel Stop		
	3			Print
	4		Disengage	
	5	Forward to Zero		

Fig. 8. Table showing Order of Movements for Different Operations on the Adding Machine

will release the first one. That is to say, but one key in a column can be depressed at a time, thus avoiding possible error. As a further advantage, when the wrong key has been pressed, the operator simply presses the right one and the wrong one is restored to normal position.

This effect is secured by means which are ridiculously simple. The principle is illustrated in Fig. 11. When the key 1, for instance, is depressed, the lower hooked end of the stem on which it is mounted springs past the end of a long pivoted strip *R*, which extends for the whole length of the vertical row of keys. Here the key is held by its hooked end. Supposing now the operator presses down on key 2. This also

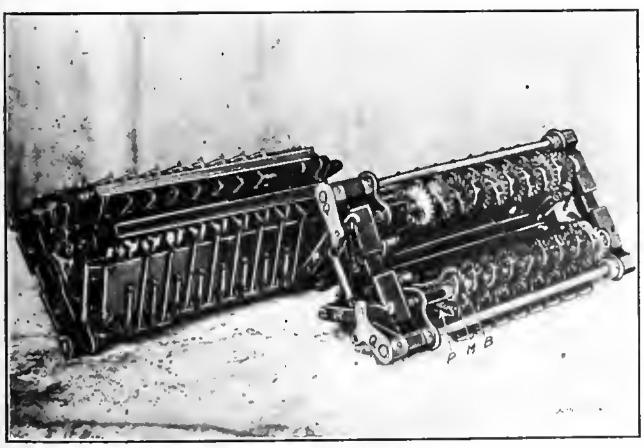

Fig. 9. Front and Rear Views of the Accumulator Section into which the Numbers are added

will open out the pivoted strip *R* to allow the hooked end of the stem to pass, and in so doing it will, of course, release the hooked end of key 1, which will immediately fly back in its normal position under the influence of spring *S*. Any key which may be pressed down will throw back strip *R*, and release any key which may be at the time depressed. One key *H*, the third from the left in the first row on the accumulator at the right, is shown depressed in Fig. 10, with its end hooked over the retaining strip in the same position as for key 1 in Fig. 11.

The keyboard is provided with interlocking mechanism connected with the controlling keys of the machine and with the operating lever. This mechanism, among other things, prevents the keys from being pressed down or changed after the operating lever movement is started. The keyboard also has a connection with an error key, the pressing of which releases all the keys that may be depressed at the time. This is operated by the strip shown extending across the base of the mechanism in the keyboard at the left of Fig. 10. It has also means for automatically releasing and returning the keys after each operation.

The Printing Section

The printing section is shown in Fig. 12, where it will be seen to be very much more complicated than is indicated by the simple diagrams shown in Figs. 5 and 6. The same parts, however, have been given the same reference letters, so that it will be possible to compare the engravings. This section, like that in Fig. 10, is built up entirely of screw machine and presswork parts, and is a very fine example of the combination of compactness and rigidity which is only attainable with such construction, in mechanism of this kind.

The added complication in Fig. 12 is due to a number of requirements. One of the most important of these is the "non-zero printing" action, which holds back all the zeros to the left of the last integer to be printed. By means of this mechanism, when we set up, for instance, "111.11" on the keyboard, the type will print that number instead of printing it 0,000,-111.11. Another provision is that of the rebound mechanism for the type, which allows it to strike the paper a hard blow and then quickly return. This gives clear printing without smearing or blurring the ink. Still another function that has to be taken care of is that of punctuating the numbers.

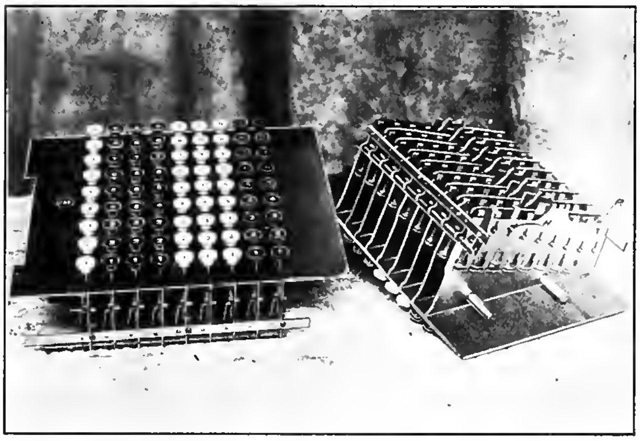

Fig. 10. Top and Bottom Views of Keyboard Section

This is controlled by the graduated slide shown just over the adding keyboard at the right of the machine in Fig. 1. By setting this slide, the numbers may be punctuated for units, for dollars and cents, and so on. When set to the graduation marked "X," the machine will add without printing at all. One of the punctuation characters is shown at *U* in Fig. 12.

It should be noted in Fig. 6 that there is enough mass to the parts of the printing mechanism to give a sharp blow of the type on the paper. This gives unusually good results in manifolding, this machine being equal in that respect to the best makes of typewriters. The ability to manifold through ten or a dozen thicknesses of typewriter and carbon paper is a new feature in adding machine construction.

The Reducing and Rack Section

In Fig. 13 is shown a top view of a machine partially dismantled. This view is given to show the arrangement of the typewriter mechanism for one thing, but more particularly to call attention to the "reducer" mechanism shown at *V*. In Figs. 5 and 6 it was shown that the racks *A* are connected with the type sectors *F* through a positive mechanism. Racks *A*, however, spread over the whole width of the machine while sectors *F*, as shown in Fig. 12, are concentrated in a small space. It is the office of these parts *V*, therefore, to effect this positive connection between the two differently spaced mechanisms. These levers correspond to the same part

marked V in the simplified diagrams Figs. 5 and 6, though, of course, the construction shown is different. At their lower ends they carry the arms making connections with the racks A, and also the tooth sectors shown at D, for registering the line of figures.

The Operating Mechanism

The best view of the operating section that can be obtained is shown in Fig. 14, where the right-hand side of the dismantled mechanism is illustrated. The principal provision

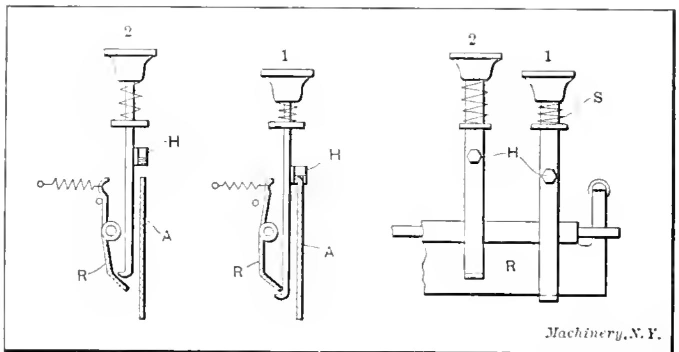

Fig. 11. The Principle of Operation of the Flexible Keyboard

which this mechanism has to take care of is that of safeguarding the more delicate parts of the machine from rough handling on the part of the operator. It causes the operation of the machine to take place under spring action at a certain known rate and with a known driving force. All the operator is allowed to do is to supply the power for stretching certain springs and releasing their action. He cannot directly apply his strength to the mechanism.

Fig. 15 shows this device. In position No. 1 the operator has just pulled the handle forward to commence operating the machine. This handle revolves freely on its shaft, the operat-

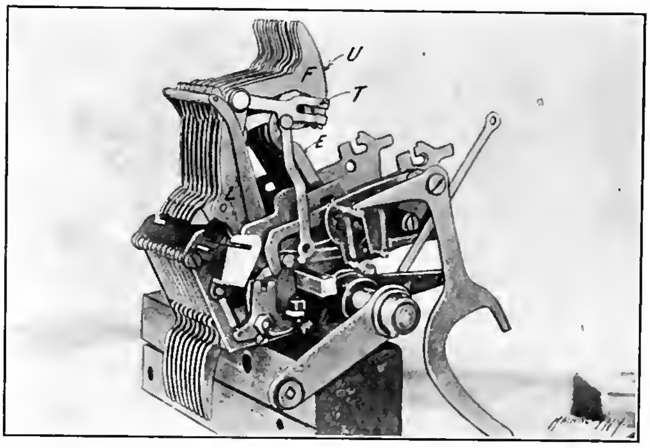

Fig. 12. The Printing Section

ing parts being driven by member E_1. As Y is pulled forward, catch C_1 releases pawl Z allowing member E_1 to fly forward by the contraction of springs A_1, through levers D_1 and links B_1. This free movement of member E_1 operates the forward stroke of the machine, and it is held to the proper rate of action by an oil by-pass governor, (shown best at G_1 in Fig. 13). Abutment F_1 stops this movement, in position No. 2.

The operating handle Y, which is now free of the mechanism, continues its forward movement under the hand of the operator until position No. 3 is reached. Here the tail of pawl Z, striking pin H_1, is thrown back into engagement again with the catch of member E_1. In moving the handle from position No. 2 to No. 3, spring A_1 has been extended, and it now acts through levers D_1 and links B_1 to return handle Y to the starting position, carrying with it member E_1 and the mechanism of the machine. This reverse movement is also under the control of the governor. Latch C_1 rises to permit pawl Z to pass, and the springs bring the whole back to position, all ready for a new stroke.

The double action of springs A_1 is very interesting. It will be seen that they operate the mechanism for both the forward and back strokes. This is made possible by the fact that they are connected to movable members at each end—in one case to levers D_1, and in the other case to operating handle Y. Their contraction to length X between positions No. 1 and No. 2, operates the forward motion, while their contraction from position No. 3 to position No. 1 operates the backward motion. The provision of two each of springs A_1, links B_1 and levers D_1, is simply for the purpose of balancing the strains in the mechanism.

Another interesting point to be noticed in connection with Fig. 14, is the double-acting pawl J. This makes it impossible for the operator to start a movement of the handle and not complete it. Handle Y is shown here at the commencement of the forward movement. Pawl J locks into successive notches on sector K, preventing its return until it has reached the final notch at the lower end. This is large enough to permit pawl J to reverse and turn in the other direction. This compels the handle to return to the vertical position, since it would lock again in the notches in sector K if any further forward action were undertaken. At the completion of this

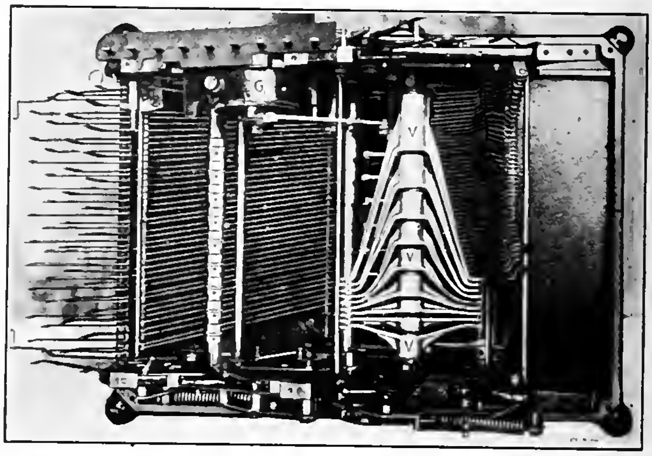

Fig. 13. Top View of Machine showing particularly the Reducer and Typewriter Sections

return stroke, J drops off the end of the sector, where it can again turn around for the forward stroke.

The Controlling Mechanism

Fig. 16 shows the most complex, and also one of the most useful sections of the machine. The stems shown projecting above the top of the keyboard at the right of the engraving are for the controlling keys shown at the left of the keyboard in Fig. 1. These are named, beginning at the top: "non-add," "debit add," "debit sub-total," "debit total," "credit add," "credit sub-total," "credit total," "repeat" and "error."

The pressing down of the non-adding key permits the print-

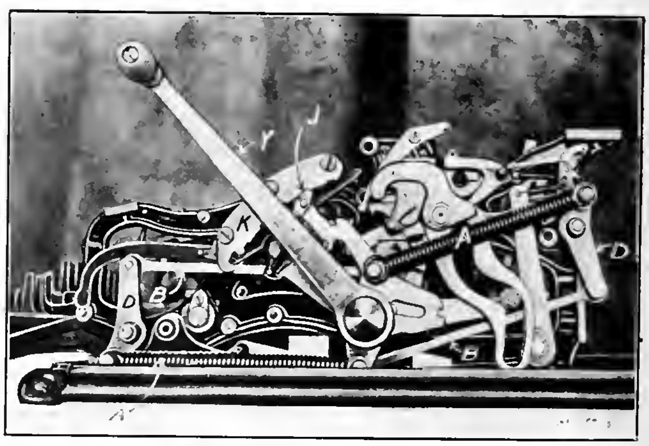

Fig. 14. Side View of Machine showing Operating Mechanism

ing of a number without adding, as explained in the first operation of the table in Fig. 8. In other words, this keeps the accumulators permanently out of engagement with the racks. The debit and credit add keys permit a number to be printed and added into the corresponding accumulator, even though the carriage is not set in the proper position for that accumulator. The use of these keys, therefore, gives a flexibility to the machine which is necessary for special operations such as horizontal adding. The debit and credit sub-total

keys take and print a total from either the debit or credit accumulators without clearing the accumulators, as illustrated and explained in Fig. 8. The debit and credit total keys, on the other hand, take the total from either the debit or credit accumulators, as the case may be, and clear the accumulator after the total is printed, as also explained in Figs. 7 and 8. The pressing down of the repeat key holds in the downward position whichever of the number keys have been depressed, allowing the same number to be repeatedly printed and added as many times as the operating handle is pulled. This is useful in multiplying by repeated additions, and for other similar uses. The pressing of the error key, as has been explained, will release every other key on the keyboard, both of the number keys and of the operating keys as well.

Now, the complexity shown in Fig. 16 is required for making the machine incapable of falsifying itself; that is to say, through it all the various functions of these keys so interlock with each other and with the operating parts of the machine, that it is impossible for an ignorant or careless operator to

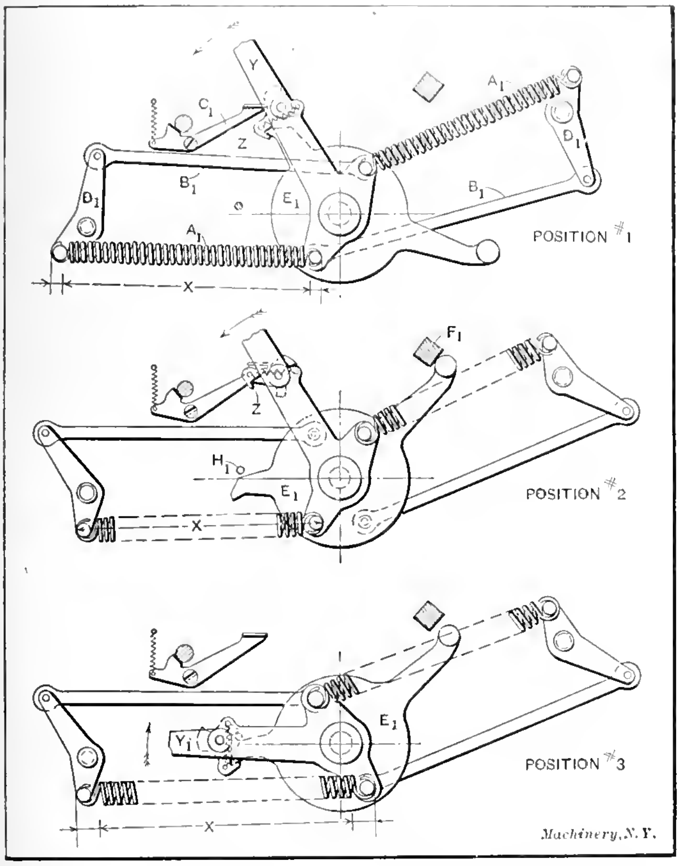

Fig. 15. Spring Control Device which safeguards the Delicate Mechanism from Rough Handling by the Operator

give wrong orders to the machine. The arrangement of the parts in this section required continuous concentrated thought on the part of the inventor, Mr. Ellis, and his assistant, Mr. Perkins, for nearly two years. The number of contingencies that had to be provided for seemed almost endless, and the amount of mechanism required seemed almost hopeless. By close study, however, the various functions were grouped, single parts were made to perform a variety of functions, and the whole range of connections was simplified so that this section has been reduced to the compact form shown herewith. It is hopeless, however, for a migratory editor or a casual reader to attempt to do more than get a vague notion of the work this section is called on to perform.

The Accumulator Controlling Mechanism

It may be worth while, perhaps, to get a notion of just how the controlling mechanism determines when the accumulators shall be thrown into engagement with the racks, and when they shall be released. In Fig. 17 sector K_1 is directly connected with the operating shaft L_1, controlled by the operating handle. It is provided with connections with both accumulators. Fig. 17 for convenience shows only the connections with the debit accumulator. Flying lever M_1 is connected with the debit accumulator by means of links O_1 and bell crank Q. Member P_1 is simply a spring detent to locate Q for either the engaged or disengaged position of the accumulator wheels.

As sector K_1 starts on its stroke toward the dotted position, it carries flying lever M_1 with it, owing to the resistance which the tail of the latter meets with against abutment R_1. When K_1 has gone far enough so that the tail has dropped off

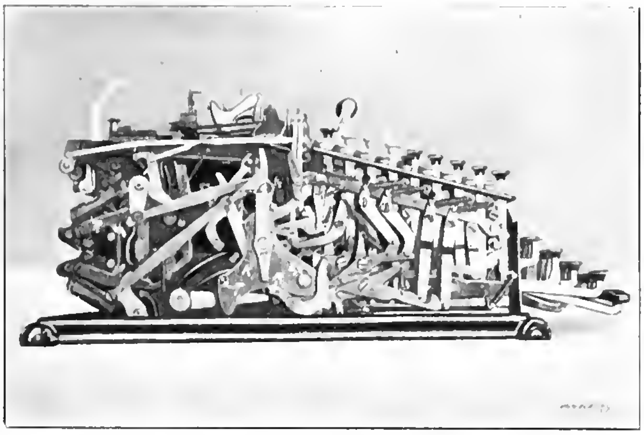

Fig. 16. Left-hand Side Frame Section for Controlling and Directing the Movements

R_1, flying lever M_1 becomes free. The movement has been sufficient, however, to move accumulator lever Q to position Q_1, which throws the wheels into engagement. If it had been desired to throw the wheels into engagement at the end of the stroke instead of at the beginning, detent R_1 would have been withdrawn from the position shown, leaving flying lever M_1 free. Near the end of the stroke of K_1, however, the end of the pawl S_1 would have struck stud T_1, making M_1 and K_1 solid, for all practical purposes, and moving Q to the position Q_1 at the end of the stroke.

If it had been desired to keep the accumulator wheels out of engagement altogether, R_1 would have been lowered out of the position shown, and S_1 would have been moved to a position clear of stud T_1. Then flying lever M_1 would have been entirely free of K_1, and no movement of Q would have taken place. The provisions for throwing the accumulator out of engagement at either the commencement or end of the return

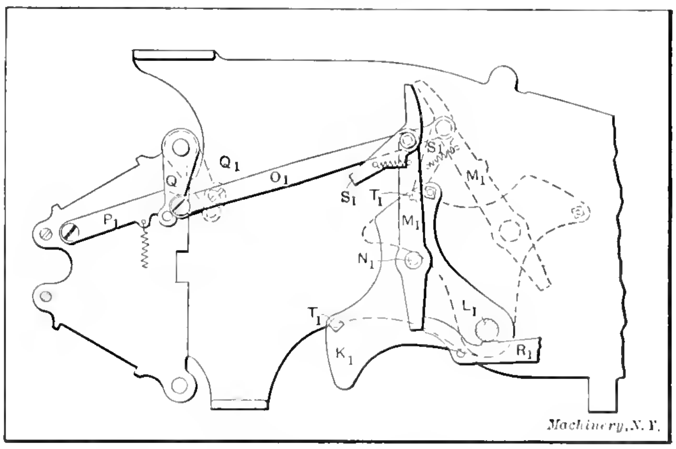

Fig. 17. Diagram showing Flying Lever Connection between Operating Shaft and Accumulators

stroke are similar to those just described, so need not be particularly referred to. This surely goes far enough into the mechanism of this controlling scheme for the average reader.

The Typewriter Mechanism

The various sections of the machine which relate to the typewriter mechanism are similar in principle to the corresponding parts on standard typewriters, though there are some added complications required for connections with the adding machines. The tabular, for instance, is provided with two kinds of stops, one of which is operated with the ordinary typewriter tabulator key. The other is located by latches on the tabulator scale, for setting the carriage at the proper position for the debit and credit columns, as determined by the

tabulator key on the adding machine keyboard. The white tabulator stop is for the debit column and corresponds with the white control keys at the left of the machine. The black stop corresponds to the black debit control keys. Except as previously described in connection with the controlling keys, the machine is locked to prevent debit adding unless the carriage is set for the debit accumulator, and the same is true for the credit accumulator.

The typewriter mechanism is best understood from the views shown in Fig. 13. The chief peculiarity of the machine as a typewriter is the compactness of the basket of keys, and the extreme length of the key levers necessitated by the interposition of the adding keyboard between the keys and the type. In spite of the handicap thus apparently placed on the typewriter mechanism, it appeared to the writer that the action of the machine was exceedingly agreeable—equal to that, in fact, of any machine with which he had ever had anything to do. This is in line with the inventor's express purpose to make the machine a good typewriter as well as a good adding machine. Diagrams showing the arrangement of the levers will be given in a subsequent article dealing with manufacturing operations.

Points in the General Design of the Machine

It is posible that, in reading the foregoing description, the reader may have been more impressed by the complexity of the mechanism than with the orderly arrangement which the inventor and designer have given to the parts. Without this orderly arrangement the machine would have been far more complex—so much so as to have been prohibitive. A rapid review may serve to make the orderliness of the arrangement a little clearer.

Looking at the machine from the front, the mechanism at the right, on the outside of the right-hand side frame, is entirely given up to the operating movements—that is, it is composed of parts whose movement is invariable. The parts on the left-hand side of the machine, on the other hand, are devoted entirely to such movements as are variable in their action at the option of the operator—that is to say, these are the parts which determine whether the machine shall print, add, or take sub-totals, totals, etc. All the space between the frames is filled with mechanism which does the actual work of calculating, as directed by the left-hand side mechanism, and as operated by the right-hand side mechanism.

To put it in another way, the machine may be considered as a manufacturing organization with the executive offices at the right-hand side, the sales or order-taking department on the left-hand side, and the shop itself—which delivers the goods—in the main part of the structure. This segregation of the different functions results in shorter connections throughout between the various moving members, reducing the number of parts to a remarkable degree.

The designer of an adding machine has to do much more than make a machine that shall add correctly. He has to make a "fool-proof" machine, one that the operator cannot put out of business by roughness or carelessness. We have shown some of the features of the machine which render it proof against error from this cause. But the designer has to do still more than this. He has to make it what might be termed "villain-proof," as well as fool-proof. The necessity for this is due to the peculiar conditions under which the adding machine works.

When an adding machine is used, implicit confidence is placed in it. It may be permissible for a bookkeeper to make a mistake once in a while in adding a column of figures, but no excuse is ever listened to if an adding machine makes a similar error. The adding machine salesman knows this, of course, and it is part of the stock in trade of some of them, when the opportunity offers, to show how a rival machine may make a mistake. Now in all probability, in order to force the machine to make a mistake, he will have to do something that the operator would not by any possibility think of doing, unless he actually set out to do it, and knew exactly how to go about it. This, however, the intending purchaser may not stop to think of. He sees that the machine may be made to make a mistake and so he loses confidence in it.

The designer of an adding machine, then, has to provide all sorts of safeguards to prevent willful misoperation of the mechanism. Without explaining in detail the precautions of this kind taken in the machine we are considering, it may be well to make note of one of them. In some machines it is possible, by pressing a key part way down, to get an undesired result; the pressing of the key part way down may affect part of the change in the control of the mechanism desired, while it may require the full movement to produce the whole result desired. In order to avoid this difficulty, particularly in the matter of the left-hand row of operating keys, the action of these keys has been made "permissive" only; that is to say, when these keys are pressed down, as best seen in Fig. 16, they allow the bent ends of certain levers to snap into place in notches cut in the sides of the stems. Now the ends of these levers have either snapped into place in the notches, or they have not. There is no halfway position, and there is no possibility of fooling the machine on that account. A good deal of the mechanism provided in Fig. 16 is required to prevent the possibility of willful mismanagement of the machine.

The writer asked Mr. Ellis, the inventor, the reason for the plate-glass windows which the adding machine builder is accustomed to place in the sides of the frame of his product. The explanation offered was that the customer was thereby enabled to see that he had gotten his "money's worth" in mechanism. With the detailed views of the machine here given, there should be no further doubt on this matter in the mind of the reader. In fact, he might well wonder how the manufacturer can afford to sell so much complication for the paltry hundreds of dollars he asks for it. Articles on manufacturing operations in succeeding numbers of MACHINERY, will, perhaps, let a little light into this dark mystery.

* * *

SAG AND STRENGTH OF MANILA POWER-TRANSMISSION ROPE

The sag and strength of manila rope cannot be determined exactly, as it varies with the load carried, the speed run, and the initial tension in the rope. In the multiple system, when the slack comes on top, the rope is allowed to sag until parts running in opposite directions would nearly touch. It then has to be shortened. The sag on the tight side may be determined quite closely if the exact power to be carried is known. Likewise, in the continuous system, where it is possible to keep a uniform tension on the rope, the sag may be closely approximated. In general, a rope should be allowed to run as slack as possible without slipping.

The sag of ropes takes nearly the form of a parabola. The amount may be approximated by multiplying the weight of one foot of rope by the square of the distance from sheave to sheave where the rope leaves, and dividing by eight times the tension on the rope. For example, the sag of Plymouth two-inch diameter rope supported ninety feet apart, running at four thousand two hundred feet per minute is $\frac{1.34 \text{ pounds} \times 8100}{8 \times 800}$ = 1.7 feet on the driving side, which would be the same at all speeds. The slack side sag may be determined after the same method, by adding to the initial tension the tension from centrifugal force. Thus, with the same rope as before

$$\frac{1.34 \times 8100}{8 \times 199 \text{ pounds initial} + 205 \text{ centrifugal tension}} = 3.3 \text{ feet.}$$

A new rope will stretch considerably for a short time, but after the parts of the rope are firmly bedded together further stretch is slow. The total stretch should not exceed five per cent under reasonable conditions. In cutting the slack out of continuous drives, it must be borne in mind that some movement of the tightener sheave must be allowed for shrinkage caused by atmospheric conditions and future resplicing.

* * *

It is stated by the United States Consul at Rio de Janeiro that the president of the Central Railroad of Brazil proposes to send to the United States groups of four mechanics each, every six months, to work in a large locomotive-building plant in this country which is furnishing locomotives to this railway. In this way it is proposed to educate a number of men in American locomotive-building methods.

MULTIPLE CUTTER TOOLS

By W. S. GIELE*

The writer has, in conversation with many practical men, encountered such widely differing opinions on the relative advantages of boring and turning tools made with single and with multiple cutting edges, that he offers his own experiences with such tools. Many men seem to hold to the belief that far more accurate work is produced by the single cutting edge than can be produced by tools having multiple cutting edges, and they are usually able to support their position by showing work of the highest excellence made with single cutters, and probably plenty of work which is decidedly not of the highest excellence made with multiple cutters.

Some experience in the manufacture of machines which required multiple cutters and the design and purchase of a number of cutting tools used in the manufacturing processes, has led the writer to analyze some of the problems involved, with the very commonplace conclusion that in this, as in everything else, there are situations where one type of construction is best adapted, and other situations where a different type of construction is best adapted. Neither is it particularly original to say that in the final analysis, the terms of the problem must be reduced to dollars and cents.

The most ardent advocate of multiple cutters will probably continue to turn up his occasional lathe job with a single tool in the tool-post, and to bore out his jig holes with a single pointed boring tool, because that is really the best way; not that it might not be done just as accurately and as well some other way, but because that is generally accepted as the most *economical* way to do the job sufficiently well. On the other hand, the man who firmly believes in the single cutting edge, will probably continue to use twist drills with more than one lip, taps and reamers with more than one flute, threading dies with more than one cutting edge, hollow mills with more than one tooth, and very likely more than one cutting edge in his cutting-off machine. And his reason for doing all these things is, again, not because he has no choice, but because he is following what has been accepted as the most economical way.

Whenever multiple cutter tools have failed, it is reasonable to inquire whether each of the cutting edges has been ground with the same care and precision as a single cutting edge would have been, and whether the drive, the feed, the support, and the piece on which the work was being done all had the same relative rigidity in proportion to the amount of metal being removed in the case of the multiple cutter, as in the case of the single cutter. The problem is not what can be done, but what will it pay to do.

As a concrete illustration, let us suppose a line of headstocks in which the spindle bearings are to be bored, varying, in a case which the writer has in mind, from 4½ to 17 inches in diameter of bore, each headstock having two bearings of the same diameter and in line with each other. The material is cast iron, and the bearings have caps of the usual form with liners varying in thickness from 1/16 to ⅛ inch according to the bore. Boring-bars or arbors are made for each size of headstock. These bars are made as short and as large in diameter as the clearances will allow, to gain the maximum stiffness in proportion to the amount of work to be done. On each bar are mounted two roughing, and two finishing heads so spaced that the two bearings will be rough bored simultaneously, and finish bored simultaneously. The roughing and finishing heads are so spaced, relatively, that the finishing tools do not come into action until the roughing tools have completed their cut.

Without discussing here the relative advantages of an odd number of cutters and an even number, it is evident that this is a job for an odd number, as with an even number, equally spaced, there would be two cutters jumping a liner gap at the same instant.

In this case, the roughing heads have three tools each, all standing in the same plane perpendicular to the axis of rotation and with equal angular spacing. The tools have ample clearance and rake, being shaped much like a round-nosed roughing tool for a lathe. These tools are jig ground and abut against wedges or taper keys, which are graduated so that it is possible to set the tools with ample exactness for rough boring, without calipering. They do the cutting on the leading side and not on the circumference. The finishing heads have a varying number of inserted cutters according to size of hole. The largest has nineteen cutters. These tools cut on the leading corner and also take a slight shearing cut on the circumference. They vary in length parallel to the axis of rotation in the different heads, but are all set at such an angle that the are embraced between the radii to the front and back corners is equal to about three times the liner gap. They are, in fact, equivalent to the teeth of a left-hand helically (commonly called spirally) fluted reamer. They are ground to size in place and gaged to limits. The holes they produce are sufficiently accurate, both as to size and finish, to run as bearings without scraping.

In feeding any boring tool through the work, a point on the cutting edge passes through the hole in a helical path and its trace as marked on the work appears as a shallow screw thread. The apparent roughness of the finish left by the tools depends on the depth and pitch of this thread; that is, the finer the pitch, the smoother the finish appears. The time for cutting a given length of hole, however, depends on the lead of the thread, other things being equal. To increase the lead without increasing the pitch, it is necessary to produce a multiple thread. In other words, for any given pitch or width of tool marks on the work, it is possible to increase the lead or feed in direct proportion to the number of cutting edges and cut down the time required to feed a given length in inverse proportion. Thus a feed of 3/16 inch per revolution with a three-cutter head, gives a pitch of 1/16 inch to the tool marks, whereas the same feed applied to a single cutter would result in a 3/16-inch pitch in the tool marks, and if the depth of metal removed is the same, the single cutting edge would have to remove three times as much stock as each cutter in the multiple tool head, and would leave a rougher finish.

It is important to remember, when making multiple cutter heads, that the clearance and rake angles on the leading or cutting side are determined by the lead or feed and not by the pitch. These angles depend on the angle between the helical path of a point on the cutter and a plane perpendicular to the axis of rotation which is easily found, being the angle whose tangent equals the feed per revolution divided by the circumference of the hole.

As far as the matter of design is concerned, the number of cutters in a head is limited only by the chip clearance which will be left between cutters and the space required between cutters for the means which holds them in place. The design of the head itself is, however, not the only factor to be considered, as the limit may be set by the rigidity of the machine it will be used on, or the strength of the drive and feed, or the strength and stiffness of the piece being worked on. The ultimate limit which governs all others must, however, always be the economic one.

The larger the number of cutters in a head, the shorter will be the cutting time for any given length of hole; and also the higher will be the initial cost. Offsetting the higher initial cost is the fact that with a multiple cutter head each individual cutter does an amount of work inversely proportional to the number of cutters, and the head as a unit will therefore have an endurance, in number of holes bored between grindings and total number of holes bored during its life, proportional to the number of its cutters. Even where the total number of holes to be bored is very large, the higher initial cost of the multiple cutter head may not be easily justified if the distance to be bored is very short or the setting-up time is a very large proportion of the total time, because in such cases a saving of two-thirds or four-fifths, or a larger proportion of the boring time, may still represent a very small proportion of the total time.

To sum up: The number of cutting edges in a boring or turning tool (which may also be made to include tools for internal or external threading) is governed principally by the following considerations:

1. Number of pieces to be machined.
2. Proportion of cutting time to total time of operation.
3. Rigidity of pieces worked on.
4. Capacity of drive and feed.
5. Chip clearance between cutters.
6. Space required for means to hold the cutter.

ECCENTRICALLY LOADED BOLT AND RIVET GROUPS

By M. TERRY*

The eccentrically loaded rivet group problem discussed by Mr. Gwinner in the May issue of MACHINERY is one of the cantilever class. As a mathematical proposition the cantilever problem is analyzed as follows: In Fig. 1, O is the point of support of any object, A is any point outside of it to which a force $(+W)$ is applied. R is the perpendicular distance from O to the line representing the direction of the applied force. Now, if two forces $(+W)$ and $(-W)$, each equal to the force W at A, and parallel to it, are introduced at O, the situation remains unchanged; but the forces $(+W)$ at A and $(-W)$ at O can be combined into a couple whose numerical value is

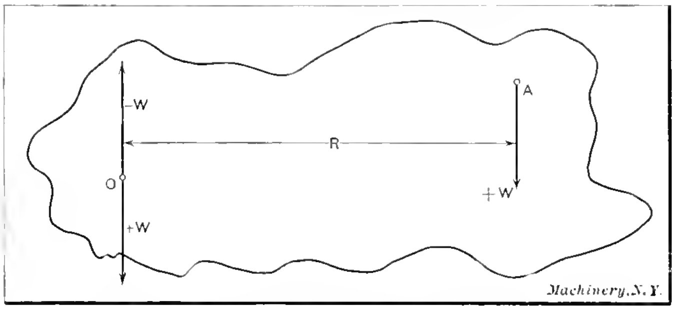

Fig 1. Diagram for Mathematical Analysis of Cantilever Problem

$W \times R$. Thus a single force W applied to a body at a distance R from its center of support is equivalent to the same force W applied in the same direction at the point of support, and a couple or moment WR.

In every practical problem of this nature the direct force W is usually considered equally distributed among the various bolts or rivets that make up the group. The bending moment WR is balanced by the resisting moment of the rivets, and only those rivets play an active part in resisting the bending moment that are placed outside the geometrical center of the group, *i. e.*, those that are "possessed of an arm."

In the following, let

M = bending moment produced by the eccentric load,

f = actual shear per rivet due to the eccentricity of the load,

R = radius of the bolt or rivet circle,

n = number of rivets located on the same circle,

Then

$$n \times f \times R = M$$

$$f = \frac{M}{n \times R}.$$

If n and M remain constant, f varies inversely as R. Hence

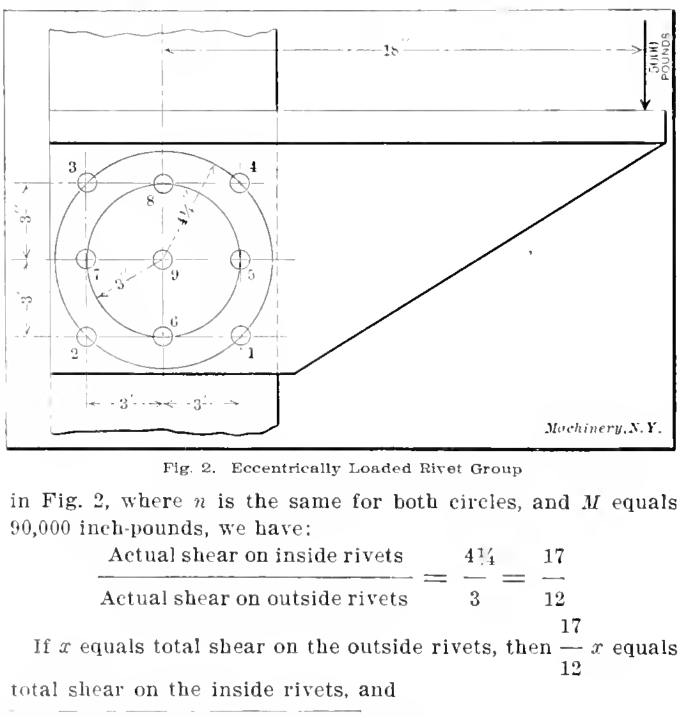

Fig. 2. Eccentrically Loaded Rivet Group

in Fig. 2, where n is the same for both circles, and M equals 90,000 inch-pounds, we have:

$$\frac{\text{Actual shear on inside rivets}}{\text{Actual shear on outside rivets}} = \frac{4\frac{1}{4}}{3} = \frac{17}{12}$$

If x equals total shear on the outside rivets, then $\frac{17}{12}x$ equals total shear on the inside rivets, and

$4\frac{1}{4}\,x$ = resisting moment of outside rivets,

$\frac{17}{12}x \times 3 = 4\frac{1}{4}\,x$ = resisting moment of inside rivets.

The total resisting moment = bending moment = $8\frac{1}{2}\,x$ = 90,000 inch-pounds. Hence,

$$x = \frac{90{,}000}{8\frac{1}{2}} = 10{,}588 \text{ pounds},$$

$$\frac{10{,}588}{4} = 2647 \text{ pounds} = \text{shear per outside rivet},$$

$$2647 \times \frac{17}{12} = 3750 \text{ pounds} = \text{shear per inside rivet}.$$

The direct load of 5000 pounds is equally distributed among the 9 rivets, producing a shear of 555 pounds per rivet.

The total shear on any rivet is the geometrical sum of direct and tangential shear. Referring to Fig. 3, it is clear that rivet No. 5 is in greater stress than any of the rest, having a total shear of 4305 pounds. Taking, as Mr. Gwinner did, 10,000 pounds per square inch as the safe shear, a ¾-

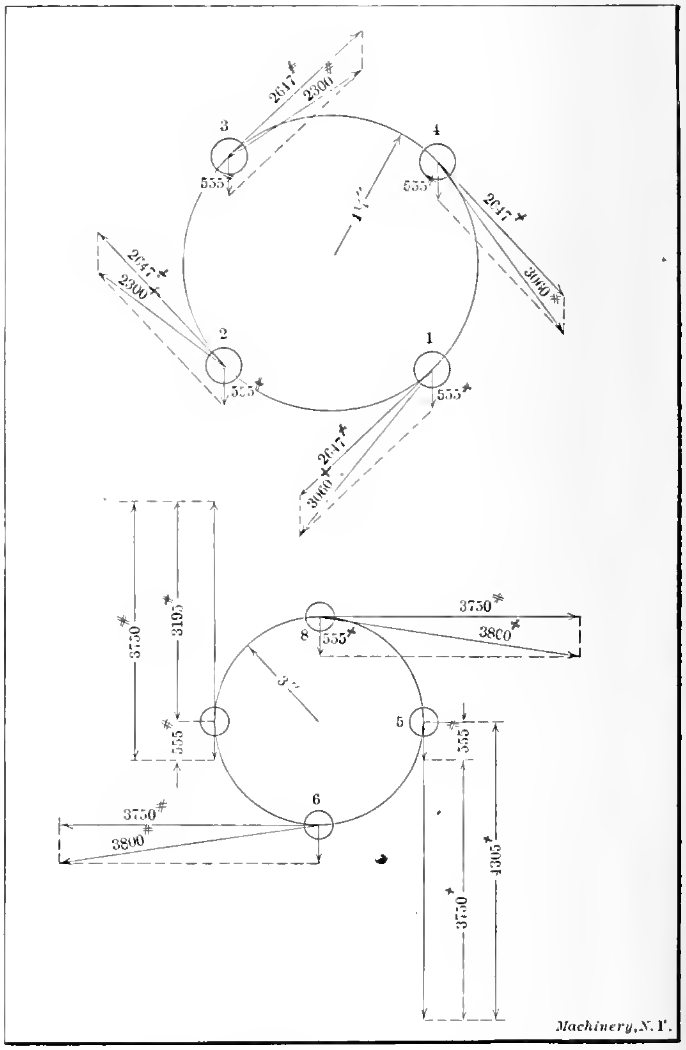

Fig. 3. Stress Diagrams for Eccentrically Loaded Rivet Group

inch rivet can be safely stressed to 4400 pounds. The shear on rivet No. 5 then is just within the safe limit. Since a ⅝-inch rivet has a safe shear of about 3060 pounds, a set of four ⅝-inch rivets can be safely used on the outside circle, if desired.

Let us now take the simple case shown in Fig. 4, and deduce the principles involved in designing a well-proportioned joint. The joint in question is likely to fail in any or all of the following three ways:

1. Rivets may fail by shearing.
2. The plate A may be too thin, making the bearing value too high, and causing the metal in the plate to "flow" at the rivets.
3. The plate A might fail at its weakest section, which is in the plane of the rivets.

* Address: 302 Williams St., Flint, Mich.

"No chain is stronger than its weakest link," and if the weakest link is strong and safe enough for its load, there is no necessity for making other links stronger. An ideal joint is one designed in accordance with this principle, but like many other ideal things it is seldom carried out in practice. Usually, the width and thickness of plate are assumed, rivets calculated, and then the plate examined for safety in bearing and bending. This method might give us, say, a factor of safety of 7 for shear, 9 for bearing and 11 for bending. Sometimes this is the best that can be done even when considerable time is spent in calculations. For instance, if we try to reduce the too high factors of safety in bearing and bending, by making the plate thinner, we may arrive at some

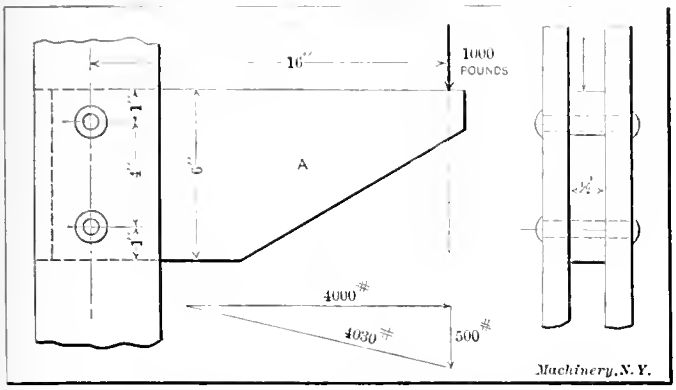

Fig. 4. Another Example of Eccentrically Loaded Rivet Group

odd-size plate which, as a manufacturing proposition, is out of the question.

In Fig. 4:

M = bending moment = $1000 \times 16 = 16{,}000$ inch-pounds,

F = tangential shear per rivet,

r = distance between rivets = 4 inches,

Resisting moment = bending moment.

$$F \times r = M,$$

$$F = \frac{M}{r} = \frac{16{,}000}{4} = 4000 \text{ pounds.}$$

Assuming that the direct load is equally supported by the two rivets, the total shear per rivet = $\sqrt{4000^2 + 500^2} = 4030$ pounds, which is also evident from the graphical solution in the lower part of Fig. 4.

Taking 10,000 pounds per square inch as the safe shear, and remembering that the rivets are in double shear, we have

$$\frac{\pi D^2}{4} \times 2 \times 10{,}000 = 4030,$$

$D = 0.51$ inch = diameter of the rivets.

One-half-inch rivets would be used in practice. This apparently exceeds the safe limit by about 2 per cent. Such slight excess is permissible, and even if the excess amounts to from 7 to 10 per cent, we need only remember that holes are drilled 1/32 inch larger, and the rivet after being driven in place will be 17/32 inch in diameter.

The bearing pressure is calculated on the projected area of the hole, and the safe unit stress for good structural steel can be taken at 20,000 pounds per square inch. The projected area of the hole = $\frac{1}{2} \times \frac{1}{2} = \frac{1}{4}$ square inch. $20{,}000 \times \frac{1}{4} = 5000$ pounds = safe pressure.

The actual pressure amounts to 4030 pounds.

Next and last comes the question of the strength of the plate.

M = bending moment = 16,000 inch-pounds,

y = distance from neutral axis to the top fiber = 3 inches,

I = moment of inertia of the section in the plane of rivets = 7,

f = actual tension per square inch in extreme fiber =

$$\frac{My}{I} = \frac{16{,}000 \times 3}{7} = 6857 \text{ pounds per square inch,}$$

which is well within the safe limit for structural steel.

There is one more manner in which this joint may collapse; this would be due to cutting off the plate too close to the edge of the rivet holes. The plate would then collapse at the upper rivet. By locating the rivets at from 2 to 3 times their diameter from the edge of the plate, one need not fear any trouble from that source.

* * *

TO DIVIDE A TRAPEZOID INTO EQUAL AREAS

By M. F. JACKSON

While in the pattern shop the other day I noticed several of the men in a heated argument over something and paused to discover what the bone of contention might be. It was an old problem about a tapered plank and where to cut it in order to have two parts of equal areas. Joe proposed to draw lines diagonally across the plank from one corner to the other, and cut the plank in two at the intersection of these lines, while George thought it best to balance the plank on the edge of a steel square, thus finding the center of gravity; for, said George: "There must be as much material on one side of the center of gravity as on the other." As a matter of fact, a student in geometry would know that Joe was wrong, as would also a student of mechanics who understood the principles of moments, know that George was also wrong; nevertheless, each had his adherents, and as the discussion was likely to be prolonged, I volunteered to work it out for them. The statement, solution and proof follow:

A patternmaker has a plank of mahogany in the form of a trapezoid (see Fig. 1) 12 feet long, 12 inches wide at one end and 9 inches at the other. He wishes to cut it into two parts of equal areas. How far from the small end must the center of the saw-cut be to effect an equal division; that is, what is the value of x?

Solution: The total area of the plank $= \dfrac{9 + 12}{2} \times 144 =$

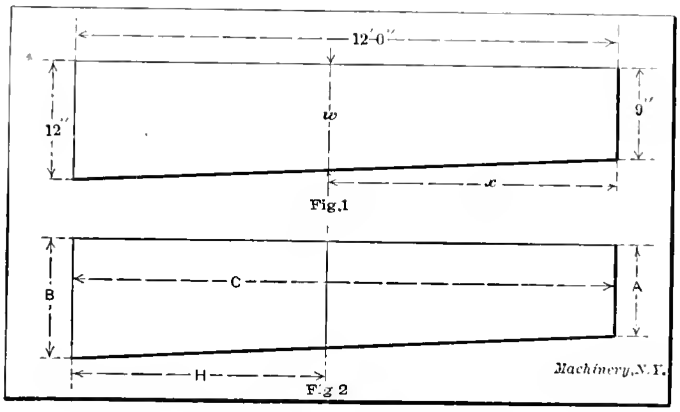

Fig. 1. Plank to be cut into Two Parts of Equal Areas. Fig. 2. Trapezoid giving Notation used in Formula

1,512 square inches and one-half of the area equals 756 square inches.

The taper per inch is $(12 - 9) \div 144 = \dfrac{1}{48}$ (1)

The width of the plank at the saw-cut is $w = 9 + \dfrac{x}{48}$ (2)

The area of the narrow end is $\dfrac{9 + w}{2} x$; but this must equal 756 square inches. Therefore $\dfrac{9 + w}{2} x = 756.$ (3)

Inserting in (3) the value of w as given by (2), we have

$$756 = \frac{9 + 9 + \frac{x}{48}}{2} x = 9x + \frac{x^2}{96} \quad (4)$$

Multiplying both sides by 96 gives

$$96 \times 756 = 96 \times 9x + x^2 \text{ or } 72{,}576 = x^2 + 864x \quad (5)$$

adding $\left(\dfrac{864}{2}\right)^2 = 186{,}624$, to both sides to complete the square gives

$$72{,}576 + 186{,}624 = x^2 + 864x + 186{,}624 \quad (6)$$

Extracting the square root

$\sqrt{259,200} = x \pm \sqrt{186,624}$ or

$x = \sqrt{259,200} \pm \sqrt{186,624} \pm 509.177 \pm 432$ or

$x \cong 941.117$ or $x \cong 77.117$ inches, the latter being the value sought.

Proof: Inserting this value of x in (2), we have $w = 9 + \frac{77.117}{48} = 10.6066$, and area of end $= \frac{10.6066 + 9}{2} \times 77.117 =$ 756.001086, the slight excess being due to the decimals.

[The formula $H = \frac{C}{B - A}\left(B - \sqrt{\frac{A^2 + B^2}{2}}\right)$ the notation of which is indicated in Fig. 2. may be used for dividing a trapezoid into equal areas.—EDITOR.]

REPAIRING AND IMPREGNATING COILS

By RALPH W. DAVIS

To a person who is not familiar with the methods used in electrical construction, the question of insulation appears to be complex and difficult, so a short account of the modern procedure may be of interest.

The coil shown in Fig. 1 happened to be a repair job, but new work follows the same line of treatment. The great size of this coil, which is one of a set for a 4000 volt, series arc transformer, can be judged by a comparison with the 3-foot rule that is suspended before it. The cost of repairing the coil by the method to be described was only about one-seventh the cost of a new one. Of course, when repairing, the largest item of first cost, which is that of the copper, is eliminated, and there is, practically speaking, only the labor cost, which depends largely on the extent of the injury.

The process of repairing this coil was as follows: The coil, when received, was carefully measured, after which it was torn apart or "unwound," and all injured wires repaired. It was then formed up again by winding over a wooden form made to the recorded dimensions. The winding is usually done in a worm-driven winding lathe. The re-formed coil was then removed from the form and wound with cotton tape and the terminals put in place and insulated. After all metal parts were carefully covered with adhesive tape, the coil was ready for the bath in the impregnating compound.

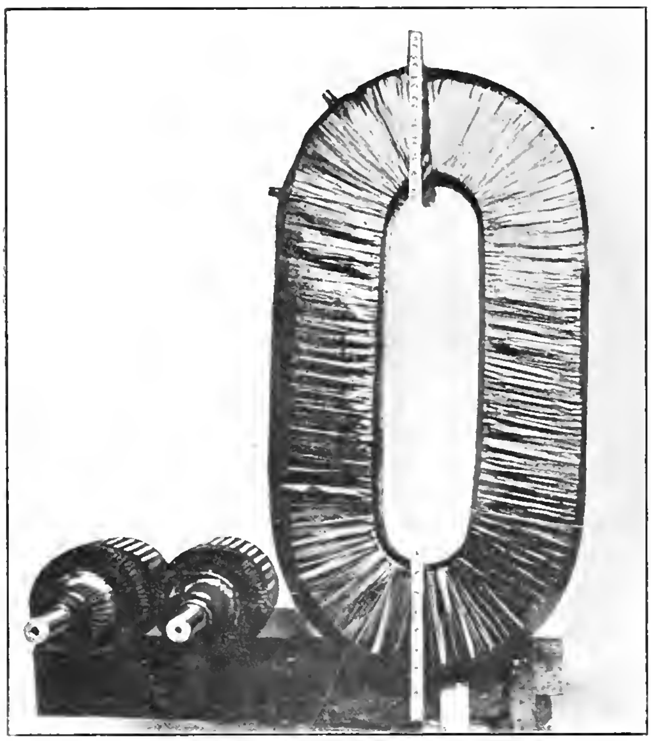

Fig. 1. Large Transformer Coil

It is necessary that the coil be subjected to a high drying heat for about six hours, the temperature being kept at 335 degrees F. It is then placed in a vacuum chamber, where a 29½-inch vacuum is maintained by means of a pump having a water-cooled condensing chamber. All moisture is thus expelled and the coil is absolutely dry and ready for the liquid portion of the bath. This liquid is a combination of several good insulating and moisture resisting elements. In Fig. 2, the cylinder at the left is the liquor chamber where the compound is mixed and heated until it reaches the proper constituency. At the right, and connected to the liquor chamber, is the impregnating chamber, in which the coils are suspended by means of a specially designed rack that keeps each coil separate from the other. The compound, at a temperature of 340 degrees F., is "run over" from the liquor chamber, and a pressure of 70 pounds per square inch is applied to the impregnating chamber by means of a small combination vacuum pump and compressor.

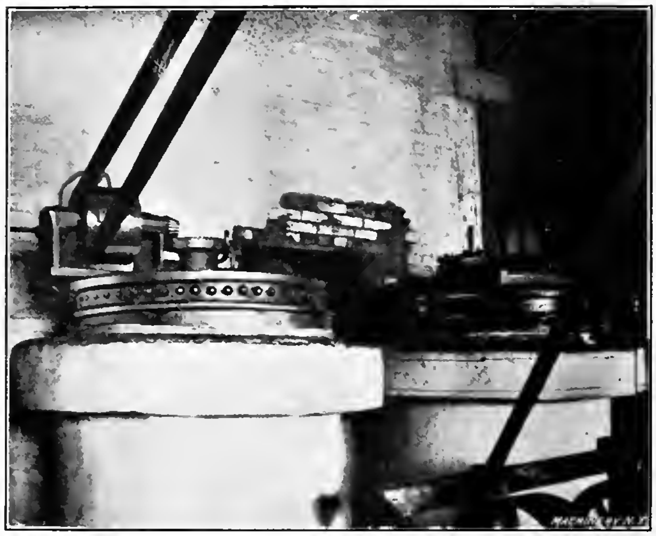

Fig 2. Tanks in which Coils are impregnated with Insulating and Moisture-resisting Compound

Under this condition the coil is kept for eight hours, allowing the compound to penetrate to every portion of the winding, and by reason of its high insulating quality, it places additional insulation between the winding. Actual tests show an increase of 100 per cent. The compound also acts as a preservative on the tape and cotton insulation, and the coil is firm and solid. After being removed from the bath and drained, the coil is jet black, but a covering of a more pleasing color may be added if desired.

This treatment is especially useful for armatures and field windings that are subject to moisture or hand usage, such as would be received in steel mills, coal or iron mines and outside construction. The small armatures are impregnated after the windings are in place, while large armatures have each coil treated before being placed in position.

A complete impregnating outfit for ordinary work can be bought and installed for $700, while larger sizes, of course, are more costly. An outfit which will handle 2500 pounds of railway field coils at one time will cost about $1,350. Fig. 2 shows the liquor and vacuum chambers of a plant of this size. Note the heavy asbestos heat insulation and also the massive covers. The mechanism on top of the liquor chamber (at the left) operates the mixing blades. The combination vacuum pump and compressor, previously referred to, first obtains the vacuum needed, and then by an arrangement of bypasses and piping, the same pump provides the required pressure. The chambers are usually heated by steam, which is admitted to the jacket about the chambers, but where steam is not available, the jacket is filled with high flash oil heated by a gas burner, and kept in circulation about the chambers.

The impregnating compound is a commercial article made by several companies, and it is in several grades. The point at which it will soften and begin to drip determines the particular grade to be used, as some coils are subject to greater heat than others, but with all grades the action of the vacuum to take out all air pockets, followed at once by the immersion in the heated compound under pressure, insures every portion of the coil's receiving its portion of the compound, which rarely happens with the old method of dipping in varnish.

COMPRESSED AIR RECEIVERS

By O. J. MacFADDEN*

An air receiver plays an important part in obtaining the highest efficiency and most economical operation of any compressed air installation. It is essential that the cubic capacity of the receiver be in the right proportion to the capacity of the compressor. For all practical purposes the receiver should have a capacity of from 15 to 20 per cent of the free air capacity of the compressor (per minute), but in large installations the percentage is sometimes lower, running down to about 10 per cent. To obtain good results the receiver should be placed as near as possible to the compressor, and in any case not more than 50 feet distant.

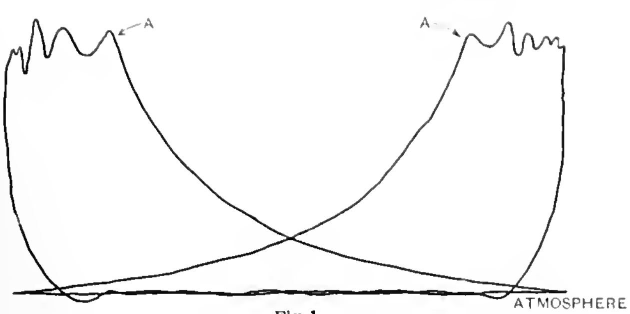

Fig. 1

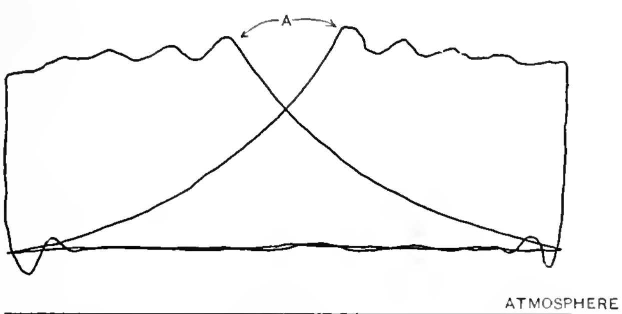

Fig. 2

Figs. 1 and 2. Typical Indicator Diagrams from Single-stage and Two-stage Air Compressors

Receivers may be placed in either a vertical or horizontal position, the vertical being preferred in most cases owing to the economy in floor space thus obtained. In many cramped installations the receiver is suspended from the ceiling by means of hangers or on the wall by means of brackets.

On entering the receiver, the discharge air from the compressor is reduced in velocity, and cooled to a certain extent, a large percentage of the oil and moisture held in suspension being deposited thereby, giving a relatively dry and clean air at the machines and tools using same. The inlet and outlet openings should not lie in a straight line opposite each other, as a through current would result which would interfere with efficient cooling and depositing of the moisture; the usual practice is to take the air in at the top and discharge it at the side near the bottom where the air is cooler, thus causing a change in the direction of flow and allowing of more efficient cooling and depositing of the moisture. Atmospheric conditions affect the amount of moisture deposited, and the receiver should be drained often in warm weather.

If the air from a compressor were discharged directly into the main, a loss of power would result, due to the piston of the compressor forcing a cylinder full of air into the main against a pressure momentarily higher than the normal. In other words, the effect of the strokes of the compressor piston would be to set up pulsations and cause fluctuations in pressure. This action would also have a tendency to increase the friction in the discharge pipe.

In comparing the pulsations caused by the discharge on a single-cylinder and a multiple-cylinder stage compressor it will be noticed that the latter has less pulsation to a marked degree, on account of the discharge valves opening sooner in the stroke and producing a longer duration of discharge. Fig. 2 illustrates this to good advantage, being an indicator card from a two-stage compressor, the card being taken from the high-pressure cylinder, 10 inches bore, compressing to 100 pounds per square inch gage. The points marked *A* show the commencement of discharge, and it will be noted that about one-half the stroke is utilized for it. The discharge valves of a single-cylinder compressor working at the same pressure open much later in the stroke, causing the total discharge to occur during a shorter part of the stroke, thus setting up a violence of discharge pulsations.

Fig. 1 shows a card from a 10-inch bore single-cylinder compressor, compressing to 100 pounds gage. The points marked *A* show the opening of discharge valves, and by comparing with Fig. 2, it will be seen that the duration of discharge is very much less in Fig. 1.

The receiver, if the capacity is sufficient, prevents any appreciable rise or fall of pressure due to the discharge of air and absorbs all pulsations. In regard to the receiver acting as a reservoir of power, this is true only to a certain limited extent; the storage feature can be of much value only in certain cases, such as in small plants where an exceptionally large receiver is employed in connection with a small compressor, the compressor being operated only long enough to raise the air to the desired pressure in the receiver, then being shut down, and the air used from the receiver to operate pneumatic tools or machinery which would allow a variation in working pressure of from 20 to 40 pounds, permitting the pressure to drop to that extent in the receiver before the compressor is put into operation again.

In the common form of receiver construction, steel of 60,000 pounds per square inch tensile strength is used; all circular seams are single-riveted and the longitudinal seams double-riveted. The heads of vertical receivers are usually dished, one being concave and the other convex, and in the case of horizontal receivers both heads being convex. Air inlet and outlet flanges, tapped holes for the pressure gage, pop safety valve and drain cock should be provided in the right proportion to suit the capacity of the receiver, always placing the drain cock at the lowest possible point to allow complete drainage of all moisture and lubricating oil deposited by the

air. For ordinary pressures from 80 to 125 pounds per square inch, receivers are designed to stand a cold-water test of from 150 to 165 pounds pressure. In receivers of 36-inch diameter and larger a manhole is usually provided in the lower part of the shell. The accompanying table contains a list of standard-size receivers, together with data as to capacity, weight, etc.

DETERMINING COMPARATIVE VALUES OF LEATHER BELTING

Large buyers of leather belting, particularly purchasing agents of corporations who get estimates for supplies from a number of manufacturers, naturally feel the need of uniform specifications, so that they may have a basis upon which to compare prices. The result has been a great variety of specifications with some of which it is impossible for any belt manufacturer to comply, while others frequently exclude the purchase of some of the best brands of belting.

Old Idea Exploded

The truth is that the old idea that only certain materials for tanning and rules for currying and stuffing leather as well as for fixing certain lengths for pieces could be used, is exploded. It was claimed a few years ago by a large belt concern (not now in business), that a steer hide whether taken

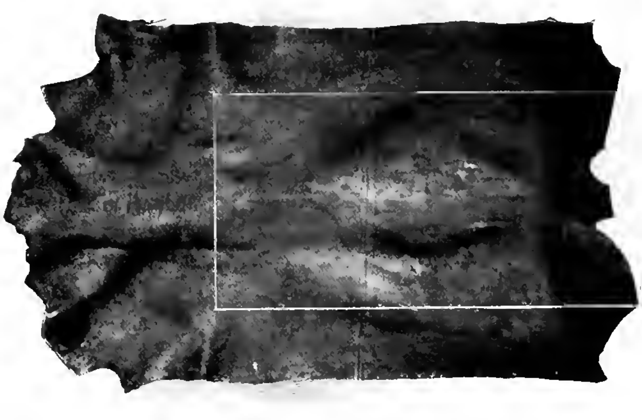

Diagram showing Portion of Hide used in Making Belting

from a small or a large, a young or an old animal would cut pieces of exactly the same length, suitable for belting—no longer, no shorter. But now any man familiar with hides knows that this is absurd. We could as well claim that there is no more cloth in the coat of a giant than in that of a dwarf, as to suppose that the good portion of the hide is of the same size, whether the steer from which it is taken weighs 1000 pounds or 1500 pounds. This being the case, it is evident that to cut the pieces taken from a large hide to the same length as those taken from a medium-sized one must waste good leather in the large hide and consequently increase the cost of production and the price to the buyer. If all hides were of the same size, thickness and consistency throughout, like a plate of steel, it would be a simple matter to make good belts, but they are not; hence no hard and fast rule can be laid down for their construction.

Making a Good Belt—Improvement in Methods of Currying and Tanning

The best leather was at one time supposed to be cut from directly over the back of the animal, but very careful tests have proved that the strongest leather is not there, nor toward the butt end of the hide, but just back of the shoulder and about one-third of the distance from the backbone to the belly.

Again the old ways of currying and tanning have given way to improved scientific methods which were scoffed at and condemned in their infancy as innovations and fakes. Our grandfathers did not know how strong their tanning liquors were; they guessed at the amounts of materials used, applied the greases to the outside of the leather, and got but little into the center fibers. To-day we have our laboratories and appliances, which insure vastly more uniform results than were then obtained. Then "pure oak tanned leather" was considered the only stock from which to make the "best belts," but now there are belts which have never seen "pure oak bark" or any "oak bark" at all, which command highest prices. Thus it is evident that it is not alone a question of rule-of-thumb tannage, of currying, or of the length of pieces, but one of the use of brains—the employment of the best talent and machinery in all the processes of the work combined with the strictest supervision.

What Constitutes a Good Belt

It naturally will be asked what then constitutes a good belt and how the buyer is to compare values without specifications. Replying to the first part of this question and granting that good leather is provided (which by the way may or may not be oak tanned), *uniformity of material is of the first importance.* By the term uniformity we do not mean exact uniformity of thickness, but uniformity of working efficiency; *i. e.*, a belt in which all the pieces rigidly class in the same grade, not one piece of first grade and perhaps the next piece to it of third, as is not infrequently the case. A belt composed of ten pieces of leather may have in it one piece of poor stock which will put the whole belt out of commission. The determination of a belt's working efficiency requires expert knowledge. Mere piping or wrinkling of the grain or hair side of the leather is not necessarily a serious matter, as some hides will pipe comparatively near the backbone while others maintain their solidity almost to the flank.

Probably the next most important thing to the user is a thoroughly stretched belt, one that does not have to be taken up every few days.

How a Buyer Can Determine Cooperative Values of Belts

As to how a buyer can determine comparative values of different makes, this cannot certainly be decided by weight, thickness or length of pieces. "The proof of the pudding is in the eating," and the proof of leather belting is in the result obtained from its use. It does not take an expert to tell which is cheaper, a belt that costs $50 and lasts six years and stretches but little, or one which costs $45, lasts four years and stretches much. To determine what makes of belting to use, keep a record of the service of each belt and it will not take long to determine which is the cheapest. The results obtained will very likely surprise the average belt user.

RECORD HEAT FOR A SMALL CUPOLA

The following is the record kept of a heat which was taken for a small cupola 36 inches in diameter in the works of E. Leonard & Sons, London, Ontario, Canada. Coke was used as a fuel, and the composition was agricultural scrap, broken small and mixed with 40 per cent pig iron, each pig being broken into four pieces. The blast engine was 9 inches cylinder diameter by 8-inch stroke, working at 120 pounds steam pressure with atmospheric exhaust and making 290 revolutions per minute. The fan was a No. 5 Sturtevant, making about 3500 revolutions per minute. The piston pressure as noted on the water gage was 16 ounces per square inch, but the pressure occasionally dropped to 12 ounces. The pressure was on for 3 hours 35 minutes, and the amount of metal poured was 45,000 pounds. One large casting was made of about 41,000 pounds and the balance of 4000 pounds was made into small castings. The fan belt was shortened about 2 inches each time the cupola was tapped, and 15 pounds of rosin was used on the belt during the heat. C. Cariss

London, Ontario.

A SOFT SNAP

"Say, Bill, I've got a fine job now in the office of the *Lallapaloosa;* we don't have *your* cast iron rules and regulations. We can go to lunch when we *feel* like it—none of that foolish stuff with our Old Man about staying in till 12 and getting back at 1."

"That's fine, but do you mean to say that anyone can go and come when he feels like it?"

"Sure, Bill. Oh, of course, we have to punch a time clock, but *every one there* has to do that!"

DONKIN'S DIVIDING ENGINE—EARLY MACHINE TOOLS*

By W. S. DAVENPORT†

There is an old and well-known saying, "The Ancients stole many of our best ideas," and many an inventor after working hard and long on some device which he considered original and valuable, has found to his sorrow that someone else, months, years, or centuries before had conceived the same idea and carried it out with more or less success.

Recently, while on a Transatlantic voyage, our ship received a wireless telegraph message from a disabled sister ship of the same line, and sailed back over her course 150 miles, found the vessel, and towed her safely into port. Naturally our conversation turned to the wonders of wireless telegraphy, when a worthy Scotchman, now a professor in a Canadian university, stated that messages had been sent by electricity from one mountain to another in Scotland without wires a hundred years ago, more or less, but the people believed it to be witchcraft, so the inventor and discoverer was obliged to drop the work. We cannot vouch for the accuracy of this statement, but it illustrates the old adage.

There is, however, an authentic illustration of this saying, which we recently saw, that will be interesting to the readers of MACHINERY, no doubt, and that is a device for correcting the pitch of a lead-screw. It has been thought by most of those acquainted with this device, that it was a comparatively recent invention, but it is not so. In the science department of the South Kensington Museum in London is a very fine machine, constructed in 1826, with the principle carried out in an admirable manner. It is known as Donkin's dividing engine, and is illustrated in Fig. 1 at A. The illustration shows the machine fitted to cut an accurate screw, but it was also used for graduating accurate scales, from which the above name was taken. Even at that date, the principle was old, but Mr. Donkin carried it out to a highly perfected state.

The lead-screw of the machine is between the two guides for the carriage, and is revolved by the large gear shown on the right-hand end. The nut, instead of being rigidly attached to the carriage, as is the usual practice, is fitted closely between bosses so there is no looseness longitudinally, but it is free to rotate slightly with the screw or in the opposite direction. It is obvious that if the nut rotates with the screw a fraction of a turn, the carriage will travel less than the lead of the screw, and if the nut is rotated in the opposite direction, the carriage will move a proportionally greater distance than the lead. To make the compensating rotation of the nut just the desired amount to correct the inaccuracies of the original screw, the nut has an arm fifty times as long as the radius of the screw. This long arm has a knob on one side which is held, by a suitable spring, in contact with a series of adjustable blocks half an inch wide, each block having its own adjusting and clamping screws. These blocks can be seen with their screws, below

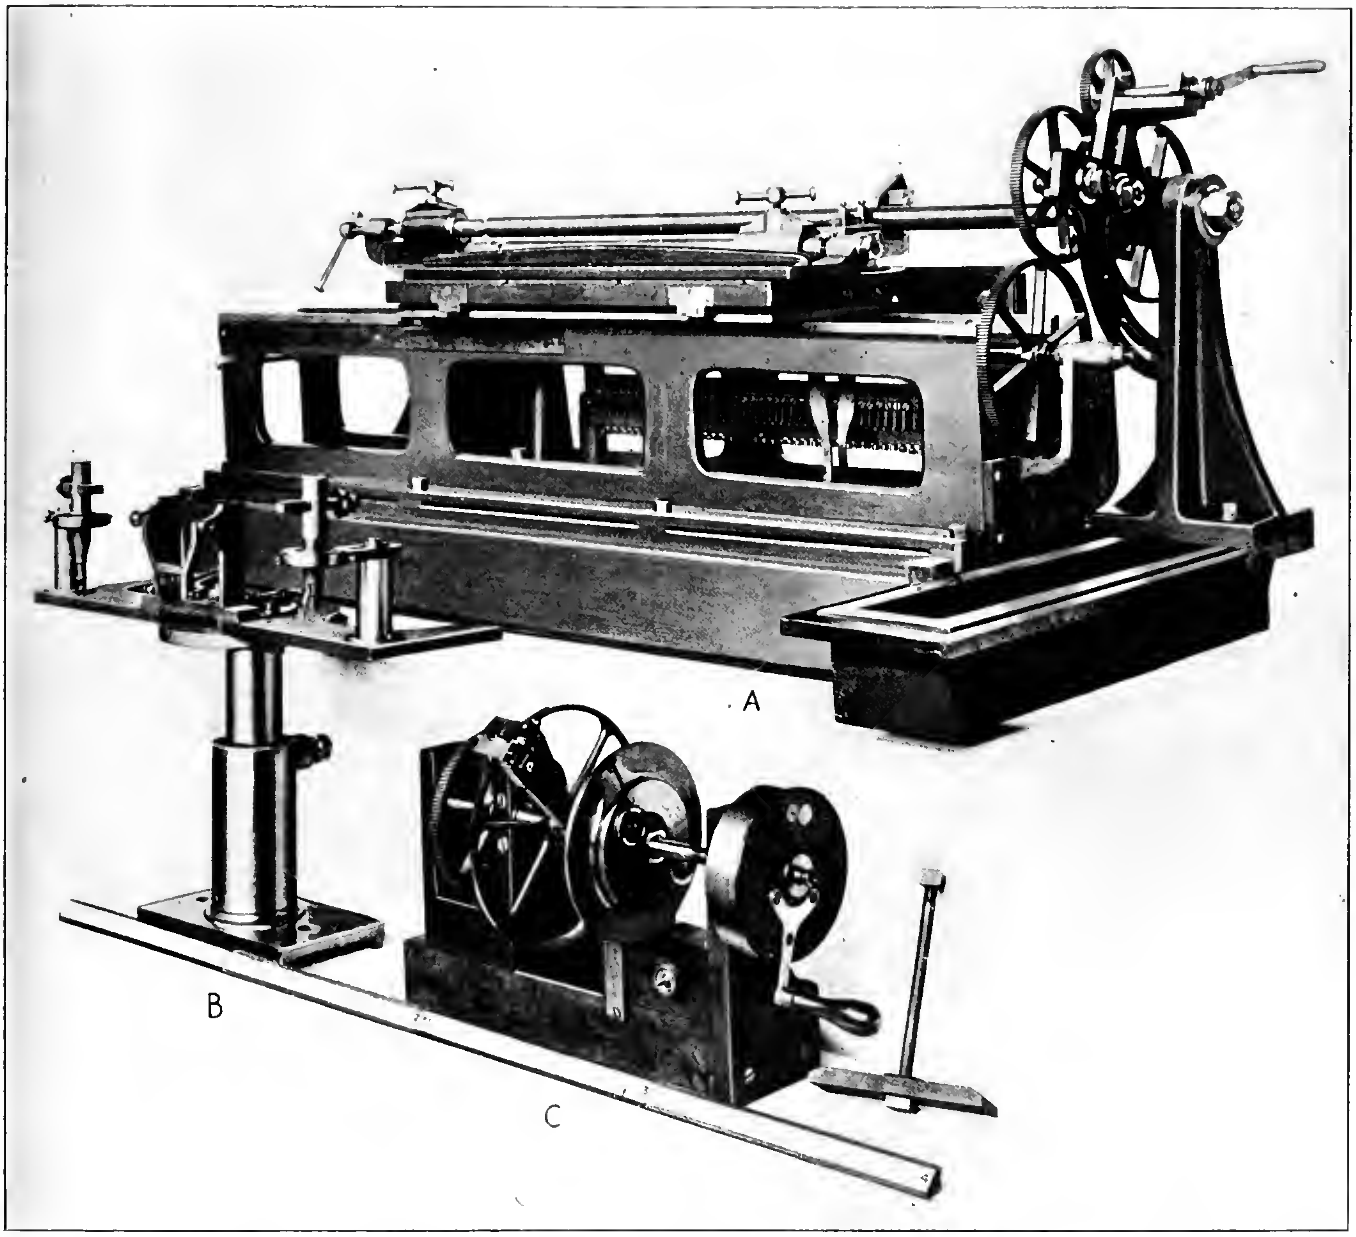

Fig. 1. Donkin's Dividing Engine and Accurate Screw Cutting Lathe. A Compensating Device is provided for Correcting Local Inaccuracies of Lead-screw

* For previous articles published on early machine tools, see MACHINERY, September, 1909, "Chapters in the Early History of Machine Tools," by Joseph Horner, and articles there referred to.

† Address: Davenport Machine Tool Co., 90 Sixth St., New Bedford, Mass.

the lead-screw. The lead-screw is 24 inches long, so there are 48 adjustable blocks. After the inaccuracies of the screw were found, the blocks were adjusted up or down as necessary, till the movement was uniform throughout the whole length. The corners of the blocks were rounded off, so the knob would ride easily over them.

At *A* in the illustration Fig. 1 the machine is shown from the back side, as this view best illustrates the principle of the compensating arrangement. The small view *B* shows the graduating device and two microscopes mounted on a table, and all supported by a post in a bracket. This device was placed on the front of the machine, and used in finding the errors of the original screws, testing the lead-screw until it was correct. The testing was accomplished by graduating very fine lines on a polished strip of brass—first 24 inches apart, then bisected, then both these divisions bisected, and so on till there were 24 lines, the microscopes being used to compare the divisions, and finally, after repeated adjustments of the blocks, the nut with the long arm traveling on the blocks moved the carriage uniformly the whole length so graduations could be made perfectly uniform. The second small view *C* shows the ratchet wheel with 500 teeth which was geared to the lead-screw when the machine was used for graduating.

In the illustration, the machine is shown arranged to thread the screw at the top, which is 36 inches long, necessitating two settings of the carriage with relation to the work; the tool carriage is attached to the nut carriage by the clamps on the rod. The lead-screw is of very fine pitch, being 50 threads to the inch. In threading, the screws were both turned by the crank shown at the top of the machine.

So far as known, this was the first accurate dividing engine made, and the first really accurate screws were cut on this machine. The principle, however, was old at that time, as it had been used in a crude way by Maudslay, who made a correction of 1/16 of an inch in 7 feet by an inclined guide for the nut, but did not correct the local inaccuracies.

In the same department is the original Maudslay engine lathe, made late in the eighteenth century, and a notice in the case with it states that this is the first lathe ever made with a self-acting tool carriage and a lead-screw for use in threading other screws. [See illustration of this lathe in MACHINERY, September, 1909, page 1, engineering edition.] Previous to the building of this lathe, slide rests had been used which could turn short lengths only, and screws were cut only with dies or toothed chasers in hand tools, which at best would produce only inaccurate leads. The head- and foot-stocks are attached to only one of the inverted V's, but the carriage slides on both, and has a cross-slide with a graduated collar on its feed-screw. This is an illustration of the original conception's being correct, although not copied on the thousands of lathes built during the greater part of a century. It has been provided, however, on the best class of tools during the last twenty-five years. Provision is made in the tool-post for three tools, but probably not for roughing and finishing tools. Doubtless two were used as supports for slender work, and one for the cutting tool. The shape of the cross-section of the inverted V's has been closely followed in American practice. The dovetailed fit of the cross-slide at the start, seems to have differed but little from our present practice.

It seems that in making screws, Maudslay had tried many devices before he succeeded in making one good enough for this lathe. He first tried to wind a metal wire or tape around a bar, but could not get as even pitch as desired. He then constructed a machine, also exhibited, which he made about the year 1800, in which round bars of hard or soft wood or metal were rotated in a long hole, and a chisel or cutting tool set at an angle and held by a graduated device, cut into the work at an angle and caused the work to travel longitudinally as it was rotated, the lead produced being controlled by the inclination in the cutting tool. [For illustration see MACHINERY, November, 1909, page 189, engineering edition.] The best of these were taken as lead-screws and from one of these the screw was made which is now in the lathe. Think of the struggles these pioneers had to originate the methods and first tools, making our present machines possible.

Near by is a "planing machine" made by Richard Roberts in 1817 and said to be the first machine made for planing metal. [For illustration see MACHINERY, October, 1909, page 91, engineering edition.] It is evident from the marks of chipping chisel and file that this was made without other tools than these. At this early date, the correct principle of grinding a slide was used, one side being a V (long and narrow), and the other a flat surface.

The table has bolt holes for securing the work. The cross-rail is supported by a standard each side of the bed with screws for adjusting for height, and has a screw for feeding

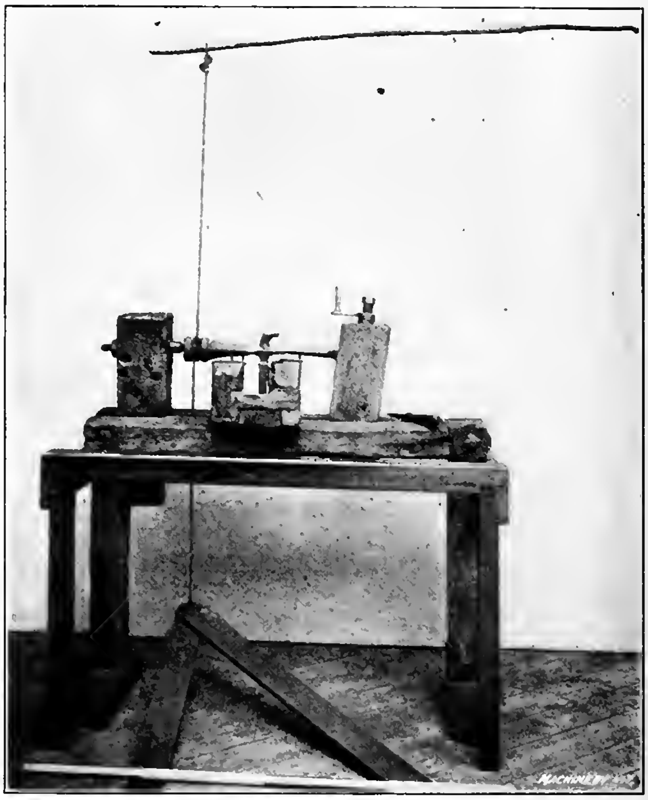

Fig. 2. Pole Lathe in South Kensington Museum, the Oldest Form of Lathe Known. This Lathe was in Active Use until about 35 years ago

the tool across the work. The tool is held in a hinged clapper arranged to lift on the return stroke, and a screw is provided for feeding the tool down to the work, which also can be adjusted to feed at an angle. With the exception of the traversing of the table, which is done by hand and chain, and the absence of automatic feed, the metal planer seems to have come into existence in a remarkably perfect form.*

Going still further back, Fig. 2 illustrates a "pole lathe" which is the earliest form of lathe made. This particular lathe was made in about 1800 by Thos. Nokes & Sons, and was in use as late as 1879 by them for turning parts of stop-cocks, etc. The work does not revolve continuously in one direction, but oscillates in each direction perhaps a dozen revolutions each way. The strap connected with the treadle is wrapped around the wooden arbor of the lathe and leads up to the spring pole. As the operator pushes the treadle down with his foot, the work rotates forward and the cutting is done; the hand tool is then drawn away from the work and the spring pole draws the treadle up again, the spindle, of course, rotating backwards. This seems very slow and crude, but is in daily use in many small shops on the shores of Lake Como, where fancy novelties are made of olive wood to sell to the many tourists who flock there every year.

Compare this very crude lathe of 1800 and the beautifully wrought Donkin's dividing engine, and it is obvious that great strides were made in the early part of the last century, and that the improvements made then were even more marvelous, relatively, than those of which we are wont to boast of at present. Maudslay, Donkin and others had the field all to themselves, it is true, but they were men of great minds and made great improvements, laying the foundation for our present progress and prosperity.

* Comparatively little is known of the early development of metal planers and of the various schemes tried for producing planed surfaces beyond that many inventors worked on the problem with indifferent success. Most of them worked secretly and what they individually accomplished is for the most part unknown. See "Industrial Biography," by Samuel Smiles.—EDITOR.

NEW FACTORY OF THE FRANK MOSSBERG CO.

By CHESTER L. LUCAS

The location of the Frank Mossberg Co.'s new factory at Attleboro, Mass., is ideal. Directly on the main line of the New York, New Haven & Hartford Railroad and but a short distance from the station at Attleboro, the two-story brick factory is situated on high, level ground. Apart from the factory district proper, the light and surroundings of the building are superior and the view of green fields from its windows is a refreshing change from the outlook upon the cinder yards and busy streets that the average factory windows afford.

The building itself faces the east. This position was necessary on account of the north and south direction of the railroad. It being impracticable to employ the usual type of mill construction with saw-tooth roof, a roof with the saw-teeth placed lengthwise of the building was used so as to supply the best light.

At the front end of the building and on the second floor are the business offices, the private offices for the officials of the company and the drafting-room. These various offices are finished in Flemish oak and are of ample size for the purposes intended. Fig. 2 shows the general appearance of one of the offices.

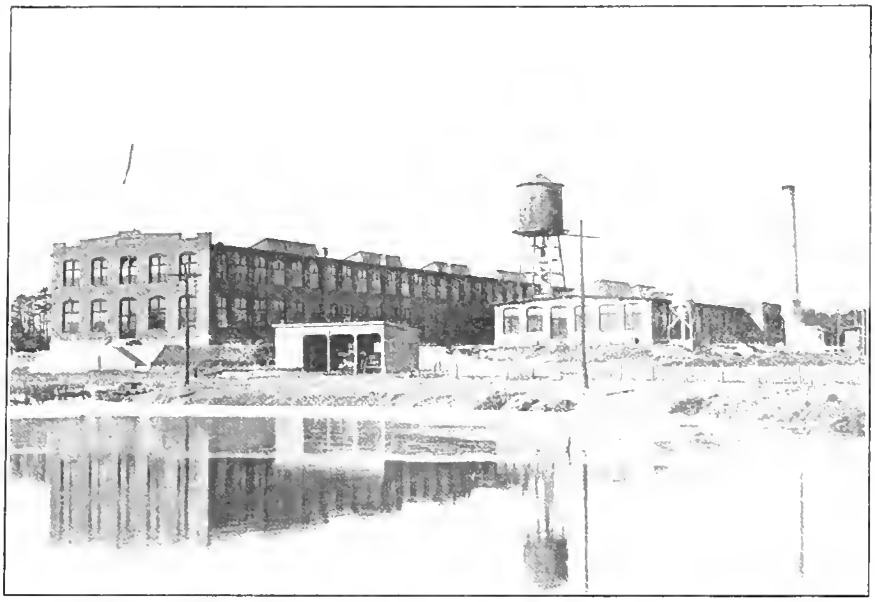

Fig. 1. Factory of the Frank Mossberg Co., Attleboro, Mass.

On the south side of the second floor is the toolroom. Here the dies and tools for the factory work are turned out. The punch and die shown in Fig. 4 are fair specimens of the tool work. The remainder of the floor is given up to light machine work, screw machines, shapers and lathes, milling machines and the like. At one part of this floor is maintained an apprentice department where the boys are started at their trade. By keeping the younger apprentices on these machines until they are accustomed to the proper use of machine tools, the machines in the toolroom are saved much abuse. The view of the screw machine department, Fig. 3, illustrates the well-lighted condition of the rooms, and throughout the factory the same good lighting is noticeable.

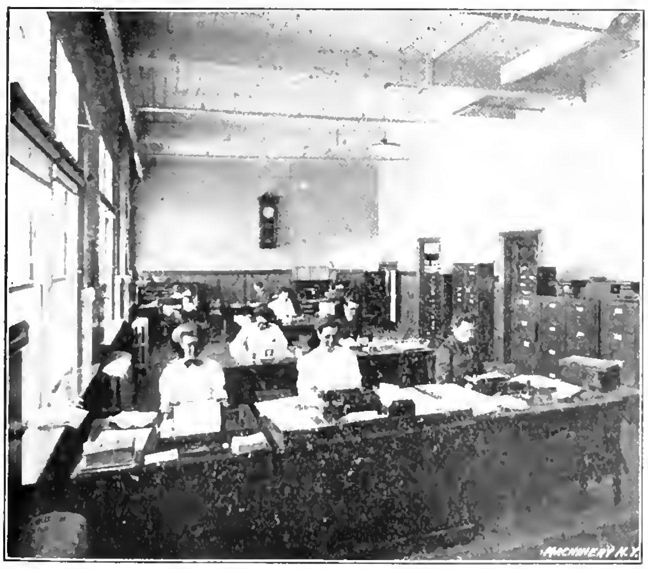

Fig. 2. Interior of one of the Offices

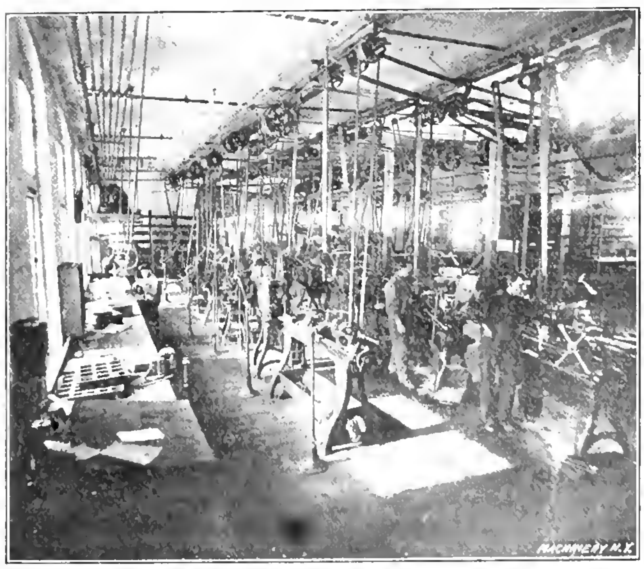

Fig. 3. Screw Machine Department

The polishing and plating departments and also the hardening department are located in the building at the right of the main factory as it appears in Fig. 1. The plating room is shown in Fig. 5. The arrangement of the tanks and various baths is most convenient. The wiring of the work is all done at the corner of the room where the work enters from the factory. At the center of the room are the various dips, potash and hot water tanks and the cleaning benches. On both sides of the room are the nickel solutions, easy of access from the central row of cleaning tanks and dips.

The current for the plating tanks is furnished by two direct-connected dynamos, one of 1500 ampere capacity and one of 500 ampere capacity. In order to avoid the expense that would be necessary for wiring the smaller work, a rotary plater has been installed that effectually cares for this item. Instead of the usual boxes of sawdust for drying the parts, this company places the plated work in a large basket and forces a strong current of hot air through them, a method that is both quicker and cleaner. The cleaning of much of the work is done in a tank with a special solution. The process employed is just the reverse of the nickel plating operations, for the current passes through the solution in the opposite direction from the one taken while plating, and this process removes the grease and dirt rapidly.

The polishing department, in which from 50 to 75 men are employed is kept exceptionally clean by means of a powerful exhaust fan driven by a direct-connected electric motor. Friction is eliminated as far as possible by the use of ball bearings mounted on the main shaft, and each shaft length is driven by an independent motor. A great deal of the brass goods manufactured receives a high polish and consequently must be lacquered to protect the finish. Instead of applying the lacquer with a brush or dipping the articles in the lacquer, a spraying process is used. Compressed air is forced through the lacquer tank and by means of a nozzle

* Address: 1 Bailey Ave., East Saugus, Mass.

from this tank the lacquer is sprayed onto the work, a better result being obtained in this way than by dipping—the process is also quicker than brushing.

The hardening room is well equipped with furnaces, most of which are operated by crude oil. The problem of storing the oil supply has been taken care of by means of a large

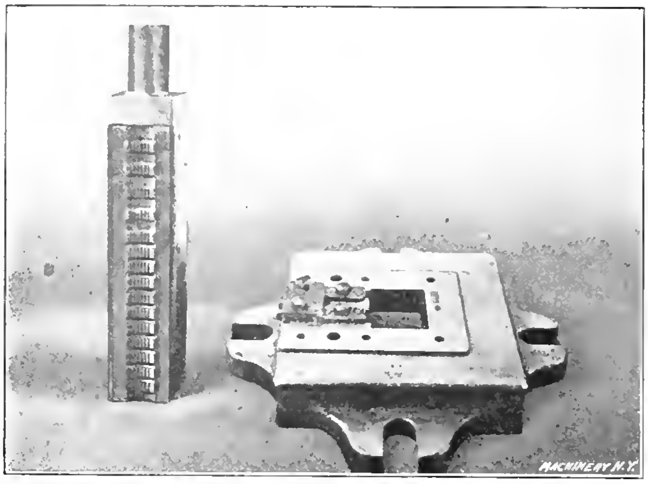

Fig 4 Broaching Tools for Gear Teeth

underground oil tank that is placed under the car tracks outside of the building so that the oil cars may be quickly emptied; at the same time the oil is not exposed to fire risks. As required, the oil is pumped into the factory and fed to the furnaces. The hardening furnaces are equipped with recording pyrometers that enable the hardeners to put the work through at the proper heat and, of course, the results are uniform. In addition to the crude oil burning system used for the larger furnaces, a gas plant is installed for making gas from gasoline. This gas is made with the proper proportion of air and is piped to the different departments where it is to be used.

At the rear of the building, on the second floor, are the inspecting, packing and shipping departments. The wrenches,

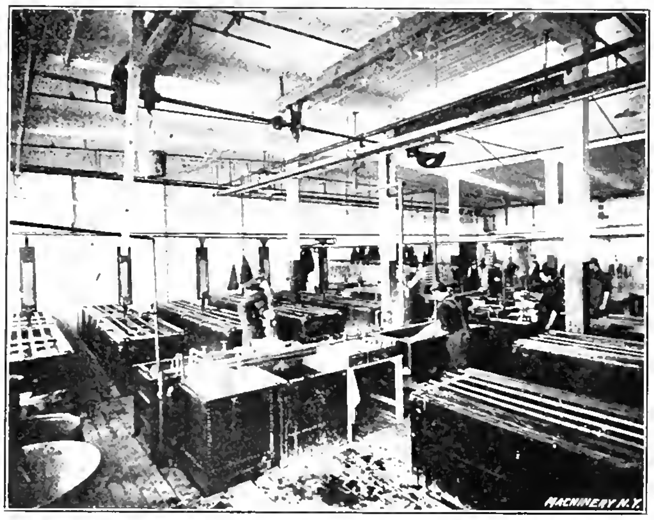

Fig 5. Nickel Plating Department

bells and other specialties pass through these departments successively to their final destination on the freight cars in the yard.

The lower floor of the factory is given over entirely to punch-press work. Fig. 6 shows a section of the department that is used for heavy press work. The press shown in the illustration is powerfully geared and the heavy frame is supplemented by four three-inch steel rods that strengthen it beyond danger of breaking. The press is motor-driven and is shown set up for piercing the sides of large wire reels. These reels are made in a large variety of sizes, from 2 to 72 inches diameter, and are for holding wire of all kinds as sent out by the wire manufacturers. A group of these spools may be seen in Fig. 7, the large spool being made of iron and the smaller ones of brass.

Wrenches, both adjustable and socket, form a considerable part of the firm's output. The group shown in Fig. 8 illustrates a few of the 75 styles and sizes of the adjustable wrenches and most of the styles of socket wrenches. At the center is shown a socket wrench complete, applied to a pipe joint. Mounted on the board shown in Fig. 9, is a set of shells that illustrates the evolution of a socket wrench from the round blank to the finished wrench. After blanking, the piece receives eight draws, each drawing the shell a little deeper and narrower. After the eighth draw, the process is divided into two groups, one for the wrench for hexagon, and one for the wrench for square-head nuts. From this dividing point, in the case of either style of wrench, the first two or three operations are to draw out the narrow part of the shell and the final two operations are the shaping of the hexagon and square sections. These latter operations are done in the drop press by placing within the shell a mandrel of the correct shape and then striking the shell sideways between dies that give it the finished shape. The other pieces in this illustration are specimens of the drawn work done in the Mossberg factory.

The adjustable wrenches for bicycle, automobile and gen-

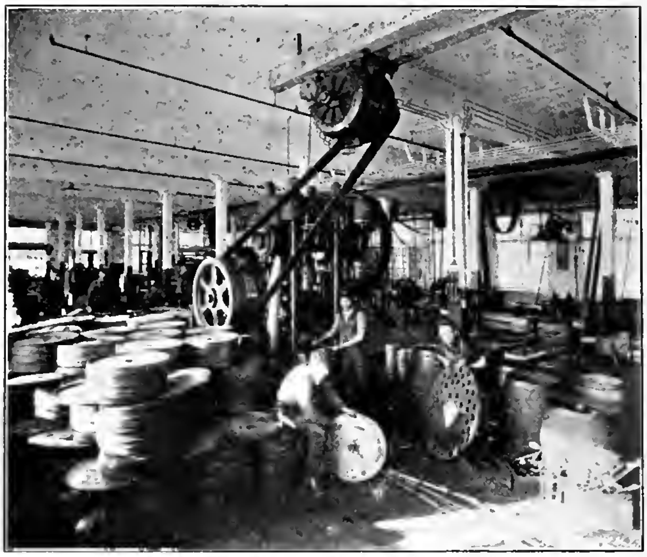

Fig. 6. Heavy Press Work Department

eral use are made in larger quantities than the socket wrenches and consequently there are more interesting operations employed in their making. One of these operations is the broaching of the wrench teeth, which is done in a punch press as shown in Fig. 12. As the position of the press did not admit of taking a detail photograph, a set of broaching

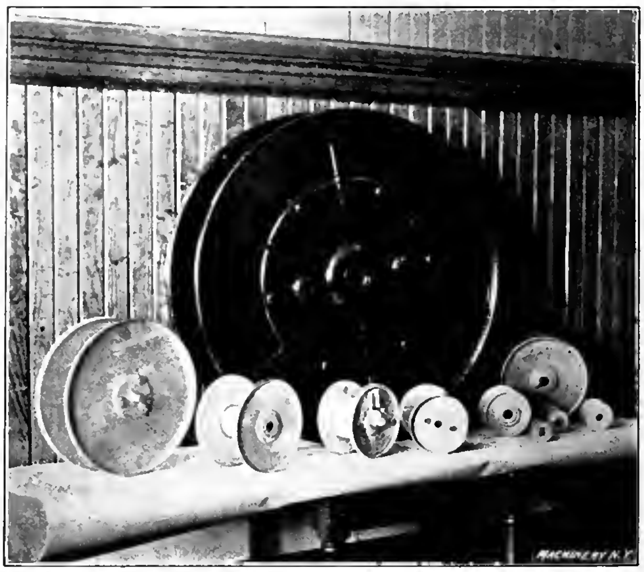

Fig. 7. Wire Spools and other Drawn Work

tools was photographed showing the construction of the punch and die, which, although not for wrench work, illustrates the principle of the broaching dies. In this illustra-

tion, Fig. 4, the die consists, primarily, of four pieces set into a cast-iron bolster. The pieces at the top, bottom and right-hand side of the rectangular opening, are of machine steel, casehardened 1/16 inch deep, and the left-hand section is of high-speed steel and is the broaching die proper. These four pieces are each a driving fit in the bolster and are doweled and screwed in place. On the top of the die section are screwed the hardened locating gages that confine the blank while being broached. The broaching punch is built up of casehardened machine steel sides. The side that does the actual broaching is of high-speed steel and consists of a number of steps as in the ordinary broach. As may be seen, the steps at the bottom do but little cutting and hence are closely spaced. Each successive step removes a little more of the stock, except the last three or four steps, which do little more than to smooth the surface and size the teeth. As the sides

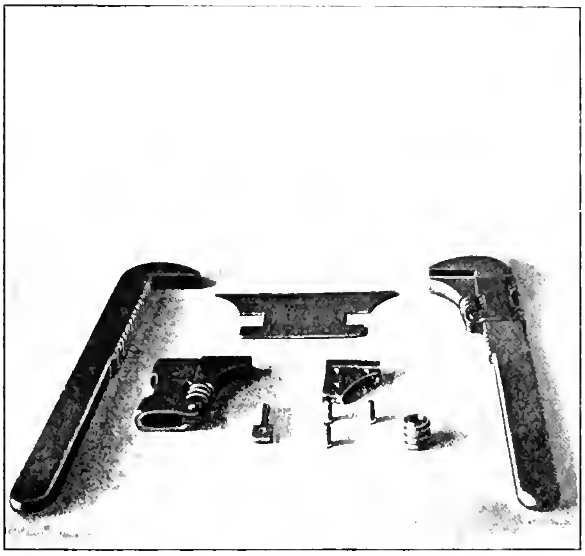

Fig. 10. Component Parts of a Wrench

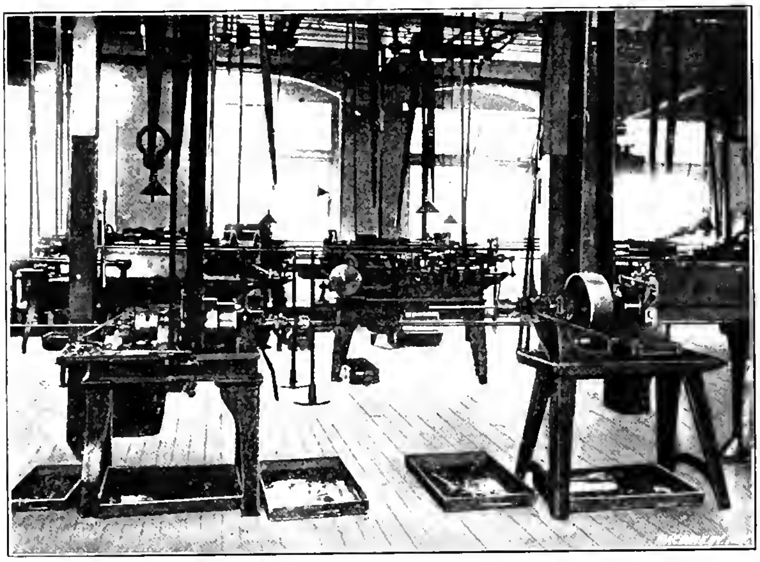

Fig. 11. Threading the Stock for Wrench Nuts

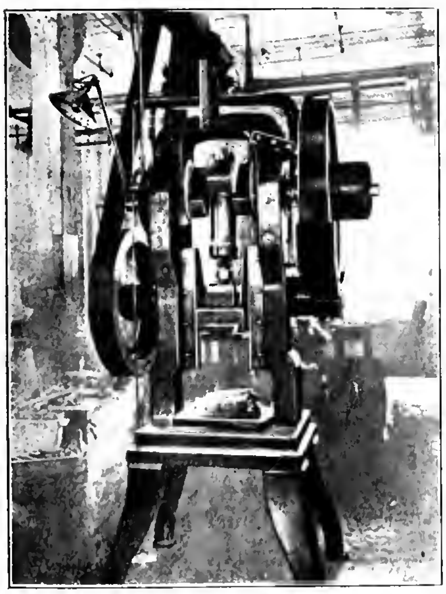

Fig. 12. Broaching Wrench Teeth

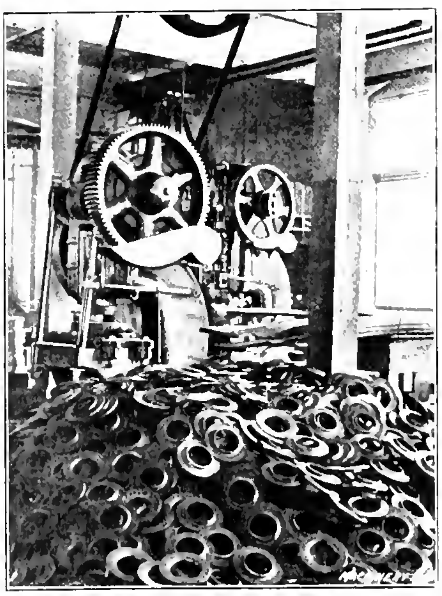

Fig. 13. Making Automobile Hub Flanges

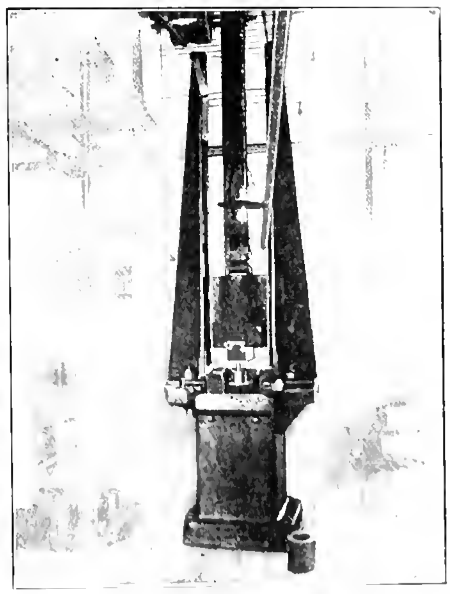

Fig. 14. Novel Drop Press Foundation

of the punch fit the opening in the die closely, the broaching teeth are kept perfectly aligned and there can be no springing away of the punch. By the use of this type of die, all the advantages of the sub-press are gained at about one-third the cost. The Mossberg people have made a special study of broaching problems and some of the work done on wrenches, typewriter, clock and adding machine parts, is indeed creditable. The inclining of the broaching die in Fig. 12 is, of course, to give the proper pitch to the wrench teeth and incidentally enables the broaching to be more easily done.

Electric lighting for presses and other tools where the light must be at close quarters, is taken care of by fixtures like that at the left of the press in the illustration. The general lighting of the shop is by tungsten lamps of the 250-ampere size. These lights with shades are suspended from the ceiling by means of spring fixtures.

After the teeth are broached, the company's name, the size and trade name of the wrench, are stamped upon the shank. As this is a simple punch-press job, no further description is necessary. The stamping operation completes this part of the wrench and it is now ready for the polishing and plating department. The sliding jaw is first punched out as a flat

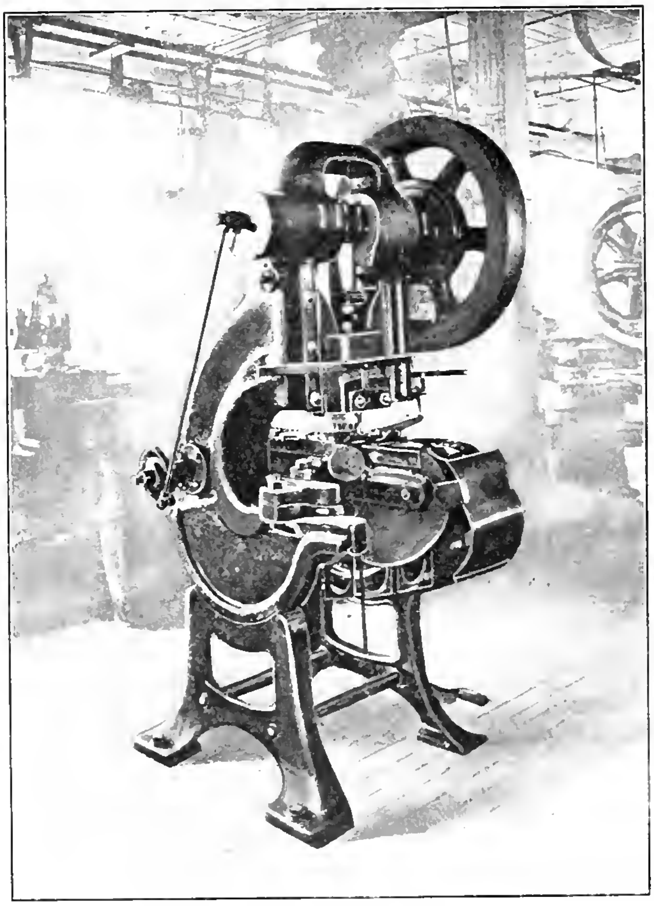

Fig 15. Endless Belt Feed for Press Work

punching and then bent to shape. Fig. 10 shows this and the other parts that compose the wrench.

Making the wrench nuts is an interesting series of operations. Fig. 11 shows the machines used in the nut department. The two machines in the foreground thread the stock automatically. All they require is the putting in of fresh bars, after which they literally eat it up at the rate of about two feet a minute, the speed varying with the size of the stock. A feature of the machine is the construction of the feed rolls that advance the bars. These rolls are grooved *lengthwise* so the bars cannot turn laterally and spoil the thread or break the die. After the bars leave the threading machines they are taken to the Acme automatics and knurled and the center hole drilled. Each of the Acmes turns out 4000 pieces per day when on a run of the wrench nuts.

Drilling the solid part of the sliding jaws and the pin upon which the nut turns come next, and then the assembling. The latter operation is done upon riveting machines and the sliding jaw is then ready for grinding, polishing and plating. While the polishing and grinding department is a large one, there is little of mechanical interest there. Casehardening in the big oil furnaces imparts a beautiful dark blue color to the steel as well as hardening it to a depth sufficient to withstand ordinary wear. Those wrenches that are to be highly finished go to the polishing and plating department for a coat of nickel. Each wrench is then inspected, wrapped and sent to the stock room as one of the 75 varieties.

While wrenches are the standard production of this factory,

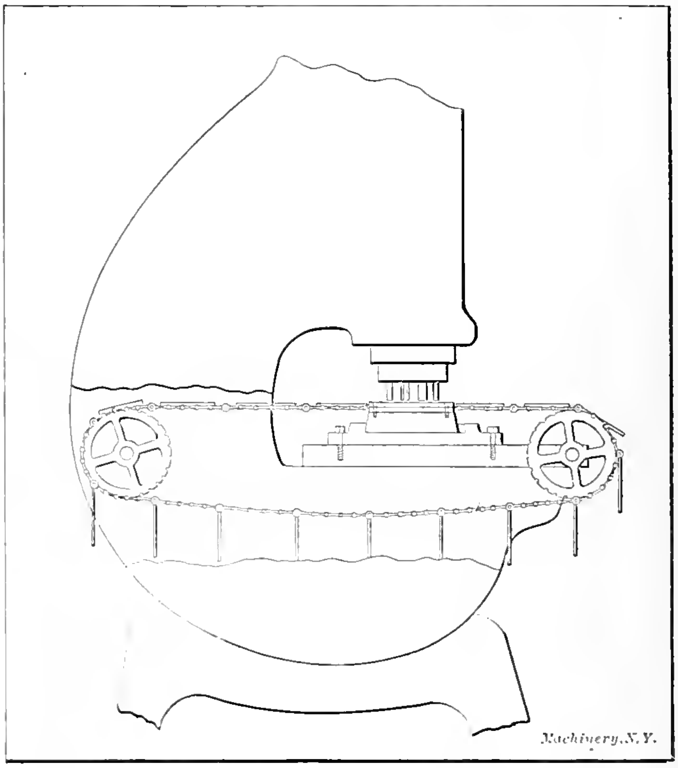

Fig. 16. Details of Endless Belt Feed

there are other branches of work done that are of more than passing interest. Fig. 13 is a striking view of the press-working of heavy steel which is being made into automobile wheel hub flanges. The material is $\frac{1}{2}$ inch thick and the punching is $8\frac{3}{4}$ inches diameter with a 3-inch hole, the stock being drawn to a depth of $\frac{1}{2}$ inch at the center. The press tools consist of a compound blanking and drawing die. The die works successfully and the pile of punchings at the right of the press in Fig. 12 backs up this statement.

That blessing in disguise, the "tattoo" alarm clock, furnishes a good deal of press work for this factory in the making of the gongs. The press work itself is comparatively simple, consisting of compound dies for blanking and drawing, and dies for piercing the holes and stamping the lettering, but the endless-belt style of feed on the piercing and stamping operation is interesting. At the front and rear of the press are two pairs of sprocket wheels connected by chains. Be-

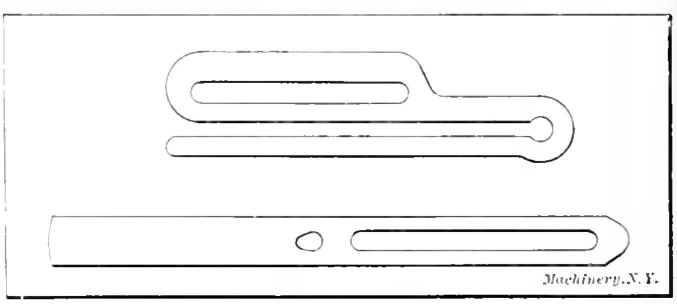

Fig 17. Punching used in Textile Work

tween these two chains are hinged at intervals, thin steel plates, each with a circular opening, large enough to admit one of the gongs to be pierced. At the front of the press the operator places the blanks in the openings as they rise with the chain, and after feeding under the die they drop out of the openings of their own weight when the hinged plates "flop" over by gravity at the rear of the press. In the photograph, Fig. 15, some of the hinged plates may be seen under the press as they are on their way up to the dies. On the

press bed is one of the blanks showing the pierced holes. Fig. 16 shows this style of feed in detail, and it should be applicable to many other press jobs. The endless chain is operated by a crank on the driving shaft of the press, as shown in the illustration Fig. 15.

It was necessary to locate a 200-pound drop-press on the second floor of the factory and just how to mount it in the best way was a puzzling question. At length a piece of 8-inch iron pipe was set up from the ground to the level of the second floor. A cement foundation was put in and the pipe itself filled with cement. At the top of the column a casting was fitted, whose top face spread out to fit the base of the press. The press was bolted to this head and it has proved to be an excellent foundation. The press and base casting are shown in Fig. 14.

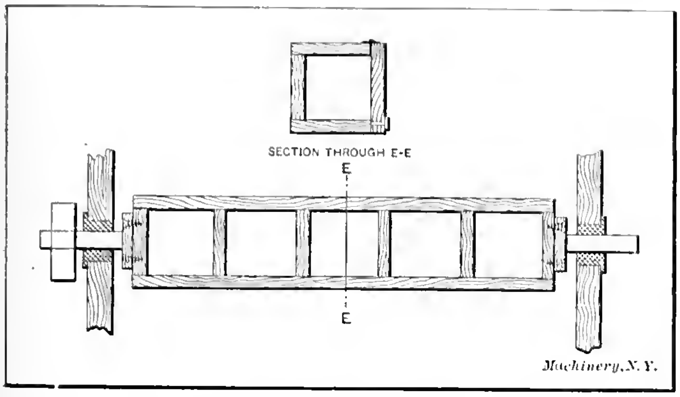

Fig. 18. Arrangement of Tumbling Boxes

Fig. 17 shows two thin sheet-metal blanks that are used in large numbers in the textile industry. They are made of both brass and steel, 0.010 inch thick, and it is very necessary that they be straight and free from sharp edges. Difficulty was experienced in getting rid of the sharp edges because ordinary tumbling methods could not be used on account of bending the blanks. To overcome this difficulty a series of tumbling boxes (Fig. 18) was devised that made the operation quick and successful. These boxes are four inches square and four feet long and are divided into partitions just long enough to take a handful of the punchings when they are all laid the same way. The boxes are not deep enough to allow the pieces to get tangled up and, in fact, they can only roll over and over. About thirty of these boxes were set up and belted together and enclosed in a little room, and the tumbling of these textile pieces was well taken care of.

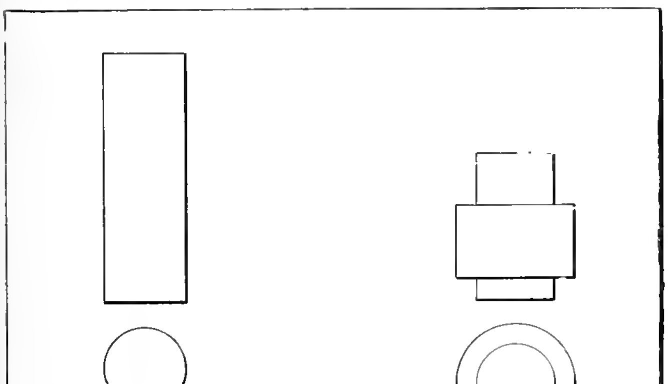

Fig. 19. A Header Job Done in a Punch Press

A somewhat unusual piece of press work is illustrated in Fig. 19 and while it is really a job for a header it was accomplished in good shape in a heavy press similar to that shown in Fig. 6. One view in Fig. 19 shows the blank, which is soft steel 1/2 inch diameter and 1 9/16 inch long, before upsetting. The other view shows the piece after upsetting; the length has been shortened to 1 inch and a ring thrown out 3/4 inch in diameter and 3/8 inch wide. Needless to say, the dies are made of high-speed steel. They last for about 10,000 pieces before giving out.

Fig. 20 shows the interior of one of the many wash-rooms which are at different locations throughout the factory, and they are equipped with wash-bowls of a new and sanitary design. The bowls are of iron with porcelain facing and each is entirely separate from the others in the line. They are supported by two pins cast integral with the bowl and can be lifted from the rack and cleaned easily. By the use of this system, each man is assured of a clean bowl of water for washing up without having to race for the wash-room at the sound of the closing whistle.

Aside from such conveniences as the wash-room just described, the Mossberg Co. does many things to make its factory conditions congenial to the men and by so doing it is able to get skilled employes and to keep them. No effort is spared to insure the most harmonious feeling throughout the different departments. During the winter months the company maintains a lunch room where food is supplied at cost to those who do not go home to dinner or bring their lunch. They have a base-ball team, and a mutual benefit association; the foremen have meetings each month to talk over the shop work and have a social hour together, and each year the shop outing is an attractive feature that includes them all, from the management down to the sweeper.

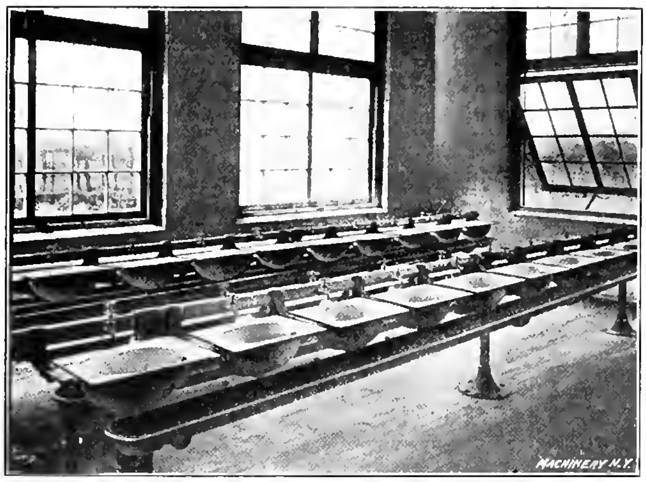

Fig. 20. One of the Wash-rooms

The officers of the company are: Frank Mossberg, president and general manager; Silas Tuttle, vice-president; Walter I. Tuttle, secretary and treasurer; E. L. Ford, superintendent, and Conrad Luttropp, mechanical engineer.

* * *

PERSISTENCY NECESSARY FOR SUCCESS

"The best laid plans of mice and men gang aft agley" is true of the affairs of the great as well as of the mean and obscure as the proverb really means. It is a common idea entertained no doubt by many of our readers that successful men meet few disappointments—that practically everything they "back" wins, but the truth is they meet many reverses that the world never hears of. The faculty that makes many if not most men successful is the try-try-again spirit. Genius has been defined as unlimited capacity for hard work, and it is largely so.

We recently heard a mechanical engineer of international fame say, when congratulated on the rosy prospects of his latest invention: "You never can tell; I've been disappointed so many times with things that worked out well on paper but which turned out rank failures when put to practical test that I never feel sure of success until it *is* sure."

* * *

The best gas engines, says Prof. Franklin in an article on the second law of thermodynamics, convert about 30 per cent of the heat of the fuel into mechanical work. The best steam engines convert about 10 or 12 per cent of the heat of the fuel into mechanical work. The ordinary run of steam engines, however, convert only 4 or 5 per cent of the heat into work.

HOW A MACHINE SHOP SYSTEM WAS IMPROVED

By M. H. WESTBROOK*

My friend Bob has been a foreman of a machine shop in C——, a neighboring city, for a few years, and the following is part of a letter I received from him about six months ago:

Things are so busy at the shop I must either ask for a few more machines, work longer hours or "go after" my men harder. Now, while I am sure they are just as fast a bunch, if not faster, than the average, and my speeds and feeds up to the limit of the best high-speed steel, I feel that if an entire stranger were to spend a few days in the shop and give me his candid opinion of what he thought should be done to increase the output, he might be able to put me next to things that, through familiarity with them, have passed unnoticed by myself. I wish you would try and come over and spend a week with me. We will have a good time in the evenings trying my new Ford, but in the daytime you get busy in the shop and don't spare my feelings in the least. If you see room for improvement just tell me where. Let me know when to expect you.

Yours as ever,

BOB

Now, as Bob and I used to be shopmates together and as he has done me many a favor, I arranged my affairs and went over to C—— and spent a week in his shop. Following are the conditions as they appeared to me:

Speeds and feeds.—The speeds and feeds, as Bob said, were all that could be desired; his men were above the average in ability and willingness, and his machinery the best and well kept up. At first I thought that conditions were O. K. and that he required more machinery to increase his output, but I was soon able by investigation to find a little slackness here and there.

Belts.—I noticed that when a belt broke the operator of the machine had to repair it himself, wire lacing being kept in the toolroom for the purpose. This resulted in a general run-down condition of the belting throughout. Some very poor lacing was in evidence and much greater time was spent lacing than should have been. A good belt-man can lace a four-inch belt with wire and pliers in four minutes. The average stoppage for belt repair took eleven minutes. I recommended that Bob put on a special belt man whose whole duty would be to repair and keep all the belting in good condition. I also recommended that every noon hour, when machinery was at rest, be spent in examining a certain section of the belting, dressing it where necessary with a good dressing made by a reliable belt manufacturer and not with one of the many forms of belt dope which are supposed only to keep a belt from slipping off the pulley. I recommended that this man be paid sufficient to insure his keeping on the job, and that belt literature be put in his hands occasionally, and that he be frequently questioned about the subject; also that he be fully informed on the value of the material in his charge.

High-speed steel.—While all the machines were using high-speed steel, no high-speed drills were in use. Now my own experience with drills is that for any but cored work we cannot afford to use common twist drills even if supplied free. I advised Bob to procure a Celfor high-speed twist drill for some work of which he had a great deal, and we made a demonstration, with the following results: The common twist drill drilling 1-inch holes in steel plate 1¾ inch thick, running at 35 feet peripheral speed per minute, feed 0.018 inch per revolution, required grinding about every ten holes. The high-speed drill running at 90 feet per minute, feed 0.025 inch per revolution, drilled 53 holes before requiring grinding. On reducing the feed to 0.018 inch per revolution several hundred holes were drilled without grinding. Bob took special interest in this as the drill work was always behind and he had been sure that he required two new drilling machines up to this point.

Drill work done on lathes.—I also found many jobs being done on lathes with boring bars and threading tools by machinists, at 34 cents an hour, that could be done equally well on drilling machines by the use of special cutters and taps at a much less cost per hour in wages and in some cases in one-half the time. The only change necessary was altering the patterns so that instead of coring the holes out to nearly the proper size in cast iron, the cores were discarded and the castings made solid; by using high-speed drills and counterbores, in addition, the best results were obtained. I have seen this weakness in many places I visit, real good drilling machine jobs being done on lathes and boring mills for no other reason than that the casting had been cored out.

Non-productive periods of machines.—I noticed that when a change of jobs was to be made on the larger machines, boring mills and planers particularly, much time was lost, owing to the machinist doing this work alone, the machine standing idle while many bolts were being removed, cuttings pulled out of the slots and swept away, and work set up and clamped. The work is progressing only when the chips are flying. I advised Bob to hire a few machinists' helpers for just this work, men trained to be "Johnnie on the spot" when machines were to be loaded or unloaded. From personal experience I know this is a paying proposition.

Tool-grinding.—This was being done by the machinists themselves, Bob stating that he did not want to stir up any discontent among them by having, as he termed it, "some dub" do the grinding for good machinists. Now, here is where I expect some readers will say Bob was wrong, that he should have put in a tool grinding system whether the men liked it or not, and that it was Bob who was running the shop, etc. It must be borne in mind, however, that the business was paying well. Bob's employers were not complaining on that score but were pleased with the results. Having surrounded himself with a number of excellent mechanics he could hardly be blamed for not wishing to create any discontent.

Inasmuch as some of Bob's men on special work had their own good ideas regarding the best form of tools to use, I advised that, instead of adopting, all at once, one of the various standard tool grinding systems, he have the patternmaker make wooden samples of each kind of tool that had proved satisfactory, number them, have some of each forged and have the special man for grinding keep them on hand ready for instant exchange when necessary. By doing this gradually he would soon have his system installed and everybody satisfied. This was done and I have since learned that in less than two months the system was extended to cover almost every class of work done with tools; each sample was numbered and a framed blueprint in the grinding department showed just what each tool was for. The men all liked it, in fact a good many took credit for aiding by suggestions as to which form of tool was the best, etc., and for having brought this system into its present condition. Among the men themselves one tool is known as Bill's tool or Jack's tool. This does no harm to the system and lets the men enjoy what honor they can extract from it. Of course, I expect that some reader will criticize and say this is no system at all, but at any rate it was a decided improvement, as the output has shown.

Bad castings.—I found the brass department handicapped owing to the castings having so much coarse sand burned into them that the tools were not standing up as they should. On tracing this up to the source, after much inquiry it transpired that the purchasing department got in a consignment of molding sand entirely unsuitable for the work and not at all what was ordered. The brass foundry foreman rather than make any trouble by refusing to accept it on account of having had the car unloaded before he discovered it, put it into use with the foregoing result. It was found that this car of sand was purchased 20 per cent cheaper than the kind ordered. I find instances similar to this occurring in many establishments to the detriment of the output. I have found also that high-speed steel is not the most suitable for brass work but prefer a good grade of carbon steel having a special temper, as the cutting edge will last longer. Bob took note of this also.

Although Bob was not able to advise me six months later that he had doubled his output, he did write to the effect that after adopting the changes suggested with a few others all of mere detail, he had kept the good will of his men and increased his output nine per cent which was sufficient to take care of the extra work without working overtime, "going after" his men, or putting in new machinery.

* Address: 39 Landerson St., Battle Creek, Mich.

MAKING OPEN-SIDE PLANERS

By ETHAN VIALL*

Owing to the limited demand for open-side planers, that branch of the machine tool industry greatly resembles the manufacture of special machinery. I was informed by the manager of the Cleveland Planer Works, that in their eight years' experience they never had orders on their books for

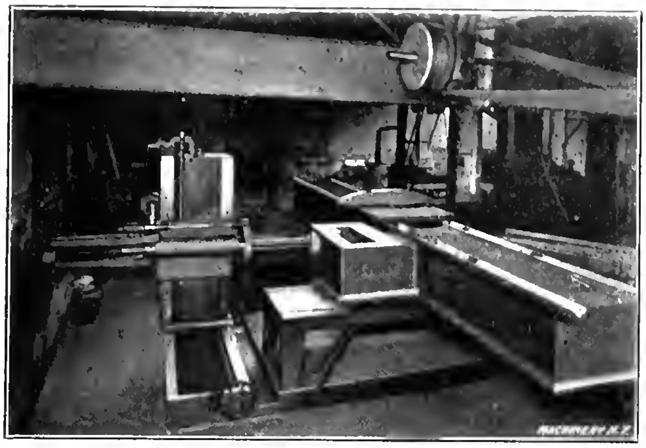

Fig 1. Large Boring Mill with 8- x 30-foot Open-side Planer Bed in Position

two planers of the same size at one time. It is owing to the varied sizes and character of their machines, that Mr. Dornbirer has been compelled to design and build most of the machinery in use in their shop, in order to profitably handle

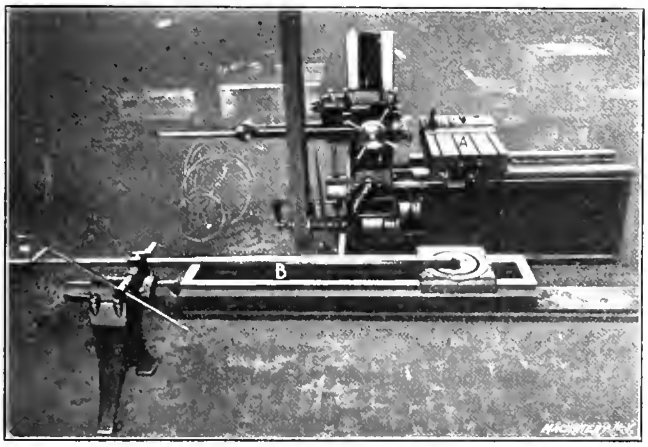

Fig 3. Cross-rail Scraping Bench with specially designed Boring Mill in Background

their work. For instance, Fig. 1 is a floor boring mill with a very long planer bed placed upon its tables for the purpose of boring out the bearings. An idea of its size can be obtained when it is known that the bed being bored is 8 feet in width at

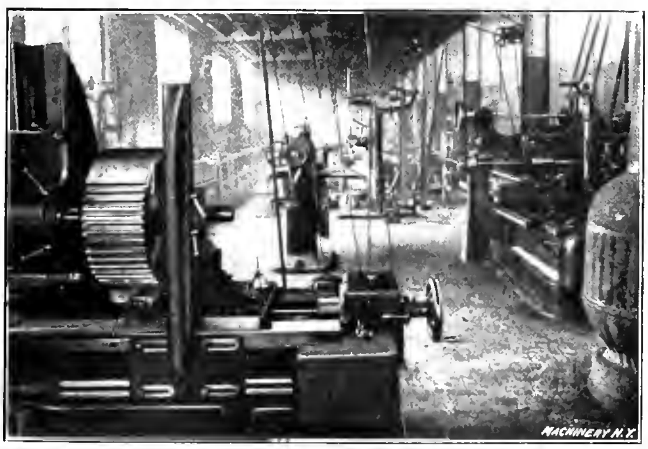

Fig 5. View of Shop under East Balcony with Walcott & Wood Automatic Rack Cutter at the Right and a Brown & Sharpe Gear Cutter at the Left

the point lying on the table nearest to the front of the photograph, and 11 feet back to the other table. All the beds for their open-side planers are planed on the bottom, which enables the operator to set a bed in position on the boring mill in a remarkably short time.

Some of the simple and efficient details are shown in Fig. 2. The alternating current motor is mounted on brackets fastened to the saddle and is raised or lowered with it. Three speeds are provided by means of cone pulleys. The feeding mechanism is in position for drilling, when the tumbler is in mesh with the center gear on the cone of gears, as shown in Fig. 2.

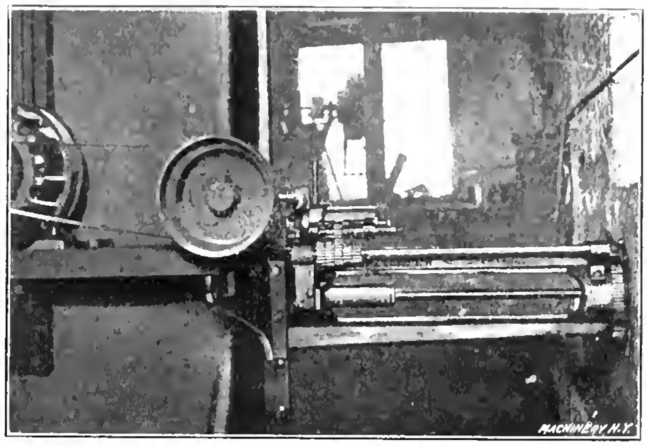

Fig. 2. Geared Bar-feeding Head of Boring Mill

Moving the tumbler to the left of this center gear gives two forward feeds, and moving it to the right gives two backward feeds. In one case the screw that feeds the bar is rotated faster than the spindle, and in the other case, slower.

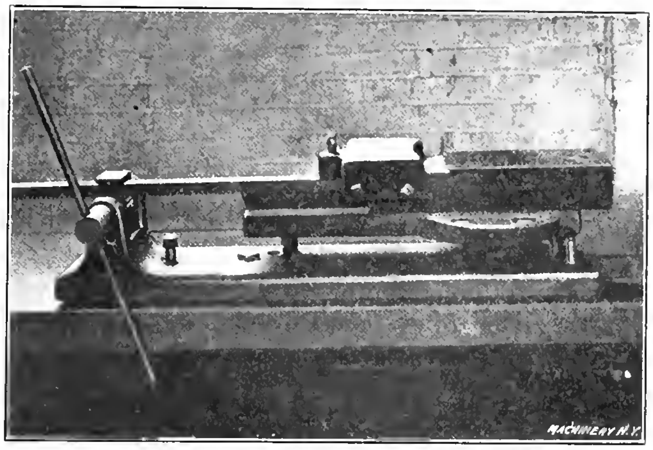

Fig. 4. Bench Scraping Block for Planer Heads

When the screw is locked so as to stand still, a quick return for the bar is obtained in whichever direction the motor is turning.

At *A*, Fig. 3, is shown another boring mill designed by Mr

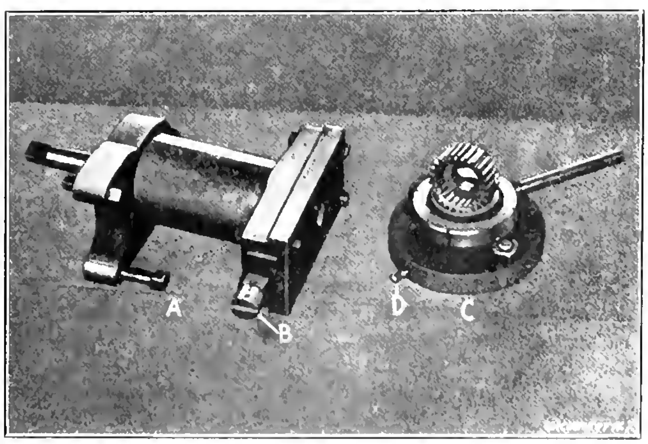

Fig 6. Milling Machine Attachment for Slotting inside of Ratchet Gears and Chuck for holding them

Dornbirer, but when they built it they embodied so many features to facilitate their work that it will be impossible to go into details in this article. At *B* is a scraping bench that is a marvel of simplicity and convenience, since the cross-rail

*Associate Editor of MACHINERY.

may be placed in any desired position simply by rotating the bench on the trunnions, thus making a hard and tedious job a comparatively easy one. It will be noted that the rack and pinion mechanism is fastened to the bench trunnion so that it always has the same position relative to the top of the scraping bench.

Fig. 4 shows a small scraping bench for the heads, which may be rotated in a plane parallel to the top of the workbench, enabling the fitter to scrape on either side with no heavy lifting or pulling.

Fig. 5 is a view of the shop under the east balcony, showing a Walcott & Wood full automatic rack cutter at the right, and a Brown & Sharpe gear cutter at the left.

At *A*, Fig. 6, is shown a vertical slotting attachment for a milling machine, used for slotting the inside of ratchet feed gears. The cutting tool is shown at *B* and the method of attaching the device to the milling machine spindle is plainly indicated. At *C* is the universal chuck used to hold the ratchet feed gears while slotting them on the inside, the indexing being accomplished by means of the pin *D*, which engages in accurately spaced holes in the base flange of the collet holder.

The saddles are graduated on the machine shown in Fig. 7. Under rotating base-plate *A* is a worm gear having a projecting hub *B* over which various sized bushings, to suit the different sized saddles may be placed. The worm gear has 180 teeth and the slack or lost motion between it and the worm, is taken up by rotating an eccentric bushing which forms the bearing for the worm spindle. Two notches are provided in the periphery of the index plate exactly opposite each other so that the handle may be easily moved half a turn, which moves the worm gear plate one degree. The marking head is clamped to the spindle around which the worm gear and its hub rotates. The marking is done by pulling the small hand lever *C* once for each indexing of the saddle, and, by the automatic turning of a small ratchet-cam, a latch is lifted at every fifth stroke of the lever so that the fifth mark is three times as long as the other four.

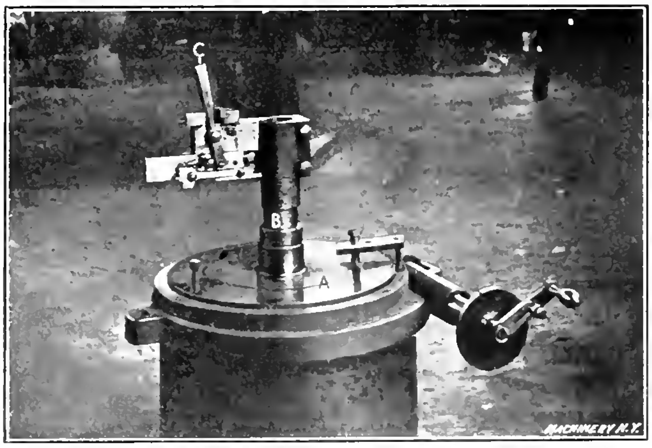

Fig. 7. Indexing Machine for Planer Saddles

One of the interesting points to be noticed in this shop, is the unusual use of draw-in collets for all sorts of work. A milling machine with only a twelve-inch index center has been fitted with draw-in collets up to 2 inches, and a set of collets for another machine runs up to 5 inches in diameter by 16 inches in length.

POSTING REGULATIONS IN SHOPS

In some shops we see a variety of posted rules and regulations forbidding workmen to do this and that under penalty of discharge. In other plants apparently as well organized and disciplined there is a noticeable absence of posted regulations. The question is: Which is the preferable practice? It is our opinion that the posting of rules and regulations is generally resented and that it is best to avoid insulting the intelligence of the workmen by forbidding them to do things common sense tells them they must not do if they expect to retain employment. The most rigid rules governing the affairs of life are largely the unwritten laws. Let the rules of the shop be unwritten but fully understood.

PERTINENT POINTS ON JIG AND FIXTURE DESIGN*

By C. NOSRAC

There are several points of vital importance in the design of jigs and fixtures for the production of interchangeable parts that are often overlooked by the designer, and also in many cases by the toolmaker, yet which, if they had been given the proper attention at the proper time, would have resulted in a marked increase of accuracy and efficiency in the jig. It is practically conceded that the ideal jig should be so designed that it will do a maximum amount of work in the minimum amount of time with the least possible amount of labor on the part of the operator, and with the smallest initial cost. The attainment of any such condition in practice, however, is very rare. Nevertheless, the designer has it in his power to save many dollars for his employers by giving attention to the few most essential points when originating the fixture. A mistake frequently made in the design of jigs for small work is that of making the jig too small. It must be remembered that the vertical alignment of the holes in the jig depends on the accuracy with which the jig rests upon its feet on the drill-press platen, and it must also be remembered that drill-press platens are usually covered with drill chips which get under the feet of the jig, serving to throw it out of the horizontal plane and make it rest unevenly. It follows then that if one leg of the jig is elevated from the platen a fraction of an inch, the drill bushing will stand at a certain angle out of the perpendicular, and also that the larger the base area of the jig is made, the less the angular inaccuracy will become. Furthermore, if the jig is made small and provided, as they often are, with a handle, in order that the operator may have something to take hold of, the chances of inaccuracy of the holes are increased by the possibility of his tilting the jig during its operation by what may even be an unconscious pressure on the handle. Handles on jigs are as a rule unsatisfactory in many cases and they will be found especially so by the operator if the jig to which one of them is attached suddenly "takes charge," and the handle strikes him on wrist or chest.

Material for Jigs

There has been a great deal of discussion among designers, and also among manufacturing firms throughout the country, about the relative merits of cast iron and steel as materials from which to construct the jig and fixture bodies. In the writer's opinion the decision on this point should depend to a great extent upon the usage to which the fixture is to be put and the character of the work which it is to handle. For small and medium sized work, such as typewriter, sewing machine, gun, adding machine, cash register, phonograph and similar parts, the steel jig offers decided advantages, but for larger work such as that encountered in automobile, engine, and machine tool fixtures, the cast iron jig is undoubtedly the cheaper, and more efficient to use. The steel jig should be left soft in order that at any future time additional holes may be added or the existing bushings changed as required. With a cast-iron jig this is a difficult matter, as the frame is usually bossed and "spot finished" at the point where the bushings are located. This, of course, makes it very difficult to build up on the jig frame in order to locate or change the bushings. When designing the jig, these points should be remembered and provision made for them, where possible.

Drill Bushings

The drill bushings should be made of tool steel, hardened and lapped, and where convenient should be ground inside and out. They should also be long enough to support the drill on each side regardless of the fluting, and they should be so located that the lower end of the bushings will stop about the same distance above the work as the diameter of the drill, so that chips will clear the bushings readily. Of course, where holes are drilled on the side of a convex or a concave surface, the end of the bushing must be cut on a bevel and also come a little closer to the part being drilled, to insure

* For information previously published on jig and fixture design, see "Defects in Jig Design," November, 1909, and "Standard Designs of Jigs and Fixtures for the Manufacture of Small Interchangeable Parts," with accompanying references, July, 1909.

the drill having adequate support while starting into the work. The bushings should also have heads of sufficient diameter to prevent the operator starting the point of the drill all around the hole instead of in it, thus mutilating the jig body. Long bushings should be relieved by increasing the hole diameter at the upper end in order to give the drill freedom from its bearing portion. The length of the bearing portion in the bushing should be equal to the length of the lead of the spiral on the drill. The lower end of the bushing should have its edges rounded in order to permit some of the chips being shed from the drill easily, instead of all of them being forced up through the bushing. It is also good practice to cut a groove under the head so that when grinding the bushing on the outside, the wheel will not have to "corner." Correct designs for short and long bushings are shown in Figs. 1 and 2. Clearance holes should be provided below the work. The drill bushings should not be driven

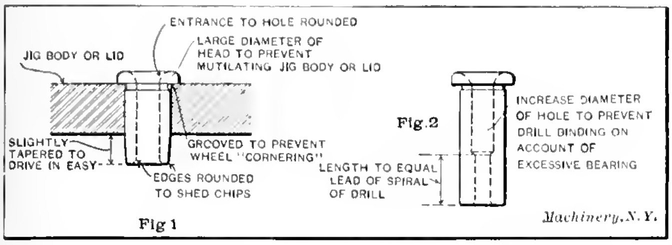

Fig. 1. Correct Design for Short Bushings

Fig. 2. Correct Design for Long Bushings

through hardened steel blocks as these parts will naturally change to a certain extent during the hardening process and the hole locations will consequently be inaccurate when the bushing is driven through. The length of the bushing should be limited so that special drills will not be required to reach the work when getting into difficult corners. When designing the jig, provision should be made for this by building the fixture closer around the work.

Clamping Devices

When designing the clamping device, as few operating screws or handles should be used as will accomplish the desired result, for it takes considerable time to turn a screw one or two revolutions four or five thousand times a day, which is nearly an average number of operations for many jigs. Making the screw with a double or triple thread is sometimes used to advantage in decreasing the number of turns necessary to release the piece. Jig lids should be hung on taper pins in order that wear in the hinge may be compensated for and the resulting inaccuracy due to the lost motion in the hinge prevented. The included angle of taper on hinge pins should be only one or two degrees and the pins should be spirally grooved to within 3/8 inch of each end, in order to hold oil for lubricating the hinge after the pin is driven in. The hinge pin should be a tight fit in the central portion of the hinge, which is usually the jig body, and a bearing fit in the ears of the lid. In this manner the greatest wearing surface possible is obtained. (The foregoing points are clearly illustrated in Fig. 3). All clamping screws and similar parts should be long enough and so located as to be conveniently taken hold of to operate, and of sufficient size to prevent hurting the operator's hands on account of the pressure necessary to manipulate them. The screws should be located so that they will resist the tilting action of the block, and the dowel pins should be fairly close to the screws and of liberal dimensions in order to resist the shearing strains to which they will be subjected. When clamping or locating the work in the jig it is essential to have the clamping pressure exerted in a direct line against some solid point of support to prevent the tilting tendency, and the thrust should also come on such a point of the work that it will be resisted by solid metal, as the power of a screw is frequently underestimated by both the designer and the operator of the jig, with the result that the work will frequently be sprung by the clamping device, and drilled in this position, which would naturally spoil the accuracy of the location of the hole after the work was released from the jig and had expanded back to its normal shape. It should be further borne in mind that when clamping rough castings in a fixture they can be supported only on three points, and "tickler studs" or adjustable stops should be placed on the fourth point of the support and also under any weak portions of the piece through which holes are to be drilled or machining operations are to be performed, in order to resist the springing action of the cutter. Posts in which clamping and locating screws operate should be of liberal proportions and should not project above the fixture body any further than is necessary in order to keep down the tilting action to a minimum; and all handles for clamping devices should be so located that they will not be awkward to operate.

Equalizing bars are frequently used to divide the strain of clamping between two points, or to place the pressure upon three points in case it is so needed.

Resting Studs

Resting studs for supporting the work in the jig are usually made of tool steel, and hardened and ground, and should be of such a length that the piece which the jig is to hold will be held up above the jig body far enough to clear the chips which soon accumulate during the drilling operation. In this connection it is advisable to give a generous amount of room around the piece being operated on in order that the jig may be easily cleaned, and that there may be plenty of room for the chips to fall out. Resting studs should also be provided under all points where drill pressure or reamer pressure will come and also under other points where it is necessary to absorb the strains. Jigs and fixtures should also be made to stand as low as possible above the machine platen as the higher up they stand, the more angular error will occur when drilling long holes as chips get under the rest and feet.

It is also customary to equip jigs with suitable lid stops of such a shape and so located that they will not interfere with the manipulation of the various functional parts of the

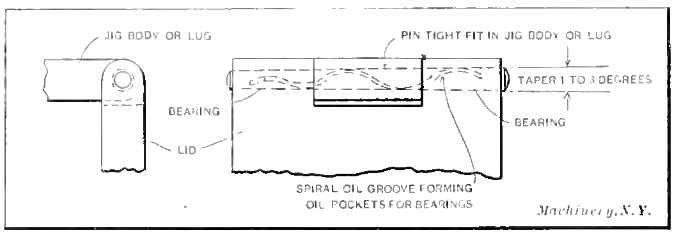

Fig. 3. Improved Hinge-pin Construction

jig. It is usually unnecessary to swing the jig lid entirely back. Therefore, the lid stop may be so placed as to support it after it is swung past the perpendicular, thus saving the extra time required to reach back the extreme distance for the lid every time the jig is closed.

Locating Blocks

Locating blocks and similar parts should be of very solid construction and especially where pressure due to the action of the clamping device will exist, and should be fastened with heavy screws and large dowel pins. It seems queer that designers will persistently screw a locating block onto a jig, with medium size screws or often with large screws, and yet locate the block with ridiculously small dowel pins, entirely losing sight of the fact that the screws do not take the side thrust, nor hold the block in its true location, and that the greater part of the strain actually comes on the pins, with the result that they are either partly or wholly sheared off, and a great deal of work is frequently spoiled before this condition is discovered. When selecting proper locating points on a piece of work, choose the most important one, which must be determined by careful examination of the piece, and consideration of how it is to be assembled in the machine. This locating point should be used throughout the succeeding jigs and fixtures.

If proper attention is given to the above points on jig and fixture design it will undoubtedly result in increased production and greater efficiency of operation.

The fans of the hot blast heating system in the H. H. Franklin Mfg. Co.'s plant, Syracuse, N. Y., are kept running in summer to circulate fresh air throughout the factory.

DESIGNING SCREW MACHINE TOOLS AND CAMS*

PRACTICE FOR THE BROWN & SHARPE AUTOMATIC SCREW MACHINE

By DOUGLAS T. HAMILTON†

The object of the present article is to give the average mechanic and draftsman a clear idea of the methods employed when designing special tools and cams for the Brown & Sharpe automatic screw machine. One of the first things which the writer considers necessary is a thorough understanding of the change-gear mechanism, as on this are based the fundamental principles used in the construction of the tables for

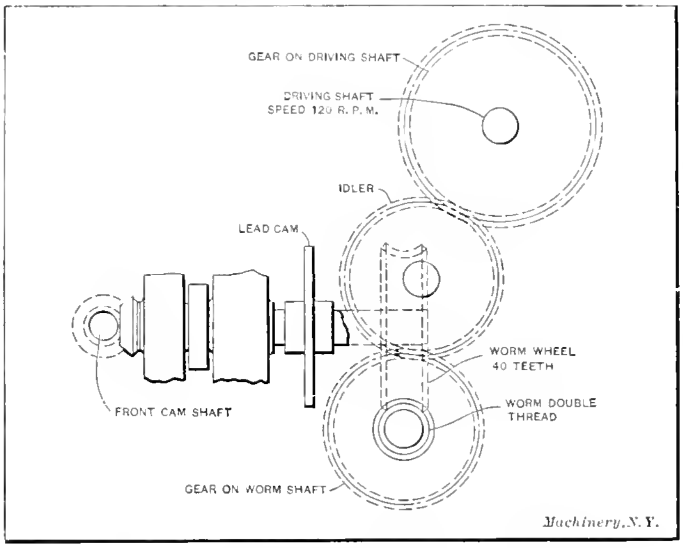

Fig. 1. Diagram of Gearing on the No. 00 Brown & Sharpe Automatic Screw Machine

laying out cams. Following this is the construction of the rise and drop on the cams, this governing the amount of clearance necessary for one tool to pass another. Then a number of general points which should be of value, especially to those who are not experienced in this class of work, are given.

Change-gear Mechanism

A system of simple gearing is used on the No. 00 Brown & Sharpe automatic screw machine, as can be clearly seen in Fig. 1, in which one driving and one driven gear is used. The worm has a double thread, so for every revolution that the worm makes the worm-wheel will travel through a dis-

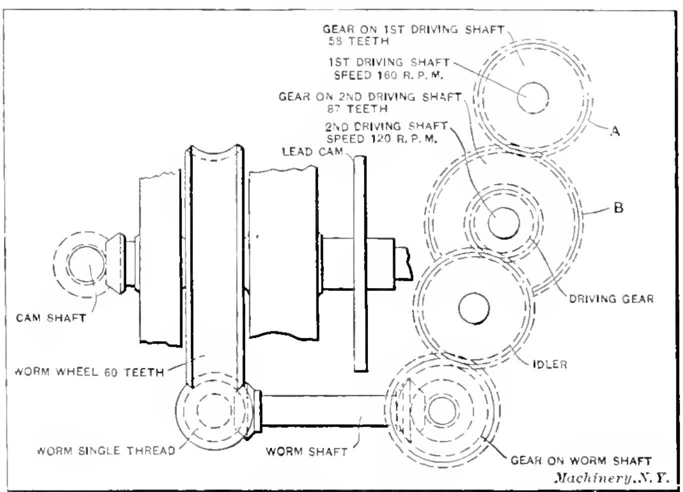

Fig. 2. Diagram of Gearing on the No. 0 Brown & Sharpe Automatic Screw Machine

tance of two teeth. To find the change gears, assume that it is required to make one piece in 12 seconds. This necessitates that the worm-wheel make one revolution in 12 seconds. As there are 40 teeth in the worm-wheel and the worm has a double thread, the worm shaft will make $\frac{40}{2}$ or 20 revolutions in 12 seconds. The driving shaft runs constantly at 120 R. P. M. or 2 revolutions per second. Then the driving shaft will make 12×2 or 24 revolutions in 12 seconds. Considering, in this case, that the driving shaft is required to run the faster, we will put the gear with the larger number of teeth on the worm shaft. Now if we have gears having 20 and 24 teeth respectively they will "do the trick," but after referring to the gears as supplied with the machine, we find that a gear with 24 teeth is not available, so multiplying each by two (which does not change their value) the gears will be: 40 gear on driving shaft; 48 gear on worm shaft.

On the No. 0 Brown & Sharpe automatic screw machine there is also one driving and one driven gear, but on this machine the gear which is called the driver is placed on the second driving shaft as shown in Fig. 2. Then, before finding the change gears it is necessary to find the speed of the gear on this second driving shaft. The first driving shaft runs constantly at a speed of 180 R. P. M. Then the speed of the second driving shaft $= \frac{180 \times 58}{87} = 120$ R. P. M. To find the change gears, assume that it is required to make one piece in 36 seconds. (To obviate confusion, we will call the second driving shaft the main driving shaft which runs at 120 R. P. M.). Since the cam shaft is to make one revolution in 36 seconds and as there are 60 teeth in the worm-wheel and the worm has a single thread, the worm shaft will make 60 revolutions in 36 seconds. The driving shaft which runs at 120

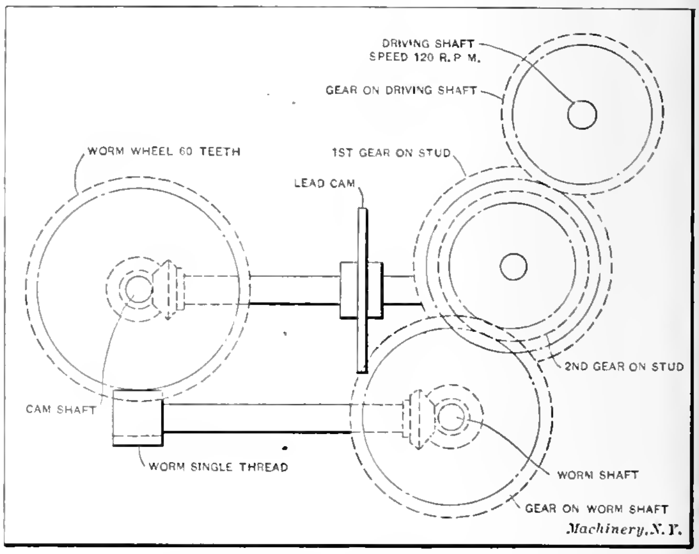

Fig. 3. Diagram of Gearing on the No 2 Brown & Sharpe Automatic Screw Machine

R. P. M. or 2 revolutions per second will make 72 revolutions in 36 seconds. Now as the worm shaft is required to run the faster, we will put the larger gear on the driving shaft. Then the gears can be found by the following formula:

$$\frac{120 \times D}{W} = \frac{3600}{S}$$

where D = gear on driving shaft, W = gear on worm shaft, and S = time in seconds to make one piece. Then, $\frac{120 \times D}{W} = \frac{3600}{36}$ or $120\ D = 100\ W$. Then $W = \frac{120}{100} = 1.2\ D$. Let $D = 30$. Then $W = 30 \times 1.2 = 36$. If the speed of the driving shaft is less than the speed of the worm shaft the result will be just the opposite. For example, let $100\ D = 120\ W$. Then $D = \frac{100}{120} = \frac{10}{12}\ W$. Let $W = 36$. Then, $D = \frac{10}{12} \times 36 = 30$.

A system of compound gearing is used on the No. 2 Brown & Sharpe automatic screw machine making it necessary to

* For additional information on Brown & Sharpe automatic screw machine practice see "Threading Operations," MACHINERY, June and July, 1910, and other articles there referred to.
† Associate Editor of MACHINERY.

find the various gears by factoring. To explain the method of finding the gears we will take a practical example. Let it be required to find the gears to make one piece in 28 seconds. Referring to Fig. 3 we find that the speed of the driving shaft is 120 R. P. M. There are 60 teeth in the worm-wheel and the worm shaft has a single thread. Then we require the cam shaft to make one revolution in 28 seconds. The worm shaft will make 60 revolutions in 28 seconds as the worm has a single thread. The driving shaft makes 2 revolutions per second or 56 revolutions in 28 seconds. It can be seen that

TABLE I. SHOWING HOW TABLE FOR LAYING OUT CAMS IS CONSTRUCTED

Time in Seconds to Make One Piece	Gross Product in (10) Hours	Net Product in (10) Hours Gross Less 10 Per Cent	Gear on Driving Shaft	1st Gear on Stud	2nd Gear on Stud	Gear on Worm Shaft	Hundredths of Cam Surface to Feed Stock	Spindle Speeds: A Diagram of the Pulleys on the Counter Shafts, and the Position of the Belts to Give the Various Speeds Can be Given in This Space											
							Min. Sec. Pulleys *b*	2	2 47	3 03	3 75	4 62	5 70	7 02	8 65	10 67	13 15	16 22	20
							a	120	148	182	225	277	342	421	519	640	789	975	1200
							Number of Revolutions to Make One Piece												
10	3600	3200	80	52	72	60	10	20	25	30	37	46	57	70	86	107	131	162	200

the worm shaft is required to run the faster. Therefore the multiple of the two gears which are placed one on the driving shaft and the other, the second gear, on the stud should be greater than the multiple of the two gears one placed on the worm shaft and the other, the first gear, on the stud. It will also be noted that the number of teeth in the gear on the driving shaft should be greater than the number of teeth in the gear on the second stud, and the number of teeth in the gear on the first stud should be less than the number of teeth in the gear on the worm shaft. The ratio equals $\frac{56}{60}$. By dividing the numerator and denominator into factors and multiplying each pair of factors by the same number we find the gears.

$$\frac{10 \times 6}{4 \times 14} = \frac{(10 \times 8) \times (6 \times 6)}{(4 \times 8) \times (14 \times 6)} = \frac{80 \times 36}{32 \times 84}.$$

Then the gears are as follows:

80 gear on driving shaft, 36 second gear on stud, 32 first gear on stud, 84 gear on worm shaft.

How Tables for Laying out Cams are Constructed

Before a table can be constructed, it is necessary to know the range of spindle speeds obtainable and also the speed of

TABLE II. DIMENSIONS FOR LAYING OUT CAM RISE FOR NO. 00 BROWN & SHARPE AUTOMATIC SCREW MACHINE

Number of Seconds to make one Piece	Lead	Front and Back Cams
	D	R
From 3 to 5 seconds	$\frac{29}{32}$	$1\frac{1}{8}$
From 6 to 12 seconds	$\frac{3}{4}$	$1\frac{1}{4}$
From 13 to 30 seconds	$\frac{5}{8}$	$1\frac{1}{4}$

the driving shaft. Then the number of seconds to make one piece is placed in the first column of the table, and the number of revolutions to complete one piece is placed under the various spindle speeds as shown in Table I. The total number of revolutions to make one piece is found by the following formula: $r = \frac{R \times S}{60}$ where R = revolutions of spindle or (R. P. M.), S = time in seconds to make one piece and r = total number of revolutions to make one piece. The total number of revolutions to complete one piece can also be found by adding together the number of revolutions required for each operation plus the revolutions required for clearance, feeding the stock, and revolving the turret. The seconds to make one piece are found by the following formula:

$$S = \frac{r \times 60}{R}.$$

To feed stock and revolve the turret requires one revolution of the driving shaft, but it is always advisable to add one hundredth for revolving the turret so that it will be securely locked in position before the tools advance on the work. Owing to the large diameter of the roll there should never be less than 3 hundredths for revolving the turret, irrespective of the speed at which the cam shaft is running. To illustrate clearly the method employed in constructing the table, take a practical example. Let it be required to construct a table for laying out cams for a No. 2 Brown & Sharpe automatic screw machine. Let the spindle speeds be as given in column *a* Table I. To show clearly the method, we will take a spindle speed of 182 R. P. M. Assume that it takes 10 seconds to make one piece. The revolutions required to complete one piece $= \frac{182}{10 \times 60} = 30.03$ or approximately 30 revolutions. We will then put 30 revolutions under the spindle speed 182

TABLE III. DIMENSIONS FOR LAYING OUT CAM RISE FOR NO. 0 BROWN & SHARPE AUTOMATIC SCREW MACHINE

Number of Seconds to make one Piece	Lead		Front and Back Cams	
	D	R	D	R
From 5 to 12 seconds	$1\frac{1}{8}$	$\frac{15}{16}$	$\frac{7}{8}$	$1\frac{1}{2}$
From 13 to 30 seconds	$1\frac{1}{8}$	$2\frac{3}{8}$	$\frac{7}{8}$	2
From 32 to 60 seconds	1	$3\frac{1}{4}$	$\frac{13}{16}$	3

as shown in the table. Then to feed stock $= \frac{182 \times 2}{120} = 3.03$ revolutions. As shown in column *b*, the hundredths to feed stock $= \frac{30.03}{3.03} = 9.9$ or approximately 10 hundredths, and as it requires 10 hundredths of the cam shaft to feed stock, by adding one hundredth to this we get 11 hundredths for revolving the turret. The change gears are found by the methods previously described, and are placed in their respective columns in the table.

Constructing the Rise on Cams

The rise on the cam should be such that the tools will gradually slow up as they approach the work. It is not necessary

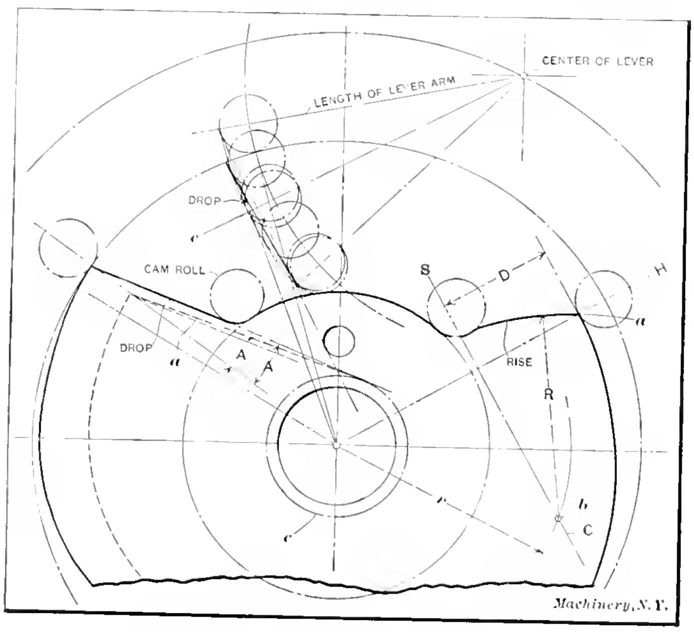

Fig. 4. Method of Laying out Rise and Fall on Cams

to lay out a uniform curve for the rise, as in most cases the cam rotates slowly, but when the cam is required to make one revolution in less than 5 seconds on the No. 0 or No. 2 screw machine, a curve of a more uniform speed should be constructed.

Generally the rise can be abrupt for about three-quarters of the way up and then gradually slow down as the tool approaches the work. An efficient method of laying out a curve of this form is shown in Fig. 4. The reason for making a curve of this form is that less time is necessary for

one tool to clear another which sometimes makes quite a considerable difference in the time required to produce one piece, this, of course, totaling up in the day's work. To construct the rise, refer to Fig. 4 and proceed as follows: Lay off on line H a distance D from the point a. Then through the point where an arc having a radius equal to D would cut the line H, draw the line BC at right angles to it. With a as a center, and a radius R describe an arc cutting the line BC at the point b; again with R as a radius and a center b describe the rise. Join the rise and the smallest diameter of the cam with a circle equal to the diameter of the roll. The distance r should then be measured off and recorded on the drawing to be used by the toolmaker when laying off the cams. The various values for the reference letters as given in Fig. 4 for the rise have been found suitable for the seconds to make one piece, and are specified in Tables II, III and IV.

Constructing Drop on Cams

The drop on the cams should be such that the cross-slides will drop back without shock. The turret slide drops back on a cushion spring, thus allowing the drop on the lead cam to be more abrupt, on the No. 0 and No. 2 screw machines, than it is on the front and rear cams. This is also true of the No. 00 machine, but as the drop is not great very little time would be saved by using a smaller angle of drop for the lead than for the cross-slide cams. Referring to Fig. 4 it can be seen that the lever arm swings in an arc so that to have a

TABLE IV. DIMENSIONS FOR LAYING OUT CAM RISE FOR NO. 2 BROWN & SHARPE AUTOMATIC SCREW MACHINE

Number of Seconds to make one Piece	Lead		Front and Back Cams

From 100 to 180 seconds.	1 5/8	3 1/4	15/16	2 3/16

uniform drop a harmonic curve should be constructed. But, as this drop would be more difficult to make than a straight drop, a straight or angular drop is adopted. This gives the drop of the arm a variable motion, as can be seen by referring to Fig. 4; the roll will drop quickly to about the point c, then slow up and then increase in speed as it approaches the bottom. The cross-slides are forced back by a spring which serves to keep the roll in contact with the cam. The drop on the cam should not be laid off from a circle as shown by the dotted lines at c. This would mean that the roll would drop slower when dropping a short distance than when dropping a greater distance. The drop should be laid off from the hundredth line where the operation finishes as shown by the angle A. This assures the drop always being the same speed irrespective of the distance through which it has to drop. The following angles of drop have been found suitable for the number of seconds required to make one piece as specified in Tables V, VI and VII.

TABLE V DROP ON CAMS FOR NO 00 BROWN & SHARPE AUTOMATIC SCREW MACHINE

From 90 to 180 seconds	$A = 10$ degrees	13 degrees

Clearance for Tools

In laying out a set of cams it is sometimes found necessary to make allowance for one tool to clear another, the amount of clearance necessary being determined by the diameter or width of tool used in the turret and the position of the cross-slide tools relative to the work. When determining the amount of clearance necessary, the rise and drop on the lead cam is disregarded and the rises and drops on the front and rear

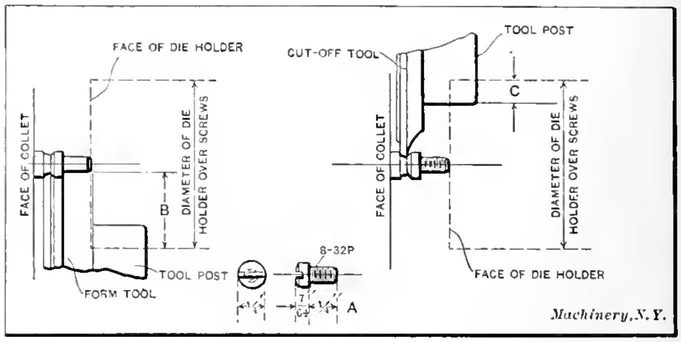

Fig. 5 Diagram Illustrating Method of Finding Clearance for Die Holder

cams are taken into consideration. To determine the rise and drop to use, make a rough lay-out of the various operations to be performed and also obtain the approximate number of revolutions to complete one piece. The revolutions are then converted into seconds as was previously explained and the rise and drop used as specified in a foregoing section. To explain clearly the method used, we will take a practical example. Assume that it is required to make a brass screw as shown in Fig. 5. This screw is made from 1/4-inch round brass rod, and can be made to advantage on the No. 00 Brown & Sharpe automatic screw machine using a spindle speed of 2400 R. P. M. backward and forward. Assume that it is required to find the amount of clearance necessary for the die holder to pass the circular form and cut-off tools. To proceed, draw in the form tool in position on the screw as shown to the left in Fig. 5, and also an outline of the tool-post. Then lay out the die holder in position to start on the screw as shown by the dotted lines. If a releasing die holder is used, take the diameter over the head of the screw, but if a "draw-out" type is used, the diameter of the cap is taken. In

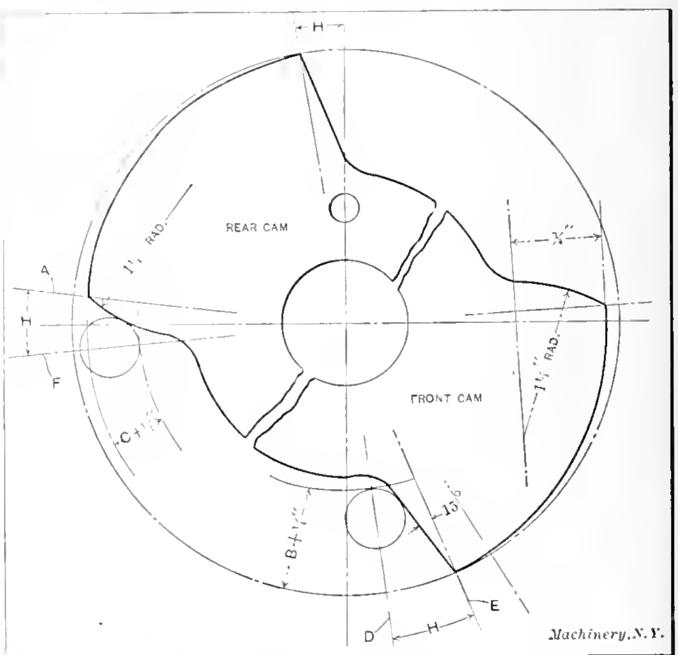

Fig 6 Method of Determining Clearance on Cross-slide Cams

this case, as the screw is threaded up to the shoulder, a releasing die holder will be used. Referring to Fig. 5, it can be seen that the die holder cannot advance on the screw until the form tool drops back equal to the distance B, but as B is the actual distance, it will be necessary to add an extra amount to insure the die holder's advancing without coming in contact with the circular form tool. The extra amount of

clearance necessary varies with the type of tool used. The following dimensions give the approximate amount which should be added to the actual clearance for the type of tools as specified:

Type of Tool	Extra Amount of Clearance
Drill holders	from 1/8 to 3/16 inch
Box-tools (with V-supports)	from 1/8 to 1/4 inch
Box-tools (with supporting bushing)	from 3/16 to 5/16 inch
Button die holders (draw-out type)	from 3/16 to 5/16 inch
Button die holders (releasing type)	from 1/4 to 1/2 inch

To find the amount necessary for clearance make a diagram as shown in Fig. 6, laying out the drop on the front cam as shown. Then add, say, 1/4 inch, to the dimension *B* and measure down from the point where the lobe finishes, as shown. Then with a radius equal to the radius of the cam roll, describe a circle touching the line as drawn and the drop on the cam. Join the center of the roll with the center of the cam circle by a straight line. The clearance is then measured off in hundredths as shown by dimension *H*. The starting point of the lobe on the lead cam for threading will be at the hundredth line *D* and the intervening space between the lines *D* and *E* will be the amount necessary for clearance.

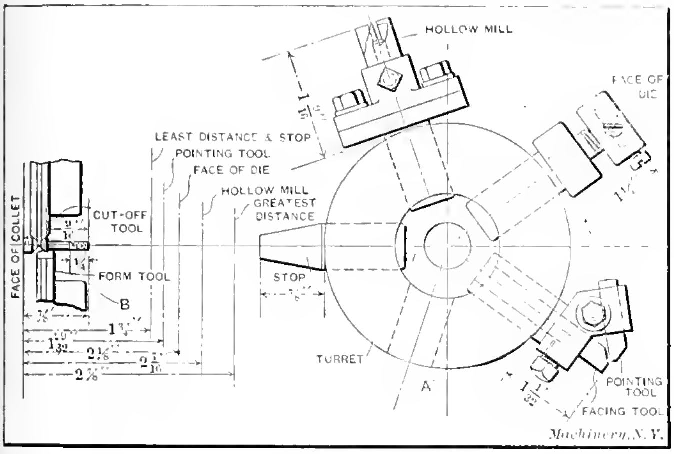

Fig 7. Position of Tools in Turret, and Forming Tools applied to Work

When the cutting-off operation follows the threading operation it will also be necessary to allow for clearance. To find the amount of clearance necessary for the die holder to clear the circular cut-off tool, proceed as follows: Make a lay-out as shown to the right in Fig. 5 and measure off the distance *C*. Add 1/4 inch to this and lay this dimension off from the starting point *A* of the rear cam as shown in Fig. 6. Then draw in a circle equal to the diameter of the roll touching the line drawn and the rise on the cam, and measure off the clearance *H* as was previously explained. The thread lobe would finish at the hundredth line *F* and the cut-off tool start at the line *A*. Clearance should also be allowed between the dropping back of the cut-off tool and the feeding of the stock. To find the amount of clearance necessary add 1/8 inch to the largest radius of the stock used and proceed as was previously explained.

To make this article more complete, the various steps followed when designing a set of cams will be given, starting at the first and covering each step until the drawings of the cams are completed.

Designing and Laying out Cams

When designing a set of cams the speed of the spindle best suited for the size of stock and nature of material should first be decided on. The formulas for finding surface speeds given in the July number of MACHINERY will be found convenient for this purpose. The quickest and best method of making the piece should next be considered and a diagram made of the tools to be used in the turret as shown at *A*, Fig. 7, leaving from 1/8 to 3/16 inch clearance between the rear face of the tool holder and the face of the turret. This amount, of course, varies to a considerable extent, depending on the length of the shank and body of the tool, and also on the distance that the work projects from the chuck. When the shank of the tool is short, care should be taken to see that the clamping devices in the turret have a good grip on the shank of the tool. The diagram of the circular tools applied to the work should also be made as shown at *B*, Fig. 7. The feeds for the various operations are then decided on and divided into the length of cut which will give the number of revolutions required for the various operations. The total number of revolutions to complete one piece is found by adding together the number of revolutions for each cut, for revolving the turret, feeding the stock and in some cases reversing the spindle; an approximate number of revolutions should also be added for clearance. When the approximate number of seconds to complete one piece has been obtained we then make a diagram of the rise and drop on the cam as shown in Fig. 6. To ascertain the exact number of revolutions required for clearance, if the approximate number of revolutions as allowed for clearance is not sufficient, the feed on some of the tools is increased, but if the maximum feed that the tools will stand has been used, the number of seconds to make one piece has to be increased. When the actual number of seconds has been obtained, we then convert the revolutions for each operation into hundredths and proportion the different lobes on the cam to the number of revolutions for each operation. To explain the method adopted in laying out the cams, we will take a practical example. Assume that it is required to make a screw as shown at *B*, Fig. 7. We first make the diagrams of the circular tools and the tools used in the turret as shown. Then to find the amount that the lead cam is to be cut down below the outer cam circle, measure the distance that the tools project out of the turret and add this amount to the distance that the piece projects from the face of the chuck. Then the least distance between the turret and the face of the chuck subtracted from this amount would give the distance down from the outer circle to where the lobe on the cam starts. For ex-

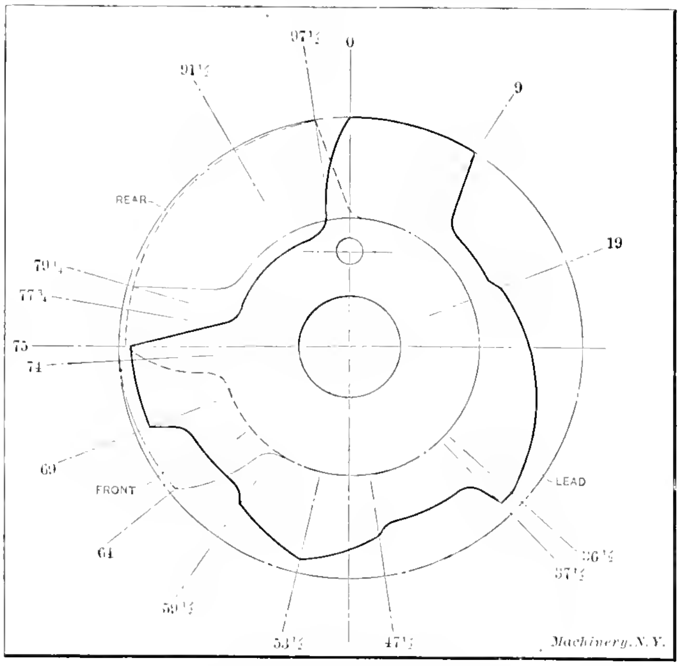

Fig 8 Commendable Method of Laying out Cams

ample, take the lobe for the hollow mill. 1 9/16 + 7/8 = 2 7/16 inch. 2 7/16 inch — 1 3/4 inch = 11/16 inch. In Fig. 8 is given a method of laying out the cams for the screw shown in Fig. 7. This method is commendable, as it can be seen whether the tools will clear one another better than if the cams were drawn separately instead of one on top of the other. If the foregoing suggestions are followed, the writer is confident that very little trouble will be encountered in designing a set of cams. The example as given is for making screws, but the same method can be followed in making any other class of work.

After the cams have been designed, a tracing should be made and kept for reference. In Fig. 9 is shown a cam drawing as adopted by the Northern Electric & Mfg. Co., Montreal. (The illustration here shown is about half size.) The cams for the No. 00 machine are drawn full size and the cams for the No. 0 and 2 machines are drawn half size, the same size of sheet being used for each. All the other neces-

sary information is put on this drawing, which has been found very convenient. It might be well to mention here that there are three prints made from this tracing. One print is kept in the designing department, one sent to the tool-room and the other is sent to the automatic screw machine department.

Practical Points in Designing Cams and Special Tools

1. Use the highest spindle speeds that the various tools will stand.

2. Use the arrangement of circular tools best suited for the class of work. (See MACHINERY, March, 1910.)

3. Decide on the quickest and best method of arranging operations before designing the cams.

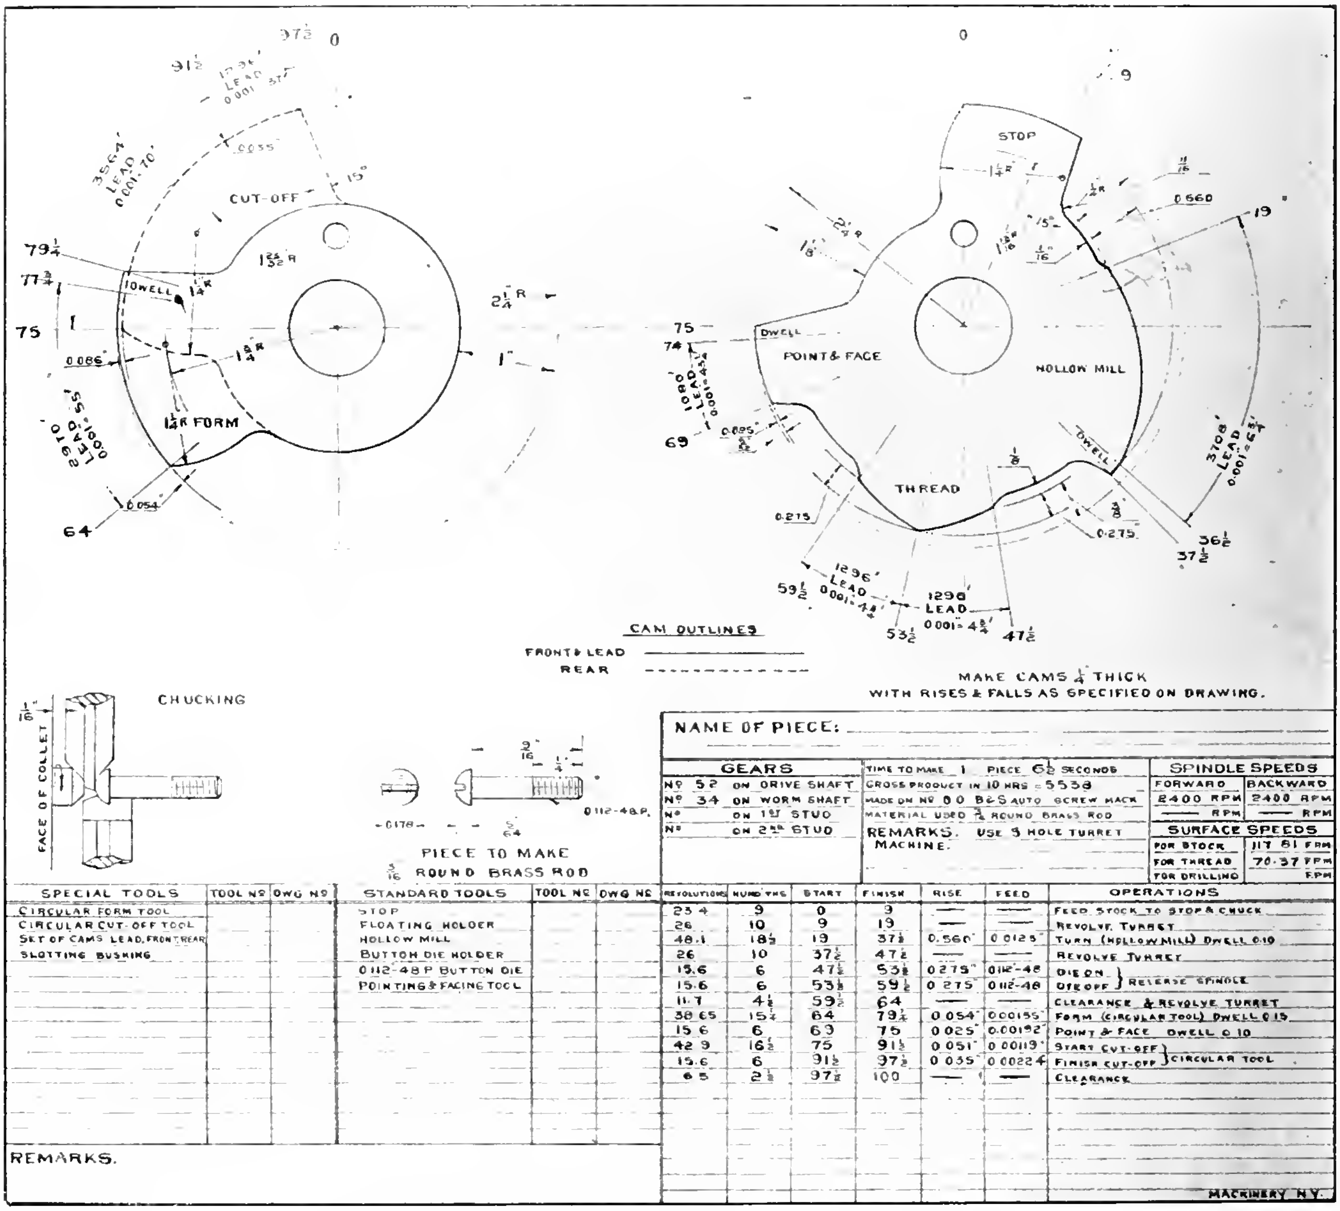

Fig. 9 Standard Cam Drawing adopted by the Northern Electric & Mfg. Co., Montreal

4. Do not use turret tools for forming when the cross-slide tools could be used to better advantage.

5. Do not use a circular cut-off tool without top rake when cutting Norway iron, machine steel, etc. (See MACHINERY, April, 1910.)

6. Make the shoulder on the circular cut-off tool large enough so that the clamping screw will grip firmly. (See MACHINERY, April, 1910.)

7. When chips clinging to the work are objectionable, the circular form tool should be turned up-side-down and placed on the rear cross-slide. (See MACHINERY, March, 1910.)

8. Do not use too narrow a cut-off blade. (See MACHINERY, March, 1910.)

9. Allow 0.005 to 0.010 inch for the circular tools to approach the work and 0.003 to 0.005 inch for the cut-off tool to pass the center.

10. When cutting off work large in diameter, the feed on the cut-off tool should be increased until near the end of the cut where the piece breaks off. After it breaks off, the feed should then be increased to pass the center.

11. When a thread is cut up to a shoulder, the piece should be grooved to make provision for the lead on the die. This requires an extra projection on the form tool and also an extra amount of rise on the cam.

12. Use circular form and cut-off tools made from high-speed steel when cutting Norway iron, machine steel, etc.

13. Use a fine feed and high spindle speed for all cutting tools.

14. Allow sufficient clearance for tools to pass one another.

15. Always make a diagram of the cross-slide tools in position on the work when difficult operations are to be performed; it is also necessary to make a diagram of the tools held in the turret.

16. Do not drill a hole more than 2½ times the diameter of the drill, but use two or more drills as required. If there are not sufficient holes in the turret, just drop the drill back clear of the hole.

17. Do not run a drill at a slow speed. Use a Brown & Sharpe drilling attachment.

18. When the turret tools operate in further than the face of the chuck, see that they will clear the chute when revolving the turret.

19. See that the body of all turret tools will clear the side of the chute when revolving the turret.

20. Do not use a box-tool for a roughing cut. Use a hollow mill.

21. Do not use a box-tool with soft supports.

22. The rise on the thread lobe should be reduced so that the spindle will reverse when the die or tap holder is drawn out. (See MACHINERY, June, 1910.)

23. When threading Norway iron, machine steel, etc., if the spindle speed used for the other tools is too high for threading, use the various threading attachments as described in MACHINERY, June, 1910.

24. When bringing another tool into position after a threading operation, allow clearance before revolving the turret.

25. Make provision to revolve the turret especially when pieces are being made in from three to five seconds and when only a few tools are used in the turret. It is sometimes convenient to use two sets of tools.

26. When using a belt-shifting attachment for threading, clearance should be allowed, as it requires extra time to shift the belt. (See MACHINERY, June, 1910.)

27. When laying out a set of cams for operating on a piece which requires to be slotted, cross drilled or burred, allowance should be made on the lead cam so that the transferring arm can descend and ascend to and from the work without coming in contact with any of the turret tools.

28. Always allow a vacant hole in the turret when it is necessary to use the transferring arm.

29. Use standard tools whenever possible.

30. When designing special tools allow as much clearance as possible. Do not make them so that they will just clear, as errors sometimes turn up causing trouble.

31. When designing special tools having intricate movements, avoid spring as much as possible and use positive actions.

* * *

LOCATING HIDDEN BOLT HOLES

By H E WOOD*

Occasionally it is necessary, particularly in connection with repair work, to locate and lay out bolt holes that come under brackets or in hidden places where they cannot be gotten at from the opposite side to lay them out with a scriber. There are several methods which can be successfully employed for work of this kind, some one of which will probably be applicable to almost any case that comes up in general shop work.

One approved method is to use studs *A* having projecting centers as shown in Fig. 1, there being a sufficient quantity of these studs to place one in each hole that is to be laid out. In this particular case the holes in the part *C* have been drilled and tapped, and it is required that corresponding holes be drilled in bracket *B* which must be attached to some other member of the machine; that is, it is necessary to lay out on bracket *B* holes which are completely covered by it. To do this the studs *A* are screwed in the holes in *C* just far enough to allow the sharp center points to project slightly beyond the surface *c*. Then when the bracket *B* is placed in position, evidently the points of the studs will hold it slightly above the surface of *C*. By giving bracket *B* a light blow with the hammer, it can easily be seen that the point of each stud will form an accurate center from which the bolt holes may be laid out. These studs should be made in the lathe so that the sharp points will be central, and a screw-driver slot should be cut across one side, as shown, to facilitate their insertion.

Another approved method would be to place the bracket (or other part) in the correct position and then with a scriber make a distinct line around the sides of it on the finished surface. When the bracket is removed, the location of the holes is transferred to it by measuring from the scribed lines to the holes and transferring these measurements to the bracket. The measurements in each case should be at right angles to the lines and edges of the bracket.

In case the corners of the part are rounded, as illustrated in Fig. 2, or the edges ragged or uneven, so that the method just referred to cannot be used with accuracy, the work may be laid out as follows: Scribe two lines *a* at right angles on the body or frame part, and two other lines *b* on the bracket, parallel to the first, the two sets of lines being any convenient distance from each other. The holes are now transferred to the bracket practically the same as described in the preceding paragraph, except that when the measurements are transferred to the bracket, the distances *x* between the parallel lines must, of course, be subtracted.

Another method that may be used (although not very accurate) is to fit plugs in the holes, letting the ends project slightly above the surface. The end of these plugs should be smeared with paint or chalk, after which the bracket is placed in position. If the bracket is rapped a few times with a hammer, it will be found upon removal that the paint or chalk will have made a mark, thus locating the hole. When this method is employed, it is best to first drill small holes, then place the work in position to see if these under-sized holes

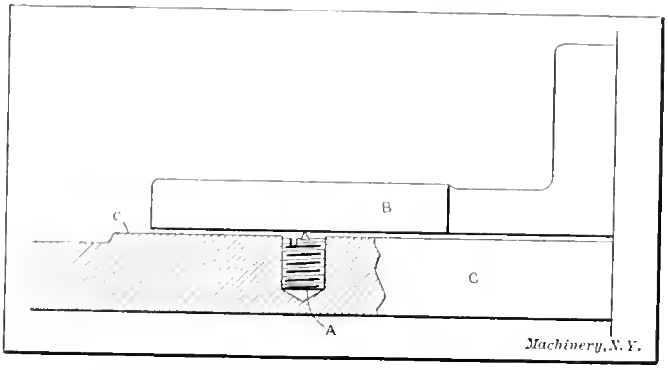

Fig. 1. Laying out Bolt Holes by the Use of Pointed Studs

are central. If they are not, there is still a chance to change their position before re-drilling to the correct size.

Still another method which is somewhat inaccurate, but which sometimes answers the purpose, is to lay the ball-peen of a hammer in each of the original holes and then strike the hammer face with another hammer which will raise a slight burr around the holes. If the underside of the bracket surface is then chalked and placed in position, the raised burrs will mark the chalked surface if the bracket is lightly tapped a few times with the hammer. The drill-and-try method mentioned should also be used when this method is employed.

Hidden bolt holes may also be laid out with a fair degree of accuracy by laying a small string, which has been saturated with paint, on the surface containing the holes so that

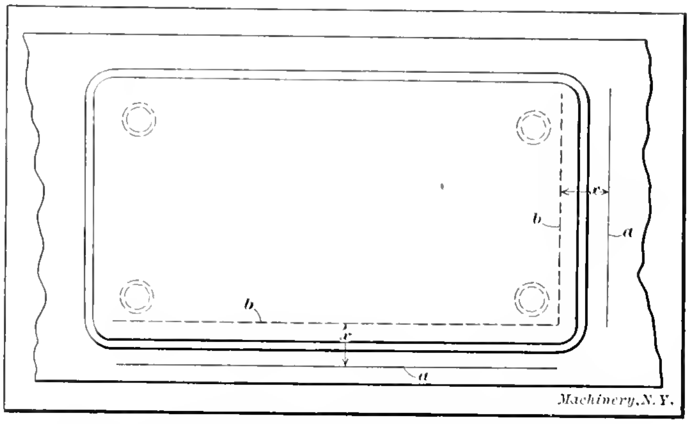

Fig. 2. Locating the Position of Hidden Holes from Scribed Lines

it forms a right angle as shown by the dotted lines *b* in Fig. 2. Now when the bracket is in position and hammered lightly or a heavy weight placed upon it, the paint on the string will make a mark on the bracket which may be used the same as lines, the holes being transferred as previously described.

Another way to locate centers by the use of lines is to first scribe lines at right angles across the centers of the holes. When the bracket is located, lines should be located on its edge to coincide with those previously scribed. The bracket is then removed and a straightedge is used to lay out lines at right angles on it. The intersection of these lines will indicate the centers of the holes.

Holes may often be transferred by the use of a paper templet. This is made by laying a sheet of heavy paper on the largest of the two surfaces. The sheet is then cut, by going around it with a hammer, to fit the edges exactly whether they are straight or ragged, and the holes are also cut by the use of the peen of the hammer. Next place the small piece or bracket on the paper, which is still in position, and mark around the edges with a pencil. These lines are then used for locating the paper templet when laying out the holes.

The receipt of a subscription is acknowledged by sending the current number. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit exclusive contributions from practical men on subjects pertaining to machine shop practice and machine design. All accepted matter is paid for at our regular space rates unless other terms are agreed on.

AUGUST, 1910

PAID CIRCULATION FOR JULY, 1910, 26,185 COPIES

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition, $1.00 a year, which comprises approximately 700 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, about 300 pages a year of additional matter and forty-eight 6 x 9 Data Sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. The Railway Edition, $2.00 a year, is a special edition including a variety of matter for railway shop work—same size as Engineering and same number of Data Sheets.

DATING ADVERTISING MATTER

It is the custom for manufacturers purposely to omit from their catalogues and other printed matter the date of publication, because the date tells the age, which is undesirable in matter that is old. Where a manufacturer issues a catalogue only once in three or four years, this reason for omitting the date may be sufficient, but we hardly think it is. Of course it is true that the recipient of a catalogue bearing an old date might feel that an old edition had been sent to him instead of the latest issued. Aside from this, is there a good reason for not dating all advertising matter issued by a manufacturing concern?

All things considered, we believe it is preferable generally, no matter how infrequently a firm's catalogues are issued, to show the year and month of publication. The dating of advertising matter is of value to the manufacturer as well as to the prospective buyer. A date has historical significance, and often is of much value in a legal contest where it might otherwise be difficult to establish proof of the time when a product was put on the market. By all means date your advertising literature, and then issue it often enough so that you will not be ashamed to have the last dates known.

* * *

GETTING THE BEST RESULTS FROM EXHIBITIONS

Manufacturers in general seem to agree that exhibitions limited to one class of products are more effective than large industrial fairs which include many kinds. The specialized exhibition or show is becoming recognized as an effective means of advertising, and it is highly important that manufacturers who spend considerable sums of money exhibiting their products at these fairs should derive the greatest possible benefit from them. The same care should be given to all the details connected with such exhibitions as is given to the general advertising and selling of machinery, and the same principles should be observed. The exhibition should be necessarily of a character to attract the attention of the visitor, and when the attention has been attracted to demonstrate the value of the machines and devices shown. In order to do this, it is necessary to have a man of high ability in charge. Any young man from the sales department will not do. The man in attendance at an exhibition should be thoroughly familiar with the mechanical construction and operation of the machines exhibited. He should be able to explain their advantages in a simple and clear way to persons not familiar with the machines shown, and in a technical manner to the trained mechanical man. Besides, he should be a first-class salesman. If such men were always put in charge of exhibitions it is certain that the returns would be greater than otherwise, and the common complaint of manufacturers that exhibitions at fairs and shows do not pay, would be largely eliminated.

To sum up, it should be remembered that an attractive exhibition is not enough; advertising which merely attracts the eye but does not appeal to the intelligence of the prospective purchaser is not of the highest standard. The additional cost incident to improving the exhibition advertising so that it will be effective is much less, in proportion, than the initial cost. It is poor policy to spend a large amount of money on space rent, decorations, freight charges, installation, etc., and then to defeat the object in view by placing an incompetent man in charge.

DEFECTS IN MACHINERY DEVELOPED AFTER SHIPMENT

A thorough inspection system will disclose faults in machine construction and so provide for their correction that the product at time of shipment will be O. K., but no inspection could provide against defects that sometimes develop between the time of shipment and receipt by the buyer. A few cases in point will serve to illustrate:

Several years ago a machine tool builder shipped four engine lathes which had been thoroughly inspected, particularly as to truth of spindles. After the lathes were set up in the buyer's shop the spindles were found to be badly out of truth, and a hot letter of complaint was forthwith sent to the builder. The superintendent of the maker's shop who had personally witnessed the tests of the spindles could not believe the report, and went himself to find out the cause of the trouble. Sure enough the test-bar ran out several thousandths in every spindle!

The dumbfounded superintendent could not remedy the trouble nor give an explanation. He finally had the lathe heads removed and shipped back to the shop. There a careful investigation showed that the keys holding the head gears on the spindles had been fitted too tight, but the tight fit had not sprung the spindles appreciably until they had been subjected to the vibration and jar of the railroad trip. Reducing the keys slightly allowed the spindles to readjust themselves and run true.

Another case is that of a planer built by a well-known concern, which was received with the bed sprung so that at corners diagonally opposite the ways were one-sixteenth inch low. The buyer, fortunately a machine tool builder himself, set out to discover the cause of the fault. It was simple. The bed had been crated properly but badly placed on the car, the consequence being that one corner was unsupported. A long railroad trip with many delays had resulted in causing the corner to settle by its own weight and the metal had taken a permanent set. Instead of making the planer manufacturer trouble, the buyer simply set the bed on supports and loaded it so as to spring it back into shape. It required several days to accomplish this, but it was done with perfect satisfaction.

If users of accurate machinery fully appreciated that the heaviest machine members acting as a beam or cantilever can be deflected by the mere pressure of the hand and that the deflection of the beam is proportional to the stress up to a certain limit, the need for properly setting and handling machinery parts not intended to act as beams would be better understood. Nothing is so stiff that it does not bend under load. Lack of support or improperly placed supports will invariably cause trouble in machine tool use.

KEY-OPERATED DRAFTING MACHINE

We have often been impressed with the need of a simpler and more rapid means of making mechanical drawings, especially for inventors and designers. Ideas come quickly and sometimes vanish as suddenly as they come. They have to be brought down while on the wing, as it were, and the faster the pencil moves, the more accurately will the details be recorded.

Literary men know how laborious and unsatisfactory is the writing out of ideas with the pen, in long hand. A man thinks faster than he can write and some of the happiest phrases are lost before they can be written. The typewriter has made it possible to write almost as fast as one thinks, and it is a great conserver of ideas as well as a saver of time and labor. The expert operator becomes practically unconscious of his fingers which automatically strike the keys and write his thoughts.

Now, if some ingenious inventor would design an easily worked key-operating drafting machine with which his ideas could be graphically put on paper without the drudgery of measuring and using instruments, what a boon it would be to many. At the stroke of a key or combination of keys, a center line would be drawn and then in rapid succession would follow other lines in just the proportions the designer has fixed them in his mind, and in the correct relative positions. The drafting machine has greatly reduced the labor of making drawings but still leaves much to be desired. Is it too much to expect that something of the kind outlined, limited perhaps to drawings of small size, will be available in the not distant future?

* * *

OBSOLETE METHODS OF LARGE CORPORATIONS

Most mechanics whose duties or interests have led them to make visits to machine shops engaged in other lines than machine tool building, have doubtless been surprised to note the scarcity of some of the most highly developed forms of machine tools in the shops of the half dozen or so great manufacturing corporations, most of which were originally formed by the combination of smaller units. In such shops the standard design of engine lathe, for instance, still holds sway for large quantities of work which in smaller plants is profitably performed on turret lathes and chucking machines of the hand and automatic types. This condition can be described in no other way than as a tendency; but in some of the shops this tendency is very strongly marked.

The fundamental reason for it probably springs from the very conditions which make such corporations possible. Most of them have, to a greater or less extent, placed themselves beyond competition. The success of the concern may be built on a natural monopoly involving the supply of raw material, on an artificial monopoly in the form of patents, on financial connections which control important markets, on a superior selling organization made possible by the completeness of the line produced, on the careful cultivation of the territory, or on all these conditions combined. In few cases, probably, does such a concern attain and hold its position on account of superior ability in manufacturing. High development in this particular is naturally found in smaller shops, where the brightest minds of the concern are intimately in touch with the processes of manufacture, and constantly thinking out improved methods.

The significant feature of this condition is that very little pressure is brought to bear on such large companies to reduce the cost of production. In competition with smaller firms, more highly developed in this particular, the big concern possesses overwhelming advantages, like those enumerated above, which have produced its present preëminence. In what little competition there may be with other large corporations, similarly situated in respect to such advantages, the cost of production does not have to be carefully considered, because all the competitors are likely to be on the same footing.

This condition results in a tendency to cling to the older methods of manufacturing which do not call for such a high degree of administrative skill, or such close attention to details on the part of the manager. In completing a lot of machines, for instance, the old-fashioned way is to make up only a sufficient number of each of the parts to complete the lot, even though there is every probability that succeeding lots of the same machines will be required, and although many of the parts could be made cheaper in larger quantities. On machinery built in this way the selling cost is determined by keeping track of the cost of labor, material and overhead expense, and adding to them the desired profit. Economic conditions require nothing further, and this arrangement simplifies and makes possible the difficult task of managing a very large manufacturing enterprise.

But it should be possible, and it will become necessary, to avoid such economic waste. In time the smaller and better organized works will secure some of the commercial advantages of the larger organizations; and the latter, under the pressure of competition among themselves will be forced to adopt more economical methods.

THE VALUE OF BEING WELL INFORMED

An authority once said: "The best informed man does not always get the most money, but he usually holds his job the longest." There is a great deal of truth in this saying, and it would be well if young men, especially, could realize that the value of knowledge and experience is not measured by the temporary pecuniary returns only, but also by the advantage of being able to satisfactorily fill a secondary position until a greater opportunity offers. There are many men who are able to obtain good positions on the strength of their own representation of their ability, but who are not able to keep their jobs for any length of time, owing to the fact that the foundation of knowledge and experience on which they build is not substantial enough. In the long run those men are losers as compared with the man who does not attempt to obtain positions which he knows he cannot fill, and who perhaps for the time being seems to lag behind. Meanwhile, however, this man may be storing up knowledge and experience gained by faithful application to the kind of work for which he at the time is best fitted, and in due course he is likely to find himself called upon to fill a position which in responsiblity and compensation will amply repay him for the efforts and sacrifices he has made in acquiring a thorough training in his work.

The ambitious young man who tries to increase his usefulness by acquiring an education in his chosen trade should not be discouraged if he finds that his knowledge and labors are not immediately rewarded. The knowledge he acquires is sure to be appreciated some day, and when a specially trained man is needed, the one who has fitted himself for the work to be done is the most likely to be considered. Eliminating the cases where "pull" and personal favoritism have been responsible for the advancement of persons not actually fitted for the positions to be filled, it is safe to say that most of the responsible places in shops, drafting-rooms and business offices are filled by the men who ten, fifteen or twenty years ago most earnestly endeavored to acquire a greater and more comprehensive knowledge of the occupation in which they were engaged.

* * *

In the Eastman Kodak Co.'s plant on State St., Rochester, N. Y., is an ingenious device for measuring the area of hides. The company purchases large quantities of leather for covering cameras and the machine is used for determining the hide areas. It consists essentially of a wooden frame carrying several hundred metal pins, hinged at the back and suspended on a weighing scale having a pointer which indicates square feet area on its face, instead of pounds. The pins vary in weight, the lightest ones being at the back near the hinge of the frame and the heaviest ones in front. Their weight is proportional to their distance from the pivot. The pins two feet from the pivot, for example, weigh only one-half as much as those one foot away from the pivot, and so on. In operation the frame is raised and the hide is laid underneath the frame which is then let down. The weight of the pins resting on the hide is subtracted from the total weight, thus indicating on the scale the square feet in the hide.

MACHINING ACCURATE QUICK-PITCH SCREWS AND NUTS

By FRANCIS J. BOSTOCK*

Some time ago the writer had occasion to machine a considerable number of special quick-pitch screws and nuts having quintuple threads. The outside diameter of the screws was ¾ inch, with a lead of one inch. Fig. 1 shows the appearance of one of these screws and one of the nuts. (A quadruple threaded screw made in the same manner as the quintuple screw, is shown to the left.) The requirement was that all the screws and nuts should be absolutely interchangeable with each other. It is readily understood that this requirement presents considerable difficulties.

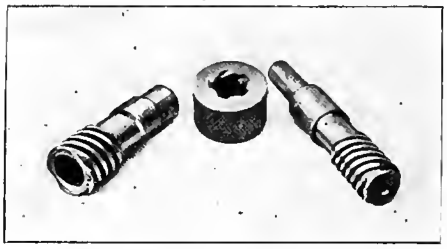

Fig. 1. Multiple-threaded Screws and Nuts made by Method Described

Several methods suggested themselves to the writer. One was the ordinary way of cutting the threads in the lathe, changing the gears around 1/5 of a revolution to give the requisite turn to the work so as to cut the next thread. Another method would have been to mill the screws in an ordinary milling machine and to arrange for some way of tapping the nuts by means of a master for giving the tap the correct turning effect while traversing the nut. This method, however, presents many difficulties, and would have caused the breaking of a considerable number of taps. The first method mentioned has the disadvantage of being slow, requiring the repeated starting and stopping of the machine, the thread being only about 2 inches long, and involving also the necessity of stopping the machine to change the gears. The use of a divisional driving plate would have introduced inaccuracies and loss of time. After careful consideration, therefore, the following method, which has proved itself to be quick and applicable alike to internal and external threads, was adopted. It insured all threads being cut exactly alike and the time of machining, as compared with the cutting of the threads in a lathe in the ordinary way, was reduced from 80 to 85 per cent.

The first step was to select a machine suitable for this work,

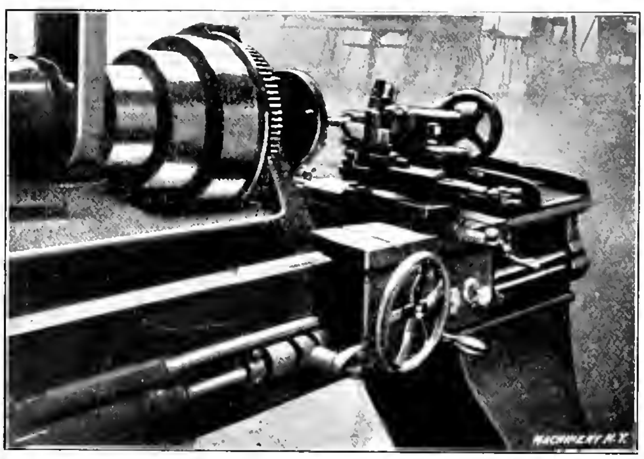

Fig. 2. Lathe Fitted with Master Cam for Cutting Multiple-threaded Screws

the feed shaft of which was driven directly from the feed screw, so as to enable this shaft to be driven at a predetermined ratio to the lathe spindle. On this feed shaft a cylindrical cam, capable of being adjusted to any desired position along the shaft, was fastened. This cam had a groove cut on its surface in which engaged a pin plunger extending from a bracket on the saddle or apron of the lathe. By this means the saddle could be moved forward or backward, as guided by the groove in the cam. The plunger could be let in or withdrawn from the groove as required. The groove in the cam was so arranged that the saddle would travel slowly while the thread was being cut, but return at an increased speed. The cam and work always revolved in the same direction, and it was only necessary to withdraw the tool on the completion of each cut and feed it in when beginning a new one. An adjustable stop was used for giving the requisite feed to the tool. The general arrangement is indicated in Fig. 2.

* Address: 22 Bristol Road, Bournbrook, Birmingham, England.

The interesting feature about the method described is that it was not necessary to stop the lathe until the threads on each piece were completely finished, the device having a provision for giving automatically the travel from one thread to the next, thus insuring all the screws being cut absolutely alike and made interchangeable with each other. Another valuable feature is that the saddle travels only just far enough to clear the work, and that as little time as possible is occupied in returning. All motions are independent of the operator, whose sole duty it is to feed and withdraw the tool for each stroke.

The master cam was designed as follows: The length of the threaded part of the work was 1¼ inch, requiring a movement of the saddle of about 1¾ inch. As the ends of the grooves in the master cam were to be rounded, the travel in the grooves should be, initially, about 2 inches. Assuming, therefore, that the saddle travels forward 2 inches, then the work must make $\frac{\text{travel}}{\text{lead}}$ revolutions, or, in this case, $\frac{2}{1}$ or 2 revolutions. Assume now that we decide to reverse in say 1 1/5 revolution; then the total revolutions of the work to one

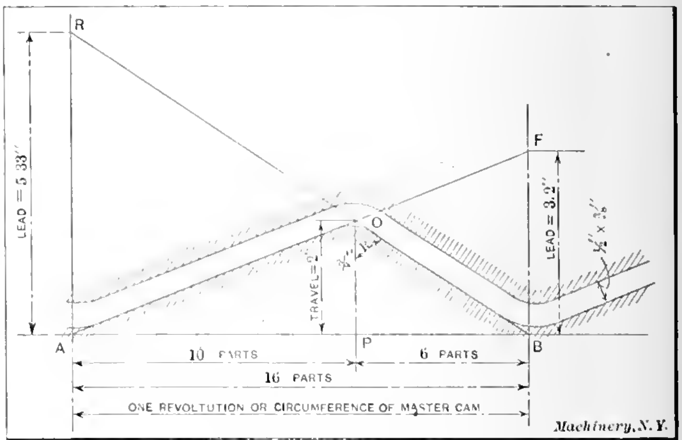

Fig. 3. Layout for Master Cam

revolution of the cam is 2 + 1 1/5 = 3 1/5. A little consideration will show that each time the tool returns, it catches the next thread to the one having just been caught, because the work has advanced 1/5 of a revolution for each time the tool returns. In the illustration in Fig. 2 it will be seen that the master cam has two grooves. One of these grooves is used for screws of different lead, and is not required for the work being described.

We will now proceed to find the requisite lead for the cutting of the cam, the lay-out of which is indicated in Fig. 3. The line AB represents the circumference or one revolution of the master cam. This must be divided into the forward and reverse periods. The forward travel is represented by 10 parts and the reverse by 6 parts, the point P being the point of reversal. From point P draw line OP equal to the travel of the saddle, *i. e.*, 2 inches. Draw from the points A and B through the point O lines AF and BR. Now AR and BF equal the leads to which the groove in a master cam must be cut, the lengths of these lines being easily found by proportion.

$$BF : 2 :: 16 : 10; \text{ hence } BF = 3.2 \text{ inches,}$$
$$AR : 2 :: 16 : 6; \text{ hence } AR = 5.33 \text{ inches.}$$

The master cam is now set up in an ordinary milling machine and grooves milled to the leads found. It is advisable, however, not to mill the grooves exactly to their meeting point, but to produce an easy radius at their junction so as to reduce the strain of reversing the direction of the saddle.

After the master cam was cut and attached to the machine, the correct gears to drive the feed shaft in the right relation to the lathe spindle were determined. The ratio of the number of revolutions made by the work to the revolutions of the

master cam is 16 to 5, and from this ratio the gears are easily found.

The measuring of the external threads was made by the wire method, but as the outside diameter was standard, only one wire was used, the size being taken from one wire and the outside diameter of the screw. The internal threads were measured by means of an ordinary screw plug gage.

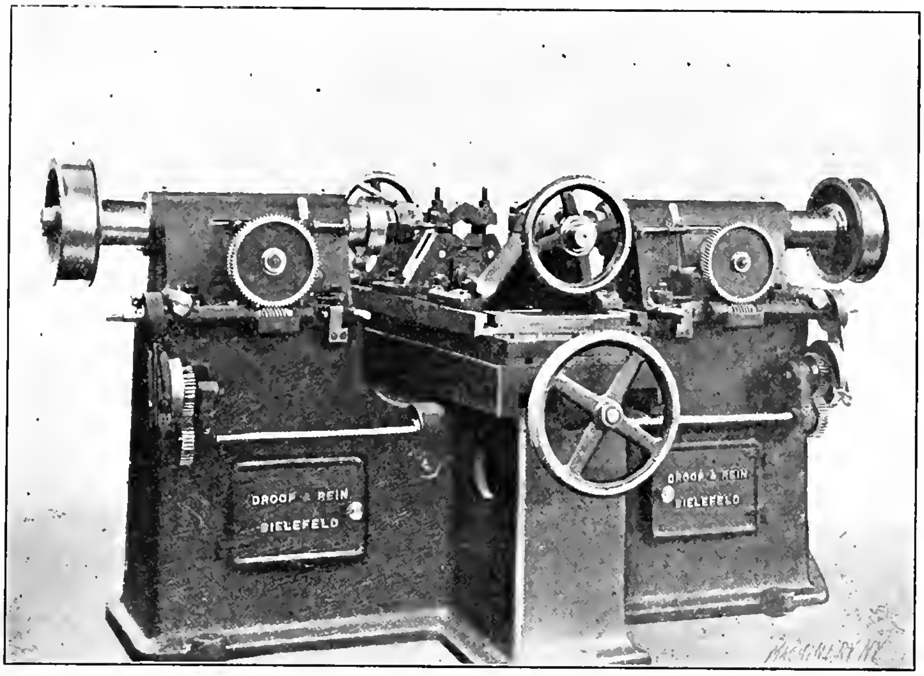
* * *

SPECIAL KEY-SLOT MILLING MACHINE

A special machine for milling slots and key-holes in shafts, bushings, cross-heads, piston-rods and similar pieces, is shown in the accompanying engraving. This machine has two horizontal spindles arranged on each side of the work-table so that the mills operate on both sides of the work simultaneously. The table is given a reciprocating motion by means of a slotted crank at the rear, and at the end of each stroke, the two spindles are fed in toward the center of the work. The stroke of the table is, of course, adjustable and it may be determined by a scale on the slotted crank.

The feeding movement for the spindles is transmitted from the drive at the rear through the bed, by shafts, which by means of spiral gearing, drive the horizontal shafts seen at the front of the machine. These shafts, through spur gears and a slotted crank and ratchet mechanism, actuate the worm and worm-wheels shown. The shafts on which the worms are mounted impart the movement to the spindles by a pinion that meshes with a rack cut in the spindle quills. This feeding movement, as before stated, takes place at the end of each table stroke. The feed can be varied by means of the slotted cranks, and it can be disengaged automatically at any predetermined point. The disengagement is brought about by a pin attached to the spindle quill striking an adjustable screw in a latch-lever which holds the worm into engagement with the wheel, the worm being mounted on a swiveling shaft as shown. As soon as the feed is thrown out, each spindle is automatically returned by a weight suspended from a pulley at the rear, mounted on the worm-wheel shaft.

When milling slots in solid pieces such as piston-rods, etc., the tools are prevented from touching each other at the center of the work, by adjusting the trip mechanism of one spindle so that it is withdrawn when within about 1/32 inch of the center. The other spindle is also automatically withdrawn after its milling cutter passes into the slot milled by the opposite tool.



Special Machine for Milling Slots in Shafts, Bushings, Piston-rods, etc.

Slots can be milled with either parallel or taper ends, though in the latter case a special swiveling table is used. The milling spindles are made of the best crucible steel and they are hardened and ground. The machine has a pump for supplying lubricant to the mills, which, after being used, drains to a reservoir in the lower part of the machine body.

The particular machine illustrated will mill slots up to 7⅞ inches in length, and it can cut a keyway 5⅝ inches long, 1 3/16 inch wide, and 3½ inches deep, in thirty minutes. The distance from the spindle centers to the main table is 11⅞ inches, and to the swiveling table 7⅞ inches, while the maximum distance between the spindle heads is 21 inches. This machine is the product of Droop & Rein, Bielefeld, Germany, who also manufacture two others of similar design. One of these is equipped with four spindles which adapts it to the milling of two slots simultaneously, while the other has two spindles, and is similar to the one illustrated, but is electrically-driven.

* * *

The legend "Patent Applied For" so often seen on manufactured machinery generally means that the inventor couldn't even get a combination claim patent which is usually not worth the paper it is written on.

LABOR CONDITIONS IN AMERICAN AND GERMAN MACHINE SHOPS AND FOUNDRIES

By W. H. DOOLEY*

The German government recognizes the duty and exercises the right of regulating the metal trades in the interest of the employed, but in doing so it is careful to keep in view the equal duty of fostering national metal and engineering industries, and consequently the German law is in many respects much less stringent than the English and American laws, which seem to have been enacted under spasmodic influences, without conscious recognition of any principle. This might be explained by the fact that the German government has been obliged to cultivate the great metal and engineering industries with much care. Consequently, the German legislature has been obliged to strike a happy medium between two claims, that of the employed for protection and that of the community at large for the promotion of industrial enterprises, whereas in both America and England the necessity for encouraging manufactures has not hitherto existed, and the legislatures have merely, from time to time, taken up the duty of protecting the employed with such drags upon their actions as the private interests of employers have been able to effect. The protection, in short, has been all on one side. The time when this line could be pursued with safety in this country and England has now passed.

The metal-working manufacturing industries have come to such a delicate balance that the possibility of their toppling over must be taken into account, and consequently the interest of the community is concerned in any course which is likely to have that effect. It is certain that if our metal industries do not need encouragement from the legislative branch of the government they certainly do require protection from serious shocks. It is, therefore, instructive to note the careful manner in which the German government has struck this happy medium, and the results.

The most stringent regulations passed by the government are those affecting children and women, and it is in this respect that the state has clearly in view the interests of the community as represented by the employed. The total number of children under fourteen years employed in the metal trades in Germany was 1087, and 543 in the machine trades. These children are between thirteen and fourteen, and the hours of employment are restricted to six with half an hour interval for meals. Between fourteen and sixteen they may work not more than ten hours, they must have an hour's pause at midday and half an hour both in the forenoon and afternoon, unless their working day is not more than eight hours and no continuous spell exceeds four hours. During the pauses any

* Address: Lawrence Industrial School, Lawrence, Mass.

participation in the work of the factory or shop is forbidden, and even remaining in the rooms is allowed only when their own department of the work is brought to a complete standstill or it is impossible for them to go elsewhere.

When past eighteen they cease to be youthful workers and are under no special regulations except that all under twenty-one must be provided with a "work book" or register containing name, age, birthplace, nature of employment, date of engagement, discharge, and other particulars. All boys under eighteen are obliged to attend a continuation school for nine or ten hours during the week, where they receive instruction in the technical knowledge of their trade and religious instruction by their own clergyman. This time is taken out of the regular work-day without loss of pay. In a number of the larger engineering and machine shops no youthful workers were noticed by the writer.

Workmen may be fined to the extent of one-half their earnings except in cases of acts against fellow workmen, of offenses against morality, or against regulations, against maintenance of order and of security, etc., when the fines may be imposed to the full extent of the average earnings. All fines must be applied to the benefits of the factory workers, and generally go to the sick fund, but this does not affect the right of employers to obtain compensation for damage. Particulars of fines must be entered in a book, which is open to inspection by a government officer.

Every machine shop, foundry, or engineering establishment must have a set of rules hung up in an accessible place in each department stating the hours of work, with the regular intervals for meals, the time and manner of paying wages, the length of notice terminating employment and the conditions under which notice is unnecessary, and particulars of punishment, including fines and the objects to which they will be applied. Punishments which would wound self-respect or offend morality are inadmissible. These rules are equally binding on employer and employed, but before they are issued opportunity must be given to adult workers to express their views, and the rules with any objections must be submitted within three days of issue to the factory inspector, who may order amendments if the rules are not in accordance with the law or with special regulations. Punishments not in the rules cannot be imposed, nor can other grounds of dismissal be included in the contract.

It is a rare thing for a firm to have any differences with its workmen. Indeed, I was definitely informed by one firm that there had been only five cases of dispute in nine years, and these arose not from the workmen as a whole or any considerable number of them, but were cases of individual workmen making complaints. They have in Germany an institution corresponding to the Conseil des Prud'hommes in France, which they call in German "Gewerbe Gerichte," to which all cases of disputes of employes and employers of the metal industries are brought. The average number of cases tried by this bureau never exceeds 500 a year. The bureau consists of three or five people. The government appoints a chairman who is a lawyer and the representative of the employer and the employe. Sometimes two are selected instead of one. They try the case before them, but their decision is not final as is that of the arbitration board in this country. If a workman or employer does not like the decision it is only binding for two weeks. Then the workman may leave or the employer may discharge him. To illustrate a case: One of the workmen in an engineering firm thinks he should receive four marks more a week in wages. He goes to the firm and makes the demand. They refuse him. He appeals to the Gewerbe Gerichte. The Gewerbe Gerichte says, "No, do not pay it." The workman can leave at the end of a fortnight by giving a two week's notice, or if the decision is given in favor of the workman the firm is obliged to pay him the increase for two weeks at least and then they may give him a fortnight's notice by serving a legal notice.

Notice of termination of employment is usually a fortnight, but it may be dispensed with on the part of an employer on the following grounds: false representation, theft and other criminal acts; leaving work without permission or refusing to fulfill the contract; carrying fire or lights about contrary to orders; acts of violence or gross abuse directed against employer, his representative or family; willful damage; inducing members of employer's family or his representatives or fellow workmen to behave in a manner contrary to law or morality; inability to continue work; or an alarming disease. Similarly it may be dispensed with by the workers on corresponding grounds; and also for non-payment of wages in the prescribed manner; neglect to provide sufficient work for piece-workers; unprofitable prejudices; danger to life and health in the employment, which could not be inferred from the contract.

The provision of rules for the metal industries containing the foregoing and other particulars, legally binding on employers and employed, is a characteristically German method of doing business. It is in accordance with that respect for law and order which is such a marked feature of German life, and contributes materially, no doubt, to the smooth working of the metal and engineering industries. The rights and obligations of "work-giver" and "work-taker"—to use the excellent German terms—are publically defined and guaranteed by law. This conduces to tranquillity, and renders vague talk about "rights" palpably futile. The law cannot be changed by individual bullying on either side. The rate of wages is, of course, not included in the rules.

Before any foundry, machine shop or engineering establishment can be started it is necessary to give notice to the local authority. Similar permission is required for the erection of boilers, and especially noisy works. Apart from these particular provisions, the metal industries are subject to the following law:

Owners are bound to arrange and maintain workrooms, appliances, machinery and tools, and to regulate the working in such a way as to protect the workers from danger to life and health, so far as the nature of the business allows. Particular attention must be paid to the provision of sufficient light, ample air space and ventilation, and to the removal of dust arising from the work, of vapors and gases thereby developed, and of refuse incident to it.

Similarly, those arrangements must be provided which are necessary for the protection of workers against dangerous contact with machinery or parts of machinery or against other danger lying in the nature of the work, place of working, and particularly against the dangers which might arise from fire. This section is followed by one requiring the provision of arrangements for the preservation of morality and decency.

The proof of the pudding, however, is in the eating, and the test of a law is its execution. Do the German metal industries conform to the laws? They do—as regards health and comfort they are not to be excelled. The buildings are brick and in the larger plants, steel. The most striking feature of the metal and engineering plants is their clean, orderly and well-kept condition. These qualities are universal, and they extend to the dirtiest and the most untidy department of the trade—the foundry. The foundry in this country is usually a scene of dirt and disorder, unmitigated by any attempt to be tidy, and aggravated by an atmosphere heavy with smoke and gloom. The German foundries and machine shops were a revelation to me. They are as clean and well-kept and almost as light as any other shop. The remarkable order maintained is systematic, and in a large measure intended to promote the prevention of accidents. In the accident prevention rules of the Rhine Westphalian Engineering and Small Iron Industries Association, I find laid down in the first paragraph:

"The gangways in all workrooms must be broad enough to exclude as far as possible injury to persons using them by machinery or transmission parts in motion. They must be kept in good condition, and must not be blocked by the heaping of material or the transportation of articles."

Exactly the converse condition is what exists in most of our engineering shops. There is no room. The place is congested, and manufactured or half manufactured articles lie promiscuously about in all directions, blocking the passageway. The entire freedom from such disorder in German shops and work-rooms undoubtedly conduces to efficiency as well as to safety, and it is secured chiefly through the habits of order inculcated in all alike—workmen, managers and owners—by

the military discipline they have undergone. Fencing of machinery is required.

With regard to the installation of machinery and workshop appliances, I can only say that the Germans have our best machines installed. They make use of electric power, automatic tools, etc. Of course, there are small shops where one will find two men working on a lathe when it was intended to be run by a single man.

The shops are well provided with sanitary, washing and dressing accommodations. The workmen are clean and careful in their habits. They generally keep a working suit of clothes, and change before and after work. Consequently, lockers are provided. Baths are common, particularly shower baths. The practice of providing comfort and conveniences for workmen by employers is more common in Germany than in America.

The workmen are quiet and particularly intelligent. You might say they are no brighter than American workmen, but they seem to be because they do well what they are told to do. Mechanics working on an engineering order from England do not hesitate to use the original English blueprint with the English measurements. The foreman, on being asked if it would be necessary to turn them into the metric system, said, "Oh, no, the men will work from the English figures all right." Now, would or could our American mechanics do the same? The workmen are not in the least inventive; they never make suggestions as our American workmen are constantly doing, nor is there any system of encouraging them to do so, but they keep the rules and do not strike. In short, they do what they are told, and do it well. Herein is the second cause of the success of the metal industry in Germany.

Roughly speaking, the working hours are ten a day. The following schedule taken from the different metal industries in Germany, will show exactly the length and distribution of the day's work.

Hours in Engineering Works at Düsseldorf

Begin	6:30 A. M.
Breakfast	8:15 to 8:30 A. M.
Dinner	12 to 1:30 P. M.
Tea	4:15 to 4:30 P. M.
Close	6:30 P. M.

Total, 12 hours, minus 2 hours for meals, equals 10 hours, week 60 hours.

Hours in Machinery Works at Düsseldorf

Begin	7 A. M.
Dinner	12 to 1:30 P. M.
Close	6:30 P. M.

Total, $11\frac{1}{2}$ hours, minus $1\frac{1}{2}$ hour for meals, equals 10 hours, week 60 hours.

Hours in Engineering Works at Chemnitz

Begin	6 A. M. (winter 7 A. M.)
Breakfast	8 to 8:30 A. M.
Dinner	12 to 1 P. M.
Tea	4 to 4:15 P. M.
Close	6 P. M. (winter 7 P. M.)

Total, 12 hours minus $1\frac{3}{4}$ hour for meals, equals $10\frac{1}{4}$ hours, week $61\frac{1}{2}$ hours.

Hours in Steel Works at Essen (Krupp)

Begin	6 A. M.
Breakfast	8 to 8:15 A. M.
Dinner	12 to 1:30 P. M.
Tea	4 to 4:15 P. M.
Close	6 P. M.

Total, 12 hours, minus 2 hours for meals, equals 10 hours, week 60 hours.

The normal day is ten hours and the normal week is 60 hours. The great difference between the United States and Germany is the number and length of the meal intervals allowed in the latter. As a rule, in the United States the only interval allowed is for dinner and that is generally no more than three-quarters of an hour or half an hour. In some American shops when they are busy no interval is allowed at all; the men snatch their food as best they can. The machinery runs continuously and this is the secret of the great production of the American steel mills in particular and of the excessively high wages earned by them. Deliberateness and respect for meal times is as characteristic of Germans as hurry and indifference to them are of Americans.

BELL FOUNDING IN OLD FRANCE

By JOSEPH G. HORNER*

The accompanying illustrations of bell founding in France show the practice used previous to 1777, when the French encyclopedia, from which these illustrations are taken, was published.

Plate I shows in the upper part a bell foundry, with a pit in which the molds are contained, covered with a shed. The furnace, uncovered, is seen to the right. In Fig. 1 a molder is seen applying with his hands the tempered loam to form the model of a bell. He takes the loam from a cask by his side, seen to the right. In Fig. 2 the other workman pushes the loam board (the gage, or pattern) in order to unite or compress the loam, and to remove or scrape off the superfluous material. Fig. 3 shows the core of another bell; the cope is seen suspended by the tackle.

The lower part of this plate, Fig. 1, shows a detail of the

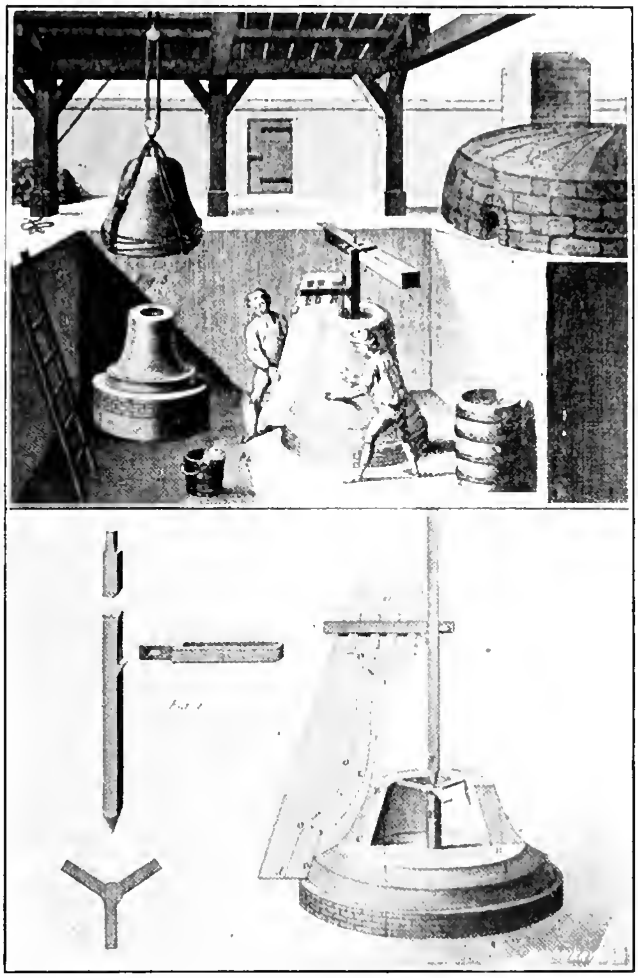


Plate I. Molding Pit and Methods used in a Bell Foundry 150 Years ago

striking bar or "compass" seen in Fig. 2 above, at *G*. Two pieces of iron compose the bar. The vertical arbor terminates at the bottom in a pivot, and at the top by a trunnion, and carries the "strong arm" mortised through it, on which the gage or striking board is fastened. Fig. 2 below shows the socket or step of iron, which is fixed by its three branches in the solid mass of the core, and the center of which carries the pivot of the arbor of the compass or striking bar. Fig. 3 shows the arrangement mounted with the striking board in place. The masonry of the core is broken away to leave visible stake *E* planted in the middle of the mold, on the head of which rests the three-branched footstep which supports the arbor and compass. The board is secured to the arm with wedges. The lines drawn on the board show the thickness of metal, just as the patternmaker puts them on to-day. Outside the metal the outer thickness of the loam cope is also drawn in.

Plate II illustrates the different portions of the mold in detail. The core is shown in Fig. 4. We are told that the edge of the pattern board in the previous plate has been cut

* Address: 45, Sydney Buildings, Bath, England

with bill-hook and chisel to the form of the interior of the bell, and that the edge has been beveled so that it does not tear up the loam. On commencing to work the core, its mold or body is put together with bricks, partly entire and partly broken, and covered inside and outside by the loam. The exterior angles of the bricks are broken, in order to give the masonry a true circle. As each brick is placed, the striking board is presented for the purpose of setting or correction. At a certain stage of the building up, the wooden peg *E*, Fig. 3 in Plate I, is put in place to afford support to the triangular step.

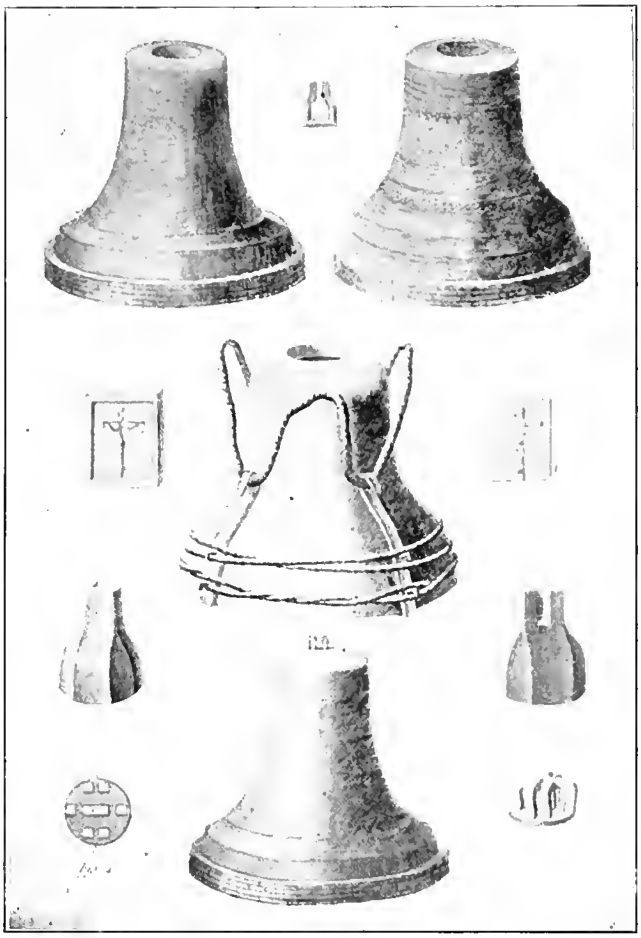

Plate II Steps in Making the Core and Mold

the arms of which are laid on the masonry. The work then proceeds to the full height. Then a bush of charcoal is let into the top of the core. All the brickwork is covered with a crust of cement made of clay, horse manure, and hair, well beaten and mixed together on a bench, with the head of a mattock. It is then put on with the hands, and the gage turned. A fire is lit to dry the first coat, which drying occupies from 12 to 24 hours. It is stated that during the drying, the molder must be careful to refresh the water parts of the mold that are dry, because uniformity of drying is necessary and some of the interior parts dry more slowly than others.

Two coats or applications of loam are made, each being dried. The second coat is finer and more liquid than the first. A third coat is then laid on, composed of cinders and soap; this greasy coat makes it easier to detach the mold yet to be built when it has to be lifted off. The final diameters and the circular truth are carefully checked before this last coat is put on, which is not dried. (It might have been a thin application of wax, though the word used is *savon.*) It is a parting thickness, serving the same function as a thick coat of blackwash, to effect a separation between the core and the mold to be built on it.

After the core is thus completed, the model or pattern of the false bell has to be struck. The board is removed from its bar and its edge cut back to the lines representing the pattern body, the edge beveled, and the bar and board replaced in its pivot.

The loam of which the model is formed is stated to be of clay, sieved and mixed with hair and horse manure; this is for the first coat. The workman takes his hands full of this, and applies it on the core in several thin applications which are amalgamated to form the thickness required. Each coat is gaged by the board and is dried by a fire. All these coats are covered with hemp to prevent the mold from cracking and splitting.

When the "false bell mold" or loam is thus finished, bordering lines are marked to indicate the positions for the fillets for the inscriptions, and proportions of the bell. Afterwards follows the building up of the cope or the last part of the mold, to prepare for which a composition of tallow, soap, and wax is used. The striking board is replaced, and a light or thin coat of this composition is swept on by the edge of the board to give an equal thickness. The board is then removed and the inscriptions are put on, and also other relief figures. Then all is ready for making up the cope. It must, according to the description, be extremely strong as it has to endure the heat due to casting, be buried in earth well trampled and beaten down, and carry the whole of the weight and force of the metal at the time of pouring. To strike this, the edge of the board is cut to the outline of the cope, the third line in Fig. 3 of Plate I. The first coat applied is of fine clay passed through the sieve and mixed with hair, horse manure, and water to the consistency of thin mortar. The molder takes the mixture in his hands and applies it softly to the surface of the model so as not to derange the letters and the figures. It covers all the parts in relief, filling and finishing the cavities of the figures and letters. This operation is continued to a certain thickness, which is allowed to dry without fire. It requires about 12 or 15 hours to form a crust. A second

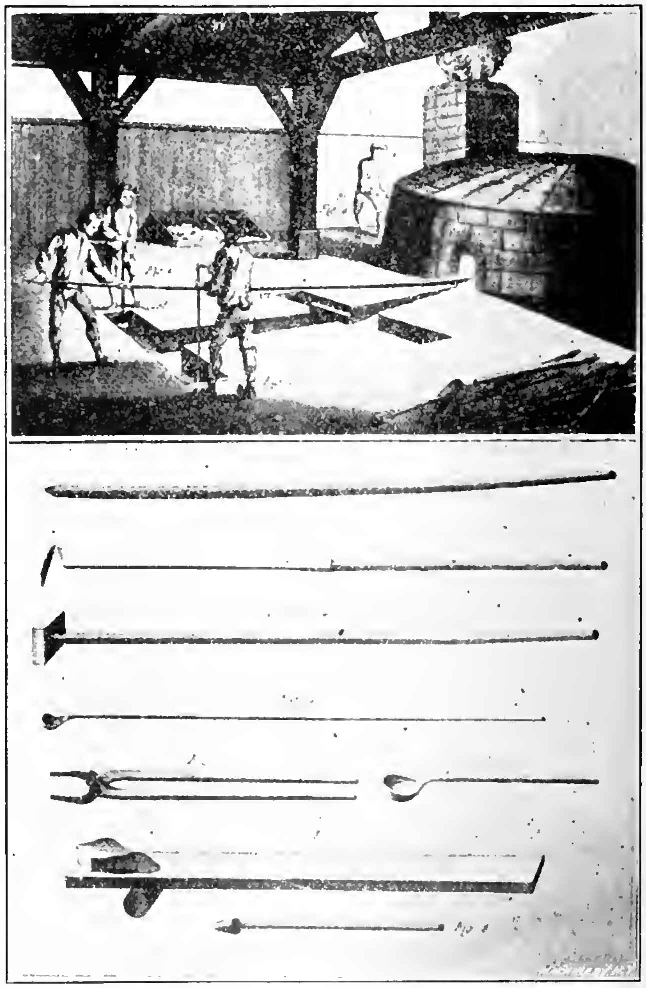

Plate III. Pouring the Metal, and Tools used in Bell Founding

coat of the same material is then laid over this coat, but not so thin, and when this second one has reached a certain consistency, the striking-board is replaced, and a fire put in the core to melt the wax in the inscriptions, and to impart, little by little, in the first coats the hollows of the letters and figures.

The next charge of loam is less thin, and each further application is more and more solid, and between these is placed plenty of hemp. Finally the cope is lifted by the hooks and

rope seen in Fig. 6. Cracks and defects are made good, if present, followed by drying with lighted straw. The model of the bell is broken away from the core, which is cleaned and dried before replacing the cope.

Fig. 7, Plate II, shows the core, which has a ring core for suspending the clapper, rammed in it. The eye is shown separately between Figs. 4 and 5. Fig. 8 is the model of a mold for the figures in wax. It is of copper, and drawn for a double section. It has a double edge that contains the wax which takes easily the imprint of the hollow portion. The letters are molded in the same manner. Fig. 9 shows the imprint in wax drawn from the mold, and in the state in which it is applied on the model of the bell.

Fig. 10 is the covering mold which contains the mold of the horns or handles, the casting, and the vents in the side opposite to the entry of the metal. Fig. 11 is the same taken from the side of the entry of the metal. Fig. 12 is a plan of the horns. Fig. 13 shows them in perspective on the upper part of the bell. These horns are made of loam cakes or cores.

The operation of pouring the metal for the molds is shown in Plate III. The furnace is of the reverberatory type. The fire, of wood, is built on a grating, fired from above, and the ashes are removed from a pit descended to by steps. These are on the other side of the view, out of sight. The master founder is seen in Fig. 1 tapping the furnace with a long pole to run the metal into the molds. He controls the flow by introducing more or less of the rod into the hole in the furnace. The molds are situated at the ends of the cross channels indicated. Two bells at the first cross channel are first cast, and the assistant founders (Figs. 2 and 3) are ready to lift the plugs of iron covered with clay at the set in the second channel as soon as the first two molds are filled. At Fig. 4 the workman pushes the metal with a rabble of wood towards the tapping hole.

When the time for pouring arrives, the canals are cleared and a charcoal fire is kept in them during the time of the melting of the metal. The ends of the rods are also heated. The tools are shown in the lower part of the plate. Of these Fig. 1 is the tapping pole, Fig. 2 is a rabble of iron with a handle of wood for skimming the metal, Fig. 3 is a rabble of wood handled with a rod of the same for pushing the metal towards the opening of the tapping hole when melted, Fig. 4 is a spoon for taking samples of metal, and by them to judge of its condition, Fig. 7 is a charging bar for use at the door of the furnace, and Fig. 8 is a clay plug for the air holes.

HIGH-PRESSURE CYLINDER DIAMETERS FOR AIR COMPRESSORS*

By J. WILLIAM JONES†

The charts in the accompanying Data Sheet Supplement are intended for rapid determination of the proper diameters of high-pressure cylinders for compound air compressors. By means of these charts it is possible to find instantly the required high-pressure cylinder diameter for various pressures and altitudes, when the low-pressure cylinder diameter is known.

The first of the three charts is laid out for sea level conditions. The diameter and stroke of the low-pressure cylinder are first computed with reference to the required piston displacement, and from this diameter the high-pressure cylinder diameter is traced on the chart as shown by the dotted lines and arrows, which indicate the method of procedure when the diameter of the low-pressure cylinder is 20 inches, and the air compressed to 200 pounds gage pressure. The ratio between the cylinder diameters when found in this manner divides the load equally between the two stages, provided the intercooler abstracts all the heat due to compression in the first stage. The two other charts are laid out for 5000- and 10,000-foot altitudes, but are otherwise used in the same manner as the first chart.

A problem which often confronts the compressor builder when manufacturing a standard line is to obtain cylinder ratios which will be approximately correct for various conditions. As an example, assume that it is required to determine the dimensions for the high pressure cylinder of a compound compressor having a low pressure cylinder of 30 inches diameter. It is required to find the correct cylinder ratios for 80 to 100 pounds gage pressures for altitudes from sea level up to 5000 feet. Referring to the sea level chart we find that the proper diameter of the high pressure cylinder for 80 pounds would be 18⅞ inches, and for 100 pounds, 18 inches. On the 5000-foot altitude chart we find that the high pressure cylinder at this altitude should be 18⅛ and 17¼ inches, for 80 and 100 pounds pressure, respectively. A convenient mean of the above pressures would be 18 inches diameter, which would meet the requirements of the case very satisfactorily.

TABLE OF ABSOLUTE RATIOS OF COMPRESSION

Gage Pressure, Pounds	Absolute Ratio of Compression		
	Sea Level	5,000 Feet	10,000 Feet
80	6.44	7.55	8.92
100	7.80	9.20	10.90
125	9.50	11.25	13.40
150	11.20	13.30	15.90
200	14.60	17.40	20.80
250	18.00	21.50	25.80
300	21.40	25.60	30.80

The ratios of the cylinder areas as given on the charts are obtained from the absolute ratio of compression. Assume, for example, that a compression of 150 pounds gage pressure is required. Then the absolute pressure equals 150 + 14.7 = 164.7 pounds, and the absolute ratio of compression is 164.7 ÷ 14.7 = 11.2. The square root of this ratio is the ratio of the low-pressure piston area to the high-pressure piston area, or,

$$\sqrt{11.2} = 3.35 = \text{ratio of cylinder areas.}$$

A table of absolute ratios of compression for various pressures and altitudes is given above.

The general formula for determining the high-pressure cylinder diameter when the low-pressure cylinder diameter, the initial pressure, and the terminal pressure are known, is as follows:

$$d = \sqrt{\frac{D^2}{\sqrt{\dfrac{P_1 + P_2}{P_1}}}}$$

in which d = diameter of high-pressure cylinder,
D = diameter of low-pressure cylinder,
P_1 = initial pressure,
P_2 = terminal gage pressure.

At sea level, of course, the initial pressure P_1 is the atmospheric pressure or 14.7 pounds per square inch.

As an example, assume that a given compressor requires a low-pressure cylinder of 33 inches diameter. Find the high-pressure cylinder diameter for compressing air to 100 pounds gage pressure at sea level.

$$d = \sqrt{\frac{33^2}{\sqrt{\dfrac{14.7 + 100}{14.7}}}} = 19.75 \text{ inches.}$$

This calculation, however, is somewhat lengthy, and the accompanying Data Sheet Supplement will be found very convenient, in that it gives the diameter required directly without any calculation whatever.

* With Data Sheet Supplement.

* * *

Other things being equal, a grinding machine of massive construction can successfully use softer wheels and run at lower speeds than grinding machines of a lighter type. The greater mass of the heavy machine reduces the amplitude of the vibrations and makes the soft wheel work efficiently where a harder wheel would be required on the lighter machine. Lower wheel speeds, of course, means less power and less wear and tear of both the machine and the wheel.

THE CONVERSION OF COMPOUND ENGINEERING UNITS

By JULIAN C. SMALLWOOD

The purpose of this article is to present a simple method by which may be found such metric-English equivalents as are not ordinarily tabulated in hand-books and by the use of which one may conveniently translate the more commonly used compound units. The method may also be used for the conversion of constants in empirical formulas, so that, if given in the metric system, they may be made applicable to English units.

Briefly, this method consists in first writing the units involved in the quantity to be converted exactly as they appear in it, and then canceling them as common factors in the terms of a fraction are canceled. The units that remain are fundamental ones of the system to be translated, whose equivalents may easily be remembered. If these equivalents are substituted in the canceled form, a number results by which the given quantity is multiplied to effect the conversion.

In mechanical and thermodynamic quantities, the fundamental units are those of length, mass, temperature, and time. All compound units of measure in mechanics and thermodynamics are combinations of these. As the unit of mass is but little used in the English system, we may consider, instead, weight which is directly proportional to it. The following are the familiar equivalents of these fundamental units:

Length:	1 centimeter = 0.3937 in.	1 in. = 2.54 centimeter.
Weight:	1 kilogram = 2.205 lb.	1 lb. = 0.4536 kilogram.
Temp.:	1 deg. C. = 1.8 deg. F.	1 deg. F. = 0.556 deg. C.

The data given in either column of this table are all that are necessary to make any conversion. Suppose, as a simple example, that we wish to find the English equivalent of the modulus of elasticity having the metric value of 700,000. This quantity, in English, may be defined as the pressure per square inch divided by its elongation per unit length. Its units may be written:

$$\frac{\text{Pressure per square inch}}{\text{Elongation per inch}} = \frac{\dfrac{\text{pounds}}{\text{inches}^2}}{\dfrac{\text{inches}}{\text{inches}}} = \frac{\text{pounds}}{\text{inches}^2}$$

That is, the units of the quantity "elongation per unit length" cancel each other. Similarly, the French units of the modulus are kilograms per square centimeter.

Substituting in the expression

$$\text{Modulus} = 700{,}000\,\frac{\text{kilograms}}{\text{centimeters}^2}$$

the English equivalents of the kilogram and centimeter, we have

$$\text{Modulus} = 700{,}000 \times \frac{2.205\ \text{pounds}}{0.3937^2\ \text{inches}^2}$$

$$= 10{,}000{,}000\ \text{pounds per square inch, approx.}$$

Let us take as a more obscure quantity, the mechanical equivalent of heat—in English, 778. This is the number of foot-pounds of work equivalent to 1 B. T. U., or, to make the arrangement of the units clearer, foot-pounds of work per B. T. U. It is desired to find how many kilogram-meters there are to a calorie; the calorie being the amount of heat necessary to raise the temperature of one kilogram of water one degree C. As heat is measured by multiplying weight by temperature, the units of the mechanical equivalent of heat may be written:

$$\frac{\text{Units of work}}{\text{Units of heat}} = \frac{\text{feet} \times \text{pounds}}{\text{pounds} \times \text{degrees F.}} = \frac{12 \times \text{inches}}{\text{degrees F.}}$$

The metric value sought may now be obtained by substituting the equivalents of inches and degrees as follows:

$$778 \times \frac{12 \times \text{inches}}{\text{degrees F.}} = \frac{778 \times 12 \times 2.54\ \text{centimeters}}{0.556\ \text{degrees C.} \times 100} = 427$$

meters per degree C. or kilogram-meters per calorie.

* Address: Chadwick, N. J.

This is then the metric value for the mechanical equivalent of heat.

If the units of a quantity to be converted are not readily recognized, they may in some cases be determined by examining those of an identical one. For example, consider the quantity denoted by the symbol R in the equation for perfect gases

$$PV = RT.$$

In this equation P is pressure in pounds per square foot; V is the volume of one pound; and T, temperature. It may be written, to show the units of R, as follows:

$$R = PV \times \frac{1}{T} = \frac{\text{pounds}}{\text{feet}^2} \times \frac{\text{feet}^3}{\text{pounds}} \times \frac{1}{\text{degrees F.}} = \frac{\text{feet}}{\text{degrees F.}}$$

For air, $R = 53.4$, and the metric value is found as follows:

$$53.4 \times \frac{12 \times \text{inches}}{\text{degrees F.}} = 53.4 \times \frac{12 \times 2.54}{0.556 \times 100} = 29.3.$$

The factor 100 is used to change centimeters to meters.

It is in a similar manner that the constants of empirical formulas may be converted. For example, Francis' formula for suppressed weirs is, in English,

$$Q = 3.33\,B\,\sqrt{H^3},$$

in which Q is the discharge in cubic feet per second; B, the breadth of, and H the head on, the weir in feet. The metric coefficient may be ascertained thus:

Units of 3.33 =

$$\text{Units of } \frac{Q}{B\,\sqrt{H^3}} = \frac{\text{feet}^3\text{ per second}}{\text{feet} \times \sqrt{\text{feet}^3}} = \frac{\sqrt{\text{feet}}}{\text{seconds}}$$

Hence, by multiplying 3.33 by $\sqrt{12 \times 0.0254}$, the metric value, 1.84, of this coefficient is obtained.

Even if the empirical equation to be translated contains more than two compounded quantities, the conversion is in no way complicated. As an illustration, consider the metric relation

$$PV = 47.1\,T - 0.016\,P$$

in which P is the pressure of steam in kilograms per square meter; V, its specific volume in cubic meters per kilogram; and T, temperature, in centigrades. The units of the quantity $47.1\,T$ must be of the same kind as those of PV and of $0.016\,P$, for, if they were not, the quantities could not be added or subtracted as indicated. We, therefore, know that the units of the coefficient, 47.1, are the same as those of $\frac{PV}{T}$, or units of 47.1 =

$$\frac{\text{kilograms}}{\text{meters}^2} \times \frac{\text{meters}^3}{\text{kilograms}} \times \frac{1}{\text{degrees C.}} = \frac{\text{meters}}{\text{degrees C.}}$$

To find the value of the coefficient of T in an English equation using pounds, feet, and degrees F., it is, therefore, necessary to multiply 47.1 by $\frac{39.37}{12} \times \frac{1}{1.8}$; the value 85.85 is thus obtained. Similarly, the units of the coefficient of P are cubic meters per kilogram and its English value is 0.256.

There are some quantities that are misleading in regard to their units. For example, one might consider that the heat of vaporization, heat of the liquid, etc., as given in steam tables are expressed in heat units only. If it is remembered, however, that such a quantity is the number of heat *units to one pound of the material*, or heat units per pound, it will be seen that the unit of temperature is the only one to be considered in making a conversion; that is, the unit of weight in the denominator cancels that in the numerator. If, then, we multiply such a metric quantity by 1.8, the corresponding quantity in an English table will be obtained.

The foregoing examples should enable the reader to apply this method to any metric-English conversion. It is only necessary to add a word of caution that, in using it, *all* the units involved should be put down exactly as they appear in the expression to be converted.

"The eye of the master will do more than both his hands."—*Poor Richard's Almanack.*

THE EXPERIENCES OF A YOUNG TOOLMAKER*

By T COVEY

"Jim," said Mr. Corbin, "I want you to help George for a few days. He is building a special tool for putting slots in a taper hole, and will need considerable help. There is also some of the work that you can do."

"All right, sir," said Jim, and he hunted up George and told him that he was to help him on the job.

"Well, said George, "this is quite a big job, and I guess I will let you rough out this operating bar for me. Here is the blueprint of it. You will notice that there is a one-inch hole clear through it. I want you to turn it off, leaving about one-sixteenth inch on it so as to give us a chance to turn it up straight after the hole is bored, and bore the hole.

"The first thing will be to center it and turn some spots for the steadyrest. I think the best way to center it will be to roughly center one end with a breast drill, then put it in that lathe with the long bed, catch the uncentered end in the chuck and let the other end run on the center. True up the end in the chuck, and turn a spot a couple of inches long close up to the chuck; then turn the bar around and let this spot run in the rest with the other end running true in the chuck; then you can face the end off and center it. Then turn a spot next to the chuck again and turn the bar around, face the end off to length, which will probably take out the old center, and recenter it. It will be well to note if there are any bends in the bar and if so favor them when centering it, but don't try to spring the bar straight. When you get it centered I will show you how to start turning it."

Jim took the blueprint (see Fig. 1) and the stock to his vise and before starting work on it measured the piece of stock. He noticed that there was over one-half inch of stock to come off the diameter. Going over to George, he said: "George, there is over one-half inch of stock on that bar. Why didn't they give us a smaller piece? I think that a piece of 2-inch cold-rolled stock would have made that nicely; then we would not have needed to center it or turn it at all."

"That piece of stock is all right," said George. "It is low-grade annealed tool steel, and when you get it turned, if you have been careful, there will be no strains in it and it will be straight. If it were cold-rolled it would be in the form of an S or a rainbow when you got the hole bored to say nothing of the slots that are to be cut in it. This bar has got to be straight when done or it will be of no use, and as it will then be only a shell it should be of stronger material than cold-rolled machinery steel."

"Why is cold-rolled steel more liable to spring than forged steel or common rolled stock?"

"Well, that is not a hard question to answer. I suppose that the difference is due to the process followed in the manufacture. On bars that are well heated during the rolling or forging the kneading effect of the operations penetrates more deeply, and therefore such severe strains are not given to the metal; and if the bars are afterward annealed such strains as there may be are mostly eliminated. With cold rolling, however, the action necessary to bring the bars to the required shape takes place mostly on the outer surface, and the high places are of course rolled more, or receive more pressure than the low ones, and for this reason, as cold rolling certainly sets up strains in the metal, the effect of the process is to produce an unstable product, the removal of any part of which is liable to affect the remainder. This is proven in practice, as it is well known that scarcely any two pieces of cold-rolled steel act the same under machining operations."

"I don't know much about the stuff, and only suggested it because I thought that it would be much easier to make the bar of it," said Jim as he went back to center the piece, which he soon finished.

"Now," said George, "take off the chuck and put on the driver; put a dog on the bar and place it between centers, then put the steadyrest on as close up to the headstock as you can, so that it will not interfere with the dog; back the jaws of the rest away so that the bar can revolve without touching them, then turn a spot eight or ten inches away from the end that has the dog on it and be very careful to get the spot true and round, because if there is any error in the first spot it will not only appear in the next but will be increased. Bring up the steadyrest, close the jaws down on the spot carefully and fasten them, clamping the steadyrest fast to the bed of the lathe; now if the bar is stiff enough, turn a spot a little to one side of the center toward the headstock end. If the bar chatters too much, you will have to turn one about half way between this place and the spot that is running in the rest; then move the rest to that and turn the spot near the center and move the rest to that. You can then go ahead and take a heavy cut from half the bar, removing about two-thirds of

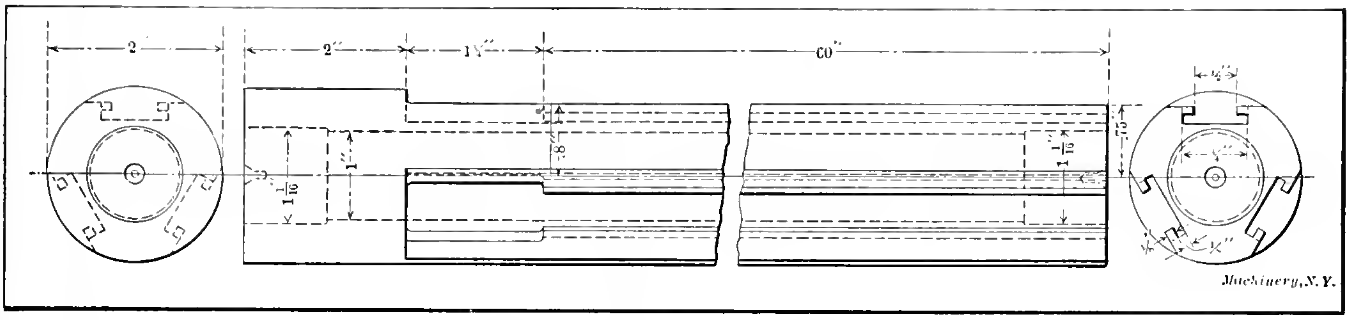

Fig. 1. Operating Bar for Taper Slotting Tool

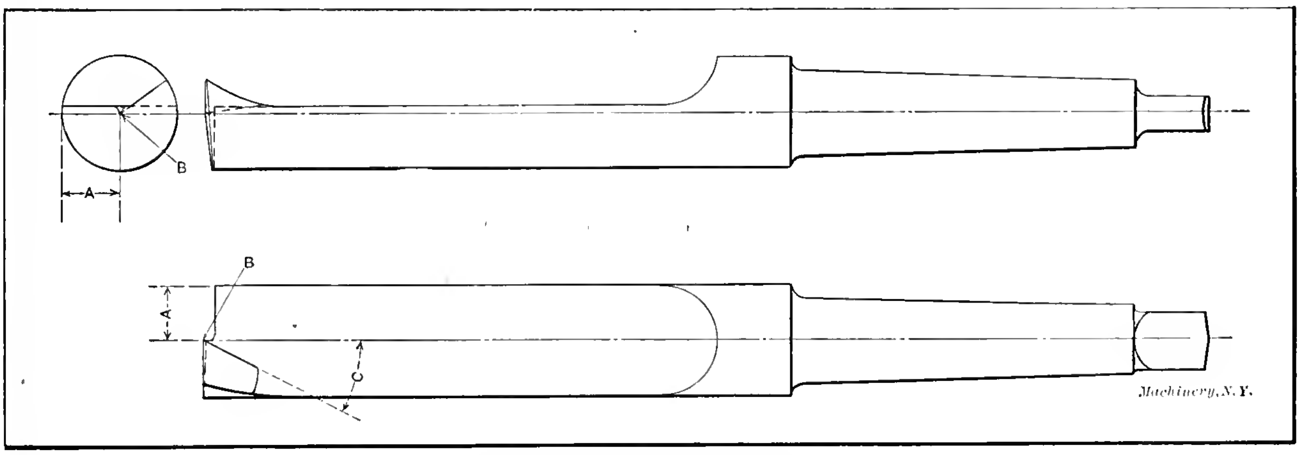

Fig. 2. Hognose Drill of Approved Form

* For previous installments of this series of articles, see "Experiences of a Young Toolmaker," with accompanying references, June, 1910.

the stock; then turn a smooth spot about four or five inches from where the cut stops, turn the bar around and rough off the other end, letting the spot last turned run in the rest. Now if you back the jaws of the rest away and start the lathe you will probably find that the bar is crooked, but as most of the strains have been removed with the outer surface the chances are that if you repeat the spotting process, beginning at the headstock end as before, and take another cut over the bar, you will then find it comparatively straight."

Jim went ahead and in the course of the day had the bar turned up, leaving about a sixteenth inch of stock on it to finish. Then he called George to look it over and tell him what to do next. George backed the steadyrest jaws away, and, revolving the bar rapidly, he found that it was pretty straight and told Jim he had done a good job so far.

"The next thing," said George, "is to get that hole in it. It is only put there to lighten the bar so it does not have to be so very accurate; still it must be straight enough to leave the walls fairly equal. I think that if we bore from both ends we will get it good enough. I am quite sure that there is a 7/8 extension shank about three feet long for drills with No. 2 Morse shanks in the toolroom, but if there is not we will have to make one. See if you can get one, and also a 3/4-inch twist drill and a 1-inch hognose drill."

Jim found that there was an extension and brought it with the drills to the lathe. George looked them over and said: "We had best drive each drill into the socket and drill and ream a small hole through the socket and the shank of each drill so that we can pin it fast in the socket while we are using it, for if we should get one of the drills stuck down in the hole we might have quite a bit of trouble in getting it out; there is not much danger if the drills are kept sharp but it is best not to take any chances. Now find a piece of steel about 1 1/8-inch diameter by about 3 inches long, catch one end of it in the lathe chuck and bore it out 3/4 inch diameter for about an inch, turn it for the same distance to a diameter of about two or three thousandths less than one inch, and cut it off with a parting tool, thus making a collar one inch in diameter and one inch long with a 3/4-inch hole."

Jim soon got the collar made and George told him to put one end of the bar in the chuck and run the other in the steadyrest, and to be very careful to have the end in the chuck running true and the steadyrest set up so as to bring the bar in line with the tailstock center, for on this depends the accuracy of the hole to a certain extent. "Let me look at it before you start boring," said George.

In a short time Jim had the bar chucked up and called George to look at it. George tried the chuck end and found it true, then he cleaned out the center in the other end put a little prussian blue on the center in the tailstock and carefully ran it into the center in the bar; then he backed it out looked at it and said: "It is just a little low but pretty good"; he raised it a little, tried it again and then told Jim to go ahead and put the twist drill in to about the depth of the flutes. Jim did this and then went to George and said: "I don't see how we can get that 3/4-inch drill through the bar with that 7/8 extension on it."

"That is easy," said George. "Drill in as far as you have gone with the twist drill with the hognose, then you can put the 3/4-drill in again and go four or five inches more, etc. Now to start a hognose drill properly you have to do one of two things—either start it through a bushing or bore the hole out for a short distance just the size of the drill. You can't use a bushing in this case, so you will have to bore the hole out for an inch or so with a boring tool. Be very careful to have the hole just the size of the drill for if it is either large or small the drill will not work good.

"A hognose drill to work right must be kept in good condition, and not be allowed to get dull or out of shape. It is a very easy matter to spoil one in grinding. The main thing to be careful of is not to grind away the center. That portion of the drill marked *A*, Fig. 2, should be ground back about three-thirty-seconds inch on this size of drill, and the wheel used should have a rounded corner. The lip is ground with a wheel having a rather square corner, and the edge of the lip leads away from the center at about the angle *C*. This is done so that sharpening the drill on the end will allow the center of the drill to come within the metal; then using a depth gage with the scale set to just half the diameter of the drill, grind the portion *A* and the lip of the drill so that the point *B* comes just in the center of the drill. The center is found by holding the depth gage against the sides of the drill with the end of the scale that is set to half the diameter pointing towards the center. You will notice that that portion of the drill cut away in making it is a little less than half of the drill; that is, it is not cut down to the center line; this shape combined with the radius at the center edge of the portion *A*, and the angle of the edge of the lip *C*, enables a new center to be obtained by grinding off the end. The inner end of the cutting edge *B* must be in the center because if it is too short or too low the drill would leave a core when drilling in solid metal, and if too long or too high would have no clearance at the center. It is best to have the cutting edge a very little short or low than long or high, as it is theoretically impossible to give the cutting edge of a hognose drill clearance at the center, but in practice they work very good with the inner end of the cutting edge central."

"Now each time that you follow up the twist drill with the hognose run the hognose in far enough to remove all the center left by the point of the twist drill, and then to start the twist drill central again clean out the hole either with the air blast, or with a piece of waste fastened to the end of a small rod, slip the collar you made down into the bottom of the hole using a rod to push it down into place. This collar will act as a bushing to steady the twist drill in starting. When you have the drill started you can pull it out with a rod that has a small hook bent on the end of it. In this manner you can prevent the twist drill from running off center, as it cannot run very far in five or six inches and the bushing will restart it central."

"How can I tell when I have run the hognose drill in far enough to take out all of the hole made by the twist drill?" asked Jim.

"You can see for the first time or so, or at any time with the aid of a small mirror; after the first time you will probably be able to tell from the way the drill feeds whether it is cutting in solid metal or not."

"If the hognose drill will cut to center, as you say it will if ground right, why use the twist drill at all?"

"This extension might not be strong enough to carry the full cut; and then the hognose working under the strain of a full cut would bear against the side opposite the cutting edge so hard that there would be great danger of the drill "picking up" and starting to cut or score, which would spoil the drill and make a bad hole. If you could keep the drill well flooded with oil you might do it, but I would not risk it. Keep plenty of oil in the hole anyway; get one of those squirt-guns out of the toolroom and use it often. Put a pan under the lathe where it will catch the oil and keep it off the floor; you can also fill the squirt-gun from it. Clean the chips out of the hole often, and don't allow them to pack tight at any time. If you are careful otherwise I think when you have the hole completed you will be unable to see where the holes meet in the center."

Jim found it a rather tedious job but in the course of a couple of days had the hole bored through. Taking the bar out of the lathe and looking through the hole, he found, as George had said, that he was unable to tell where the two cuts came together. He had George look at it and George said that it looked fine and told him to get a one-inch plug sizer; they tried it in the hole and found that it was an easy fit with no shape. George pushed it in as far as he could with his fingers and then taking a piece of cold-rolled stock that was lying near pushed the plug clear through the hole, finding a spot in the center where it was tight but still it would go through.

"Well, Jim," said he, "you have learned how to bore a long, straight hole. If you ever have a similar job to do again pin your faith to a hognose drill. It will do a good job if it is well ground and treated right. Now put the bar back in the lathe, bore out the ends to 1 1/16 inch and plug them up; then set up the bar and center again, which will be about all you can do with it."

MACHINE SHOP PRACTICE*

KEY FITTING

The proper method of fitting a key in its seat depends somewhat on the type of key used, which is governed largely by the class of work for which it is intended. In Fig. 1 several methods of securing a shaft and hub against relative rotary movements by the use of keys are indicated. The style illustrated at *A* is known as a "saddle key." This type, which is shown in perspective at *A*, Fig. 2, has parallel sides and is curved on its under side to fit the shaft. It is slightly tapered on top so that when it is driven tightly in place, the shaft is held by frictional resistance. This key should be fitted so that it bears lightly on the sides and heavily between the shaft and hub throughout its entire length. As the drive with this type of key is not positive, it is only used where there is little power to transmit. Of course, it is an inexpensive method of keying, as the shaft does not need to be machined.

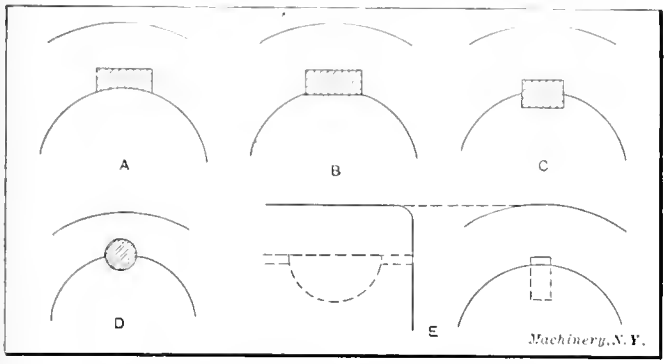

Fig. 1. Various Methods of Keying Shafts and Hubs

The "flat key" shown at *B* differs from the saddle key in that it bears against a flat surface on the shaft, which gives it a fairly good grip. This type is not adapted to heavy work, however, owing to the excessive strains to which the hub is subjected, as the shaft tends to turn. The method of fitting is practically the same as for the saddle key, there being a comparatively light bearing at the sides and a heavy bearing at the top and bottom. The "sunk key" shown at *C*, as its name implies, is sunk into the shaft, and it is more satisfactory than either of the other types referred to, as it gives a stronger and more positive drive. With this type of key, care should be taken to secure a good bearing on the sides. Ordinarily the bearing at the top and bottom of a sunk key should be comparatively light, though in some cases when it is used to resist endwise movement, as well as a rotary movement, it is given a heavy bearing on all sides. The principal bearing, however, should not be, in any case, at the top and bottom, as it is then more likely to work loose than when fitted tightly at the sides.

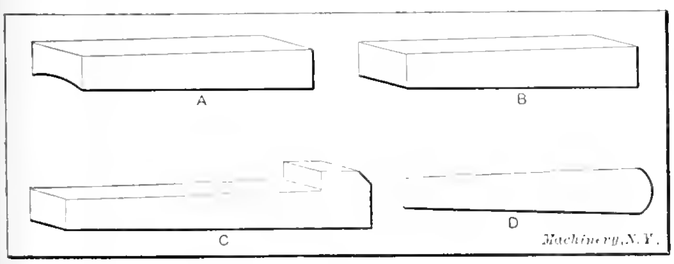

Fig. 2. Different Types of Keys

Keys are usually milled or planed slightly larger than their keyseats, so that they may be accurately fitted by filing. After a key has been reduced sufficiently to allow it to enter the keyseat, it is driven in as far as it will go by tapping lightly; it is then removed and the bearing marks filed away. This operation is repeated until the key can be driven home.

When a key is so located that it can be removed by driving against the inner end with a punch, the headless type shown at *B*, Fig. 2, is generally used. Very often, however, it is impossible to drive against the inner end; in that case the style of key illustrated at *C* is preferable, as the head enables it to be withdrawn when fitting or disassembling, by the use of a wedge or lever. The style of punch shown in Fig. 3 will be found excellent for driving out headless keys. Before driving a key into its seat, it should be oiled to facilitate its removal. It is also a good plan before driving a key in for the purpose of testing its bearing, to round the corners so that they will not interfere by bearing heavily on small fillets which may have been left in the keyseats. By covering the keyseat with a thin coat of black or red lead, the bearing can be more easily seen.

As the accuracy with which a sunk key can be fitted depends largely on the relative positions and sizes of the keyseats in the shaft and hub, it is, of course, essential that the keyseating be carefully done. Each keyway, in addition to being of the same width, should be in line with the axis of the shaft or bore and the sides should be parallel with a radial line passing through the keyway center. Obviously, when the keyseats of both shaft and hub are cut in this way, the sides, when the two are brought together, will line up both across and lengthwise of the shaft, making it possible to give the key a good bearing.

The Woodruff key, which is much used in machine tool construction, is in the form of a half-disk as shown at *E*, Fig. 1. The circular side of this key is seated in a slot which is milled to the same radius in the shaft, thus making it necessary to assemble both shaft and hub with the key in place. Little hand-fitting is necessary with this type of key. The bearing should be on the sides, and the top should be filed until it has a light bearing as with the sunk, rectangular key.

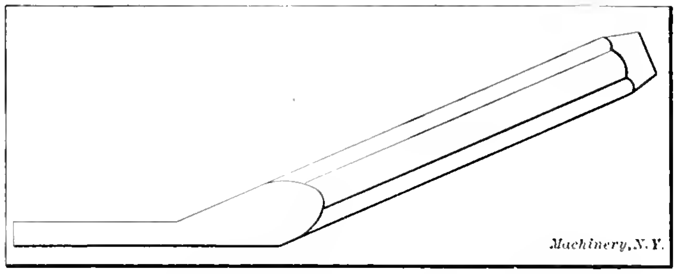

Fig. 3. Punch for Backing Out Headless Keys

Taper pins, similar to the one shown at *D* in Fig. 2, are sometimes used as keys for attaching handwheels to their shafts, and for other similar light work which requires an inexpensive method. The hole for the key is drilled partly in the shaft and partly in the hub, as shown at *D* in Fig. 1, so that the pin, when in place, resists any relative movement between the two. After a straight hole has been drilled, the pin is fitted by reaming the hole with a taper reamer.

THE PERILS OF AVIATION

Navigating the air is a glorious but dangerous sport. The New York *World* has compiled a list of twelve aviators killed within the past two years, as follows:

1908

September 17—Lieut. Thomas E. Selfridge, U. S. A., fell with Orville Wright at Fort Myer, near Washington, D. C.

1909

September 7—E. Lefebvre fell in Wright machine at Juvisy-sur-Orge, France.

September 7—Ena Rossi killed in Rome in machine of his own invention.

September 22—Capt. Louis F. Ferber fell at Boulogne, France.

December 6—Antonio Fernandez fell 1000 feet at Nice, France, after motor exploded.

1910

January 4—Leon Delagrange fell at Bordeaux, France.

April 2—Herbert Le Blon instantly killed, falling on rocks at San Sebastian, Spain.

May 13—Chauvette Michelin fell at Lyons, France.

June 17—Eugene Speyer fell at San Francisco.

June 18—Robl fell at Stettin, Germany.

July 3—Charles Wachter fell at Rheims, France, in Antoinette monoplane after its wire stays broke.

July 12—Charles Stewart Rolls fell at Bournemouth, England, in French-built Wright machine after the forward directing plane broke under strain of too rapid descent.

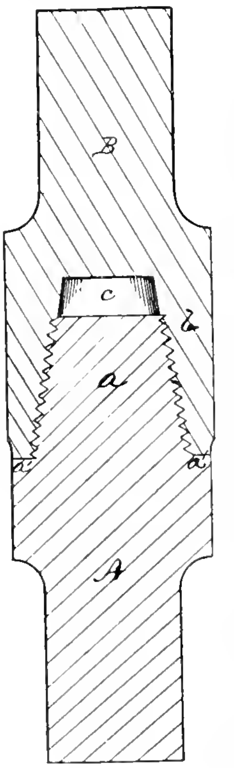
MACHINE WORK IN THE OIL COUNTRY—MAKING "JOINTS"

By V. J. M.

In the last fifty years a great many changes and improvements have been made in the method of drilling wells for oil, gas or water, and a comparison of the tools used by Col. Drake (who drilled the first well for oil in 1859 at Pit Hole, near Titusville, Pa.) with a modern outfit would cause one to think that Col. Drake surely had the right variety of "sand" to tackle such a job and bring it to a successful consummation.

Since that time the search for the green, brown or black fluid has spread to almost every civilized country on the globe. Several different methods of drilling are in use at present, but what is known as the cable system is the most common. In this system manila rope was used exclusively, but wire rope has recently been found useful for sand lines, although, as yet, it has not proved very successful for drilling. One of the prime reasons for this no doubt lies in the fact that the wire lacks the necessary spring or stretch as well as flexibility.

A common "string" of drilling tools consists of the various sizes of drills or bits, the auger stem, jars and rope socket.



To all whom it may concern:

Be it known that I, JOHN LYON ALEXANDER, of Edenburg, in the county of Clarion and State of Pennsylvania, have invented a new and useful Improvement in Joints for Oil-Well Tools, &c.; and I do hereby declare the following to be a full, clear, and exact description thereof, reference being given to the accompanying drawing, forming part of this specification, and which is a longitudinal central section of a joint embodying my invention.

My invention relates to the construction of joints for oil-well tools; and consists in tapering the pin and interior of the box, and also tapering the threaded pin, so that their strength is greatly augmented at and near the shoulders, where they are subjected to the greatest strain, and are most liable to break.

Heretofore, in the construction of joints for oil-well tools, sucker-rods, &c., it has been common to form an internally-threaded socket or box of even bore (or interior diameter) throughout, and whose thickness was about one-fourth the diameter of the joint, so that the whole amount of metal was about equally divided between the box and pin.

When in use, the greatest strain occurs either at the top or shoulder of the box, or at the shoulder of the pin, and the joint frequently breaks either at one point or the other, causing much trouble and delay.

It is at once apparent that the strength of the ordinary joint is only equal to the strength of the pin or of a rod one-half the diameter of said joint, and thus in such connections the points where the greatest strains occur are in reality the least able to resist them. It is not possible to overcome this difficulty by increasing the thickness of the box and pin, for such a procedure would increase the diameter of the joint beyond what it is practicable to use in an oil or similar well.

In order that others skilled in the art to which it appertains may apply my invention, I will proceed to describe the construction of joint whereby I overcome the existing difficulties and objections.

A and B indicate the two sections of a joint with threaded pin *a* and socket or box *b*. The pin *a*, at its base, is slightly less in diameter than the whole diameter of the joint, and tapers thence to its extremity, which may be half the diameter of the joint, or less, if desired, or, in other words, is a frustum of a cone whose base is slightly less than a cross section of the joint.

The difference between the diameter of the pin at its base and the whole diameter of the joint is due to a slight shoulder, *a'*, against which the socket *b* abuts.

b is the socket or box section, having the tapered cavity *c*, corresponding to the form of pin *a*, so that the thickness of the box or socket increases steadily from its extremity toward the shoulder, and at the shoulder it is almost solid, whereby great strength is gained.

The pin *a* and box *b* are threaded, as before specified.

In connecting the parts much time is saved and less labor required, as the pin passes about half way into the box or socket before the threads engage, and the parts being centered, there is no difficulty or delay in causing the threads to engage properly.

The diameters of the pin and box at the shoulders being equal, or about equal, to the whole diameter of the joint, great strength is obtained; and if, from leverage or other cause, the upper part of pin *a* should be broken in the socket or box, the parts would not separate unless the force were sufficient to break the box also, which is very unlikely to occur, as the box at that point would be very thick.

Additional advantages of my devices are, that they can be screwed up or set much tighter than any other joint known to me, and this without danger of breaking. Longer and heavier wrenches may be used to tighten the parts, and the parts are more readily handled and connected.

I am aware that tapering sectional joints have heretofore been made, and do not claim the same, as such construction is directed sim-

Fig 1. Specification of Alexander Patent No. 201,082 for Improved Joint for Oil-well Drills

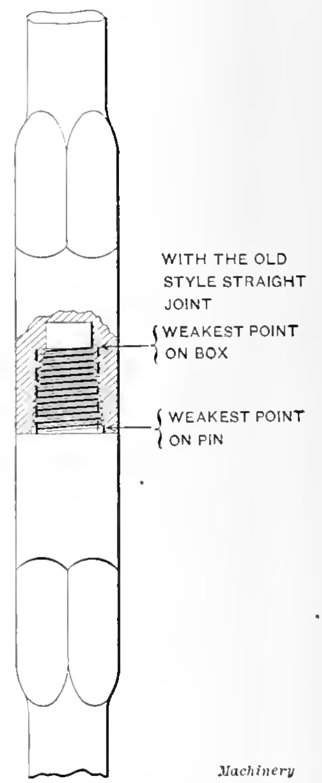


Fig. 2. Alexander's Taper Joint and the Straight Joint Compared

These separate parts are well connected by threaded joints for convenience in handling, and as the bits wear out of gage they are taken off, heated, dressed and hardened. This operation occurs quite often, the frequency with which

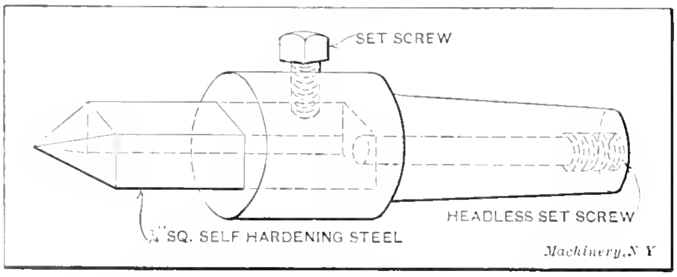

Fig 3 Square Center used in Tailstock of Lathe for Center Work

the bits require dressing depending largely upon the character of the rock being drilled. Formerly the joints were made with a straight screw thread, but the taper joint has come into extensive use and the straight screw joints have been almost entirely discarded. It was in 1878 that patent No. 201-082 (see Fig 1) was issued to John L. Alexander of Edenburg, Pa., for a taper joint for oil well tools. The model for his invention was made by James Sheridan of Franklin, Pa. It may be of interest to machinists who are working on this class of work to know that these first taper joints were made without a lathe taper attachment, the tools being fed in and out by hand.

The principal advantages of the taper over the straight

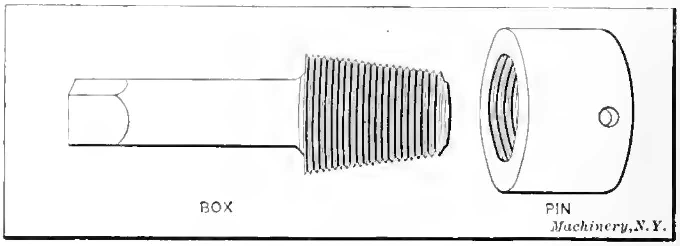

Fig. 4. Box and Pin Templets

joint are as follows: 1. Reinforcement or added strength at the weakest points (see Fig. 2). 2. Convenience in putting together as well as time saved in so doing. With the old style straight joints it was quite difficult to enter or start the thread, while with the taper joints it is a "cinch." From four to five turns are all that is required to bring the threads fully into mesh. 3. Renewal is made possible by facing back on the collars, taking the same amount off the end of the pin and re-threading. In the old style straight "joints" when the threads became worn or stripped the only way possible to renew them was to heat the box and swage. This practice had the disadvantage that the box, if worn much, would be too small in diameter after swaging. The pin had to be heated and upset in order to give enough stock. This often caused a cold-shut at the base, and the least sign of cross fracture condemns the piece unless the crack can be entirely removed in turning.

The material used in box and pin forgings is either soft steel of about twenty-six points carbon or faggoted iron, iron being preferred for the joints on the auger stem, because it withstands the jar and vibration better than steel. The box on an auger stem gets more use and abuse than the pin on the bit, especially as there is always one bit held in reserve, and all the different sized bits are used in the same box. The weight of the stem as well as the force of the blow comes upon the faces or shoulder at every stroke, and soft steel joints, especially on the lower end of the stem, upset too easily and in

consequence cause many "fishing" jobs. But for all the upper joints, such as the jar box and pin and those on the rope socket, soft steel cannot be surpassed, either in price, ease of machining or strength. The iron mostly used is old car axles, doubled over, piled up to get the proper amount, thoroughly welded and forged.

In making the forgings for boxes and pins, the blacksmith is never very particular as to size, excepting about 6 inches of the shank which is forged square to fit the standard size of wrenches. Plenty of stock is left on the collars.

When starting to machine the pin, the joint turner selects a forging with the proper sized square, say 3½ inches, puts a trial center in the pin end and grips the shank end with the chuck; then, by chipping, square centering (see Fig. 3) and

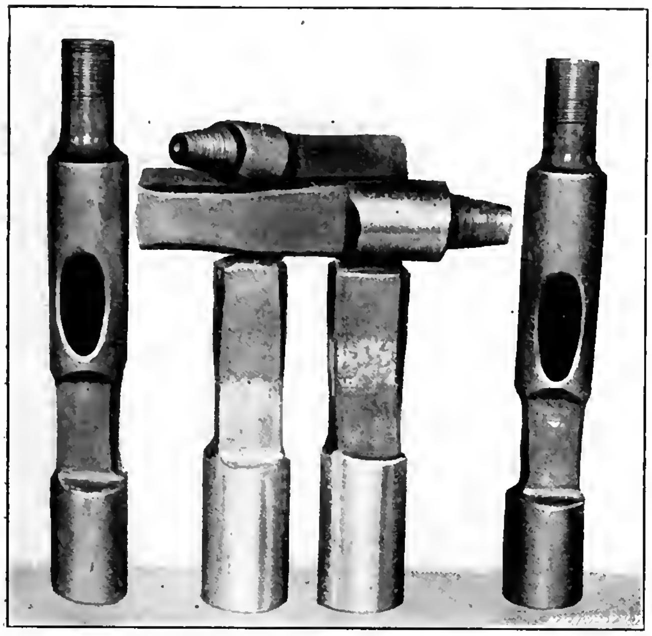

Fig. 5. Box, Pins and Rope Sockets

shifting in the chuck, he makes it run true with the wrench squares. Next the collar is turned to size by one roughing cut followed by a scrape with a broad-nosed tool, producing what is known in the oil country as the "Pittsburg finish." The collars are all made to some standard size, depending on the diameter of the hole to be drilled. Care in this respect is necessary so that in case a joint unscrews or for any other reason a part is lost in the well, the proper "fishing" tool may be "run" to remove it. The careful driller always keeps a record of the size of each joint and tool that goes into the well—and the writer has heard of some drillers who go so far as to bid the tools good-by each time they are lowered for fear they may never see them again.

The next operation is to rough down the pin nearly to size at the large end and square up the shoulder to give the pin the proper length, say 4 inches. A broad square-nosed tool is then used to bring the pin to the proper size at the large

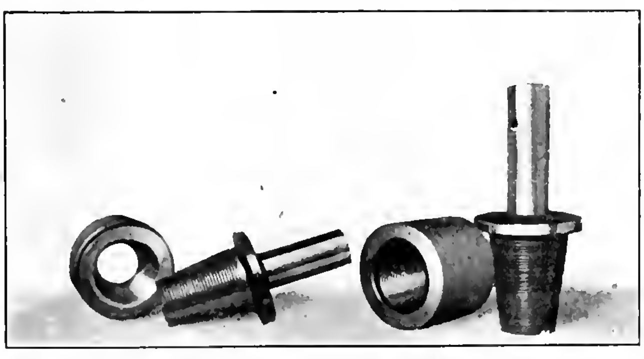

Fig. 6. Improved Templets with Collars on Pins

end, as this is the point where measurements are taken from. The taper attachment is then brought into use and the pin turned to the proper size for threading. Tapers vary from 3 to 3½ inches, and over, per foot, or from 7 to 10 degrees measured from the center line. The Gleason and Bridgeford lathes have the taper attachments graded according to a system of their own, the graduations corresponding to the taper per foot, in eighths of an inch. Thus 3 inches per foot is marked 24, which means 24/8, and 3 7/16 inches, per foot is marked 27½, which means $\frac{27\frac{1}{2}}{8}$. It is hardly necessary to say that in taper turning this, as well as any other kind, the

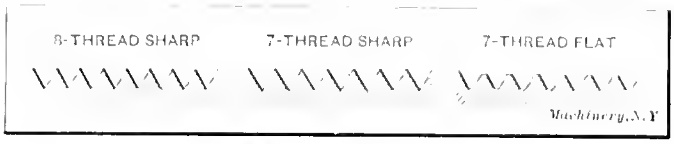

Fig. 7. Forms of Screw Thread Used on Oil-well Tools

point of the tool should be set level with the center line.

The thread is cut with a 60-degree angle, single-point tool. Many patent tool-holders work fairly well, but a solid tool forged from good high-speed steel gives the best results. The thread is cut as close up to the shoulder as possible in order that the box need not be counterbored more than ½ inch. It is good practice to use two threading tools, the first having its top face ground like a side tool, taking all the chips from the left-hand side, and being advanced for each cut by the compound rest set at 15 degrees; the second tool should be made with very little top rake and plenty of clearance on the bottom so that each side of the thread can be finished separately. There is a curious prejudice as to the lubricant for cutting threads on joints; while the drillers are not all Prohibitionists by any means, they all prefer their threads finished with a water cut. A superstition seems to prevail that lard

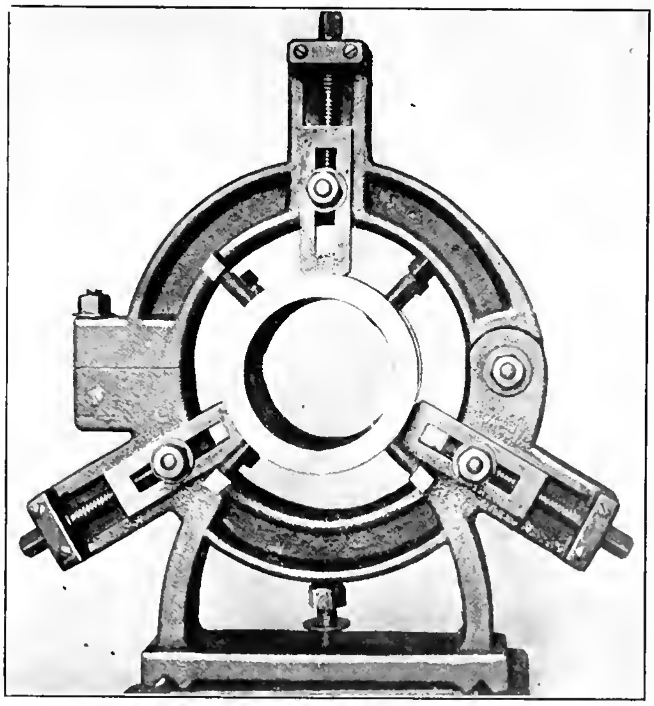

Fig. 8. Lathe Steadyrest with "Cat-head" or Revolving Ring

oil used when cutting the threads will make them unscrew unless burnt off.

After the thread has been finished, the gage or templet is screwed on, and the collar faced back to admit a finger or paddle gage between the two faces, thus bringing all the pins to the size of the gages. The gages (see Figs. 4 and 6) are made of iron or soft steel and need not be hardened. They are real boxes or pins, excepting that the boxes are shorter on the face end by ½, ⅝ or ¾ inch to suit the practice of any particular shop, and the pins have the collars cut back a like amount. When the pin templet is made without a collar it goes into the box flush and is tested by a straight-edge.

After the ring gage is removed from the pin a slight clearance or undercut is made in the collar next to the pin. This is done on the same principle that a carpenter, in laying flooring, undercuts his joints in order that they may fit closely

on the top, but the main reason is that when in use in the field the faces on the joint collars undergo a great deal of scouring to keep them clean, and by having this sharp corner removed it is easier to keep the faces level and thus avoid unscrewing.

The pin is now brought to length by paring off the small end with a side tool set at an angle of about 10 degrees, which completes the job with the exception of stamping the size on the collar. A stamp thus: 2¼ - 3¼ M 7 means 2¼ inches diameter at the small end, 3¼ inches diameter at the large

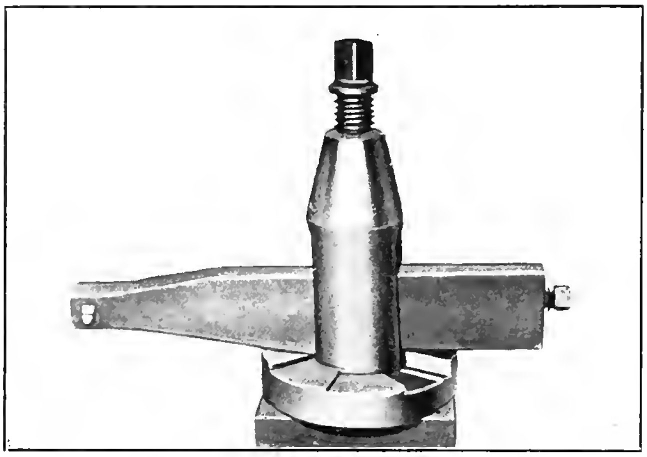

Fig. 9. Inside Thread Tool used for Drilling Boxes

end and 7 threads per inch. The M denotes this particular make, in this case known as the "Maloney." One hour is a fair average for the time taken to turn this pin. The pins on bits are turned in the same manner, excepting that a "cat-head" or a revolving ring in a steadyrest is used in centering, as the end of the pin can then be faced off and the center drilled and reamed. (See Fig. 8.) When the bits are made of tool steel throughout and the pins not perfectly annealed, this is a good method of getting a "loud" center—one that will hold up until the job is finished. If any one thing more than another tends to provoke an outburst of profanity it is to have a bit get tired of its small stingy center and go floating off into space when nearly completed.

The box is centered in the same manner as the pin and turned to size. The steadyrest is then placed near the middle of the round portion, the end faced off and a hole drilled the same size as the bottom of the threads on the small end of the pin and at least 1¼ inch deeper than the length of the pin. A very good tool for this purpose is a flat drill with the cutting edges lipped and the point ground heart-shaped. When made of high-speed steel this drill can be rapidly fed into iron or soft steel, making a 2¼-inch hole 6 inches deep, in 5 minutes. A set of jaws of hard brass for the steadyrest will last a year and will not mar the finished work. For boring the taper in the box, any good stiff tool will do, the size of hole being taken from a gage made to fit in on top of the threads in the ring templet. These are made of sheet steel 1/16 inch thick, with a scribe line, showing the depth to which it must enter when the box will be the proper size.

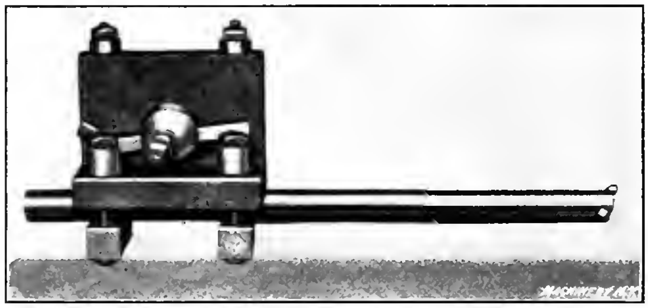

Fig. 10. Boring Tool used for Boring Taper Holes such as Tapers for Rope Knot in "Woodpecker" Sockets

For threading tools, one with an inserted cutter is best adapted for inside work; the cutters can be made of small square steel, no dressing being required. Care should be taken to have plenty of clearance so that the heel of the tool will not drag in the small end of the hole. The writer has used, for the last ten years, a tool made as shown in Fig. 9. The body is made of ⅞ × 2 inch annealed steel with a hole to fit ⅜-inch square steel; the top face is on the center line and ¼ inch

Fig. 11. Typical View of Work around "Joint Lathe" in Oil Country Shop

stock in front. A 13/32-inch hole is drilled from the back end to intersect the square hole and a piece of ⅜-inch drill rod put in for a plunger with a ½-inch set-screw behind it. This holder need not be loosened in the tool-post; simply slacken the set-screw to remove the cutter for sharpening. A boring tool for deeper holes is shown in Fig. 10.

When the thread in the box is finished, the chips are removed by spinning the lathe backwards and holding a stick of wood on top of the threads—which as the "cub" says "unscrews the chips." The gage is then screwed in and the box faced to size, care being taken to have the box bored large enough to let the plug gage enter far enough to leave stock on the face for this purpose. When the gage is taken out, the large end of the box is counterbored, removing three or four of the first threads. This is done because it is not

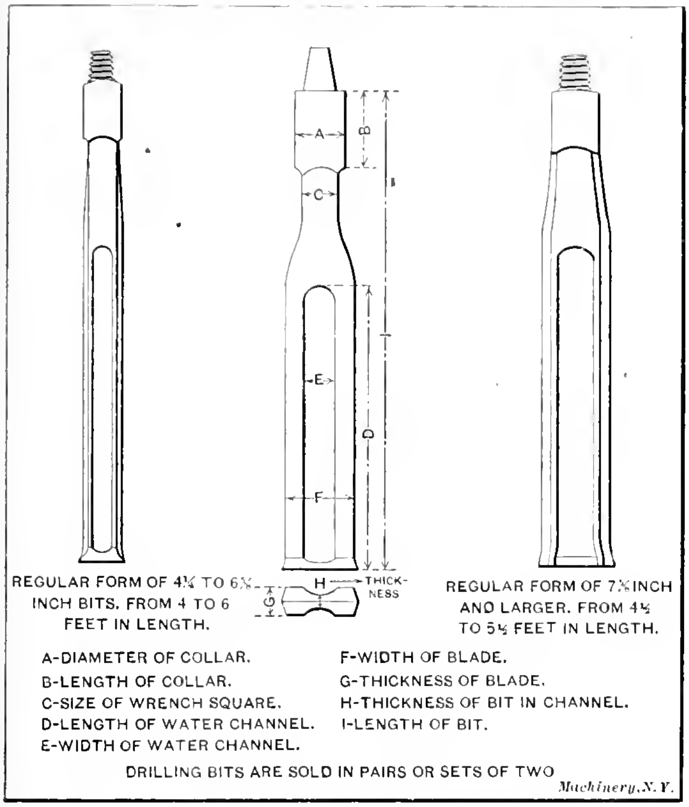

Fig. 12. Forms and Parts of Oil-well Drill Bits

possible to thread the pin clear into the collar. The corner of the box is chamfered off so that the face will correspond in size to that on the collar of the pin which fits it. After stamping, the box is complete, the time required being from 1½ to 2 hours. There is no allowance made for force fit; a good joint should have a slight shake just before shouldering, for, if made tight on the threads, when the shoulders become worn the threads get so tight that the pin is often twisted off.

* * *

VALUE OF ADVERTISING

The value of an advertisement in a trade journal or any other advertising medium, is determined *not* merely by the number of answers you receive, but by the number of actual sales resulting therefrom. There are third- and fourth-rate journals that can safely promise you hundreds or even thousands of answers to any advertisement that they may print—but what are the answers? They are on postal cards and scraps of paper, some of them so poorly written as to be absolutely undecipherable, all asking you for your catalogue and prices, but how often do such inquiries result in sales? On the other hand, an advertisement in the right kind of a trade journal may result in only ten answers, but they come in typewritten form, on firm's letterheads and are signed by someone with authority to buy and in eight cases out of ten who *does* buy, for the original inquiry was not prompted by mere boyish curiosity, but because the things advertised were needed.

It is the old, old question as to whether you prefer quantity or quality.

SOME KINKS FOR PUNCH AND DIE WORK*

By C. W. G

Before taking up the following suggestions for tool and die makers I would like to call the reader's attention to the fact that in order to acquire as much knowledge of his chosen craft as possible in the least time, he must read the journals devoted to his craft and especially those articles written by "the boys," who are actively engaged in the work. We may not find all articles literary gems, but the writer has yet to read a single article by one of "the boys" without adding some valuable information to his mental capacity or indexed notebook.

Just imagine the value each issue of MACHINERY is to both the young and the experienced toolmaker. How many years would the reader work at the trade before he found out by personal experience that this or that was the best way in which to successfully complete a particular job? On the other hand, let us follow a "roamer" or as they are called in the trade a "hobo" toolmaker. His restless disposition will not allow him to stay long in any one shop, but the few months of experience in each shop has given him the opportunity to grasp the valuable kinks, accurate methods, etc., that have taken men in that shop probably thirty years to discover. Say that this "roamer" lands in a toolroom that is devoted exclusively, and has been for the past forty years, to the most intricate class of die work, while he has just left a job where jigs were the specialty. In a few days he notices that the methods employed there are really valuable and that it never once entered his mind before that this or that clever scheme could be adopted. In a way he is a robber. Without spending more than a few days he is in possession of the valuable experience which it has taken other men a lifetime to collect. By means of a few rough sketches and an earnest attempt at a description his discovery, coupled with editorial touches, makes an article presentable from a literary point of view, and *the valuable idea* is sent broadcast. The following schemes and kinks, or whatever they may rightly be termed have been gathered here and there around the country by the writer, and while some of them are not new to all readers, it may be possible that some readers have not heard of them.

Proper Clearance Between Punch and Die

First we take up the clearance to be given the blanking die. It is a known fact that there is a happy medium where the fit of a punch and die governs their clean cutting. A loose fitting punch will cut absolutely free from burrs up to a certain point, but a little too loose or a little too tight results in ragged edges being left on the punchings. Experienced tool- and die-makers who have spent years in fitting punches can tell mentally just about how much to allow between the punch and die, providing, of course, that they have given them the thickness of the metal to be punched. But the young fellows do not care to wait until they are nearing the end of their usefulness before they are able to tell by personal experience. Therefore, the results obtained by the pioneers have been carefully recorded and information given for clean cutting on all thicknesses of stock. The general rule is to allow a clearance between the punch and die of 6 per cent of the thickness of the stock to be cut. For example, suppose that we desire to punch plain washers 0.040 inch thick. Then six per cent of that equals $0.040 \times 0.06 = 0.0024$ inch which would be the difference between the size of the punch and the die.

The above practice is in vogue in such reputable factories as the Burroughs Adding Machine Co., Detroit, Mich., and has been used by the writer with excellent results. There are many readers who are using this rule, but to those who know it now for the first time, I would advise that they make a mental note that this issue of MACHINERY has been the means of eliminating the worry on their next punch and die in regard to how much clearance to give. Of course, the temper of the stock to be punched enters somewhat into the above calculation, but not enough to make an appreciable difference.

Value of Annealing

Knocking around the country, the writer has noted that the majority of die- and tool-makers overlook the importance of

* For information previously published on punch and die work, see "Operation and Construction of the Sub-Press Die," MACHINERY, July, 1910, and articles there referred to.

first roughing the die nearly to size and then carefully annealing it. There are internal strains set up in the bar of steel during its manufacture which are sure to cause distortion of the die or tool unless these strains are removed before the work is brought to its finished size. Some steel may be found free from strains, but we have no way in which we can tell beforehand whether the steel has "settled" or not. Therefore, to guard against distortion, the careful toolmaker will not take chances, but will anneal the piece after it has been roughed out. Annealing allows the molecules, as it were, to twist and squirm, which seems to relieve these internal strains.

Some years ago the writer made the following test, which settled in his mind the value of annealing before finishing. Four pieces of tool steel were cut from the same bar and the same amount of stock was removed from each piece, finishing them all over to exactly the same dimensions. They were then marked *A*, *B*, *C*, and *D*. Pieces *A* and *B* were annealed after roughing, but *C* and *D* were machined to size. The pyrometer was used to insure heating all the pieces to the same degree, that is 1400 degrees F. The bath was clean water brought to a temperature of 68 degrees F. The pieces were heated individually in a muffle furnace and were allowed to remain in the bath exactly the same length of time (one minute). It should be remembered that it is poor practice, in fact disastrous, to allow dies, especially those having delicate parts, to become chilled in the the bath, as this results in unequal contraction which is the greatest cause of breakages. Leaving the pieces in the bath one minute enabled me to obtain a comparative test, as all conditions were parallel. The pieces *A* and *B* were slightly distorted, but the pieces *C* and *D* were distorted to such an extent that they were useless.

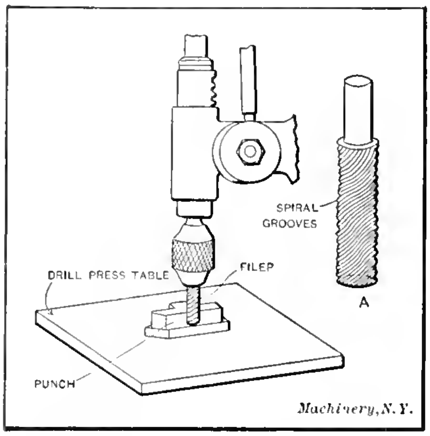

Fig. 1. Filing a Punch to the Finish Line

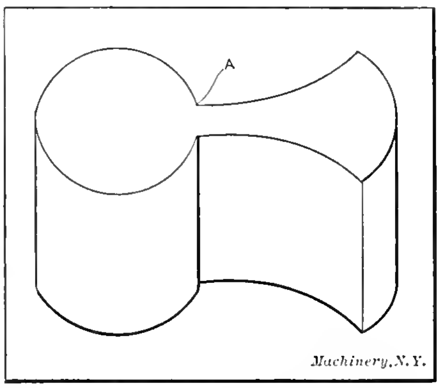

Fig. 2. Difficult Piece to harden without Cracking

How to Lay Out a Die

Another thing which the writer noted along this line, and some day expects to make a test to discover if possible just how much effect it has, is that the best results have always been obtained when long points were laid out lengthwise, that is in the same way in which the grain runs in the stock. It has been noted that dies having several long points which run lengthwise do not distort much in hardening, but that those which are laid off crosswise generally bend to a greater extent. We know in making flat springs that if we cut them out running lengthwise with the grain they will stand up much longer than if we cut them out running across the grain. From my own experience I would suggest to the young toolmaker that he lay out his die with the long projecting points running lengthwise of the grain.

Fitting Punches

Before transferring the outline of an intricate shaped die to the punch, it is good practice to coat the face of the blanking punch with solder. Then machine the solder so that it is level. Coating the punch with solder enables one to obtain a much better outline than would be possible when scribing on the hard steel, and the very narrow and intricate parts can be laid out more easily. Another feature of the solder face is that if there are weak projections it eliminates the chance of breaking them when shearing the punch through the die. If 1/16 inch of solder is evenly placed on the punch, it allows the die to cut a perfect impression in the solder, which is a great help in milling the punch, as the milling cutter can be brought down until it just scrapes the solder, and the cut taken. At the completion of the milling operation the solder is removed, when the punches can be nicely fitted by using the filer shown at *A*, Fig. 1. This filer is made similar to a spiral mill and is placed in the chuck of a drill press, as shown. It cuts remarkably fast, and also leaves a good finish on the punch.

Hardening Dies

There are more cranks on the subject of hardening than on any other subject I can recall. We each have our own pet theory and the writer will put forth his argument which is the result of years of successful hardening of steel that ought to bear out his theory. Let us assume that we are about to harden the piece shown in Fig. 2. This shape is selected to enable us to more clearly describe the theory. Steel expands about 1/8 inch per foot when at a bright heat, but for argument let us assume that the piece to be hardened expands 1/8 inch at 1000 degrees F. Then if the piece be heated quickly, the smaller portion will heat more rapidly and will be brought to 1000 degrees F. while the remaining portion will not be up to that point. Say that the remaining portion will be only 500 degrees F. Therefore, one half has expanded at the rate of 1/8 inch per foot while the other half has expanded only at the rate of 1/16 inch. There must be, of necessity, a weakening effect at the separating line *A*, caused by the unequal expansion. Granting that when heating, it will expand unequally, the reverse action will take place when we immerse it in the bath. That is, the small part will contract quicker than the larger one. Then as the heavier portion continues to contract, there must be a strain at the point separating the two parts which invariably results in a crack at the point *A*. This piece could be successfully hardened by removing it from the bath while it is "sizzling." This allows the heat from the heavier part to run out into the lighter, equalizing the heat, which removes the strain. It also causes the contraction to be more even. Some may say that to remove the piece while it is sizzling would draw the temper, but water will sizzle on steel when the temperature is a little over 200 degrees F., which is not high enough to noticeably affect the hardness of the steel.

Some toolmakers know from experience just when to remove the piece from the bath by the peculiar "singing" noise of the tongs which is familiar to most of them. Others judge from the size of the piece just about how long to leave it in the bath. But the tongs may not feel like "singing," and the bath may be cooler than imagined; the piece larger than estimated or a little hotter due to reflected sunlight, all of which tend to make the foregoing method a matter of guesswork. The best way is to place the hand in the bath alongside of the piece and remove the die just as soon as the fingers can remain on the die without "sticking" to it. Whether this theory is correct or not, it is a fact that those who will try hardening in this way will find that their hardening troubles are over.

* * *

The electrical manufacturing industries in Germany appear, from the annual statements for the business year 1908-1909, to be in a prosperous condition. The Siemens-Schuckert Co., which operates with a total capital of about $26,000,000, declared a dividend of 10 per cent on its capital, and the Siemens & Halske Co., which operates with a total capital of about $22,000,000, declared a dividend of 12 per cent.

* * *

"As keen as a razor" means something so sharp that it will cut a hair supported at one end, but what is the thickness of a keen razor's edge? It is claimed to be only 1/600,000 inch by a manufacturer advertising safety razors. It would be interesting to know how the thickness of edge was accurately measured.

LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY

MAKING GEAR CUTTERS FOR A JOBBING SHOP

In reply to the question of R. G. D. published in the July number of MACHINERY, the writer would say that while situated in Melbourne, Australia, he made cutters which were used for automobile work in the following manner:

Starting with a broken spur gear *A*, which generally has two or more of its teeth in good condition, turn a tool steel plug to fit the space between the teeth, as shown at *B* in Fig. 1. After having turned, filed and polished this plug to shape, one-half is cut away as shown at *C* in Fig. 1. This plug is then used as a cutter. Using the toolholder shown in Fig. 2, and setting this up in the planer, it is possible to cut a forming tool to the desired shape. The forming tool is held on an angle plate, as shown in Fig. 2, which has its face set off at an angle of 20 degrees. The cutter is also held in the holder at a corresponding angle, this giving a clearance of 20 degrees on the forming tool. The point of application of the cutting tool is set beyond the center of the clapper-box pin so that the tool will spring away from the work and not dig into it. The angle plate is fastened to the planer bed as shown, care being taken to have the face *A* at right angles to the direction of stroke of the planer, or in other words, at right angles to the planer bed. The forming tool is roughed out to nearly the exact shape and clamped to this angle plate as shown. A hand-wheel for operating the planer table is used for taking the finishing cut. Turpentine will be found to be the best lubricant. After this forming tool is finished it is hardened and used in the lathe for forming the milling cutter. The milling cutter is then backed off with this same forming tool.

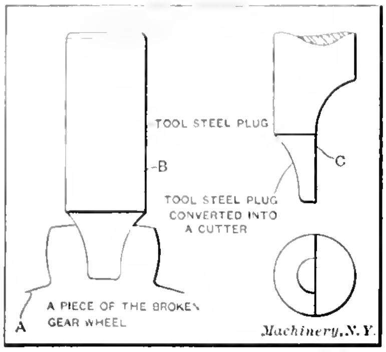

Fig. 1. Method of obtaining Shape from Gear Teeth for Forming Tool

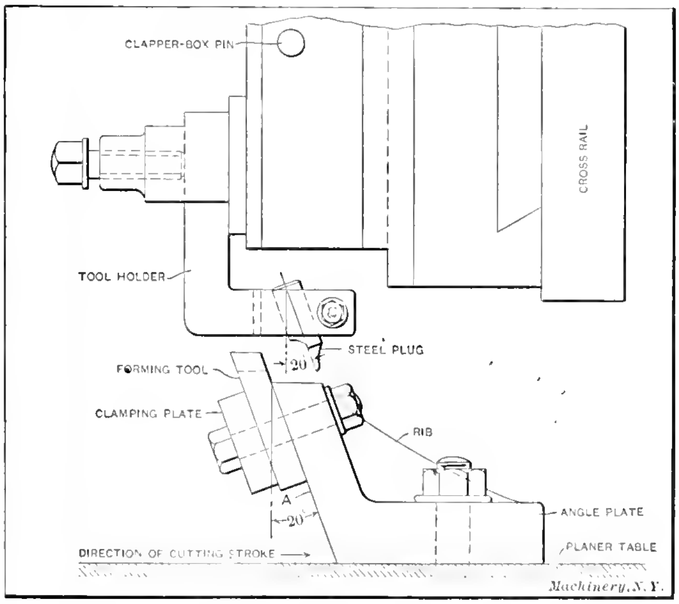

Fig. 2. Making Forming Tool on the Planer

In Fig. 3 are shown the details of the relieving attachment as used for backing off the milling cutter. *B* is a piece of cold rolled stock having its centers eccentric as shown, and having a piece *A* of machine steel pinned to it by a taper pin. A 1/2-inch hole is tapped into *A* for holding a handle which is used for operating this attachment. *C* is a tool-steel sleeve on which the milling cutter is held while being relieved. A series of 1/4-inch holes are drilled in this piece, the number depending on the number of teeth in the milling cutter. *E* is a nut for holding the milling cutter on the part *C*, and *D* is a nut for holding the part *C* on the arbor *B*. The way in which this backing-off attachment is operated is as follows:

After the cutter blank has been turned to the desired shape it is placed on the sleeve *C*, the 5/32-inch keyway fitting the keyway in the cutter and preventing it from turning while backing off. The nut *E* is then screwed on, holding the milling cutter tightly in place against the face of the sleeve *C*. The part *C* is then slipped over the arbor *B* and the pin *F* inserted in the hole shown in the part *A*, thus locating the part *C* in the desired position relative to the centers in the arbor. The nut *D* is then screwed onto the part *B* holding the face *b* of the part *C* tight up against the face *a* of the part *A*. The backing off is done by pulling the handle (not shown) which is screwed into the half-inch tapped hole. After one tooth has been backed off the nut *D* is released and the pin *F* pulled out and inserted in the following hole in the part *C*.

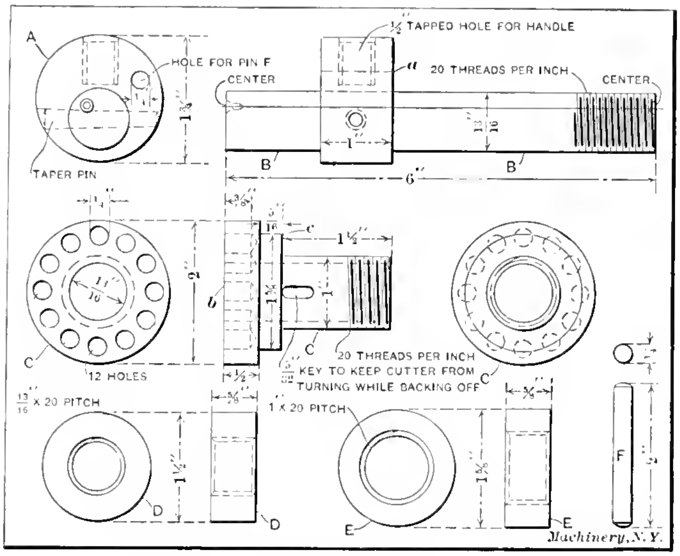

Fig. 3. Details of Backing-off Attachment used in the Lathe

The nut is again tightened and the method as previously explained followed until all the teeth have been backed off. This attachment does not give a true radial curve, but it has been found close enough in most cases, the writer having used this attachment for backing off milling cutters having a face 1 inch wide.

In the case of bevel gears, I made the diameter of the plug two-thirds the width of the widest space between the teeth, or in other words, the width of the space between the teeth at the pitch circle of the gear. After the plug had been cut away as shown at *C* in Fig. 1 it was hardened and drawn, and used as a cutter for making the forming tool as previously explained regarding the making of the forming tool for spur gears.

Hartford, Conn.

HEAT TREATMENT OF STEEL

When, in making a die, I pick out a bar of Jessop steel that is machined only with considerable difficulty, especially in drilling, I know that the bar has not been properly annealed, but I go ahead with the hope that the die may be finished without the necessity of re-annealing. When finished and taken to the fire for hardening, I first heat the die to a cherry red and allow it to cool in the air. Then I am sure it will harden properly in the last heating. In other words, whenever I find a die will not harden, I know that the steel has not been properly annealed at the steel plant and that one good remedy is to heat the steel and allow it to cool in the air before heating for hardening. It is not necessary to anneal it in an annealing pot.

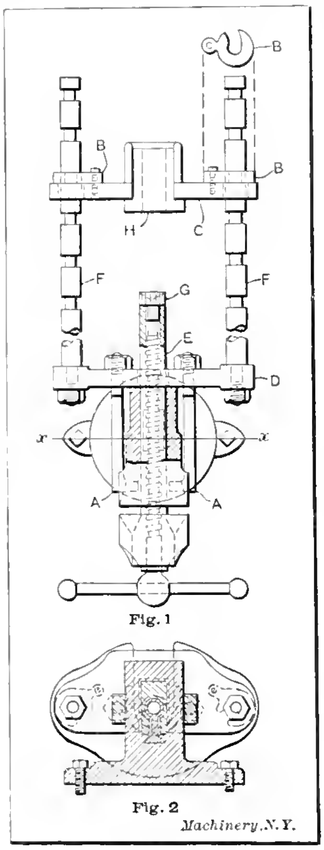
The following experiment bearing on "burnt" steel is in-

teresting: Place the end of a bar of tool steel about 3/8 inch square in the forge and "burn" about two inches—in fact melt the extreme end—then nick it so that it will break easily near the end. Allow the piece to cool in the air. After cooling, re-heat the bar to a cherry red and harden. Break off the end and you will find the steel is not burnt at all, but has just the same grain as before, due to the heat treatment. In my opinion there is really no such thing as "burning the carbon out of steel." CHARLES WESLOW

Buffalo, N. Y.

PRESS ATTACHMENT FOR A VISE

The accompanying engraving shows a vise attachment, the object of which is to enable the leverage of the vise to be used for pressing in lathe arbors, bushings, etc. There is sufficient leverage in the ordinary machinist's vise for this purpose, but the opening between the jaws is too narrow. It will be understood from the illustration that the attachment does not (except during the intervals when it is used as a press) materially interfere with the ordinary use of the vise.



Press for Arbors and Bushings which may be attached to an Ordinary Bench Vise

The attachment, a plan view of which is shown in Fig. 1, is secured to a common vise by two bolts *A*, which have L-shaped heads adapted to grip the fixed member of the vise under the jaw.

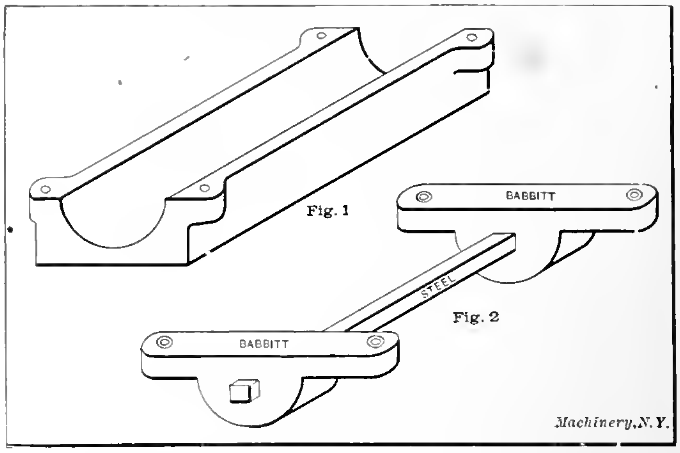
The clamp or sustaining plate *D*, in which the two bolts *A* are located, is slotted to permit the guide-bar *E* of the outer vise-jaw to pass through it. Secured to *D* are two grooved rods *F* carrying the thrust-plate *C*. The latter has drilled holes at each end large enough to admit of its being moved to different positions along the rods *F*. *C* is held in any required position by the engagement of the hinged latches *B* with the grooves in the rods *F*. While pressing an arbor into the work, one end of the arbor is centered in the conically-recessed plug *G* which fits into the end of the guide-bar *E*, the work into which the arbor has been entered being held against the thrust-plate. Some machinists might prefer to make the plug *G* with a flat end, to prevent cramping the arbor; but by careful manipulation of the work against the thrust-plate, no cramping will occur. The bushing *H*, which is shown inserted in the thrust-plate, is designed for use when handling small work.

This attachment is best adapted to the wants of those who need a small press occasionally, but who do not feel justified in purchasing a regular arbor press. The distance between the rods *F* may ordinarily be made sufficient for most of the work of a small press. If this distance should be greatly increased, the vise would need to be blocked up, or an opening through the top of the vise-bench would be required to clear work of large diameter. W. S. LEONARD

Atlanta, Ga.

SIMPLE METHOD OF MAKING A DRILL JIG

A simple and effective jig which was made by a method that is doubtless capable of many applications, is shown in the engraving, which also illustrates the work for which the jig was intended. This jig was used by a metal-pattern maker for drilling the pin holes in a metal core-box (Fig. 1) which were required to be interchangeable. One box was laid out and drilled and pins inserted in the holes. Stock bushings were then placed over these pins, and after closing the ends of the boxes so as to form pockets of the required shape at each end, babbitt was poured in, thus securing the bushings and forming the jig snown in Fig. 2. To obtain



Figs. 1 and 2. Metal Core-box and Jig for Drilling Pin Holes

the proper distance between the bushings lengthwise, a square steel rod was placed through the center.

Of course, this jig would not suffice for accurate work or for continuous use, but the method of making it could doubtless be applied to advantage for certain classes of work. The cheapness and ease with which the jig can be made, is the commendable feature. D. O. BARRETT

Freeport, Ill.

PUNCH AND DIE FOR PIERCING ANGULAR STOCK

It is a difficult proposition to pierce holes in angular stock which has been previously formed, without distorting it in any way and especially if the holes come close to the edge of the stock. A spring stripper is sometimes used for this pur-

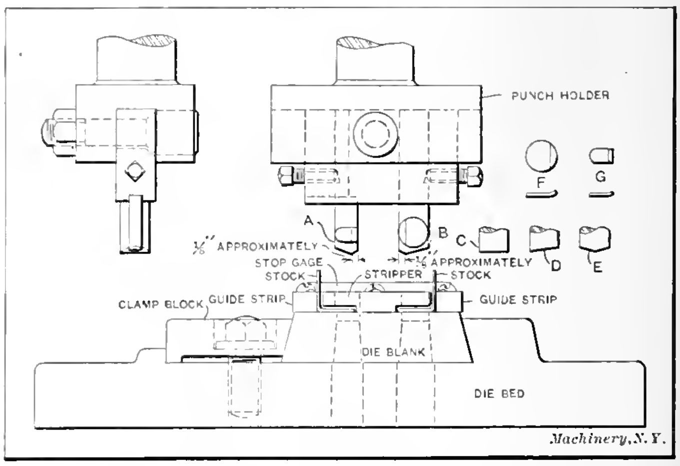


Fig. 1. Details of Punch and Die for Piercing Angular Stock

pose, but it is not always satisfactory. In Fig. 1 is shown a side elevation of a punch and die for piercing the angular stock shown in Fig. 2. This punch and die is used for punching both the holes and the slots, the blank being pushed

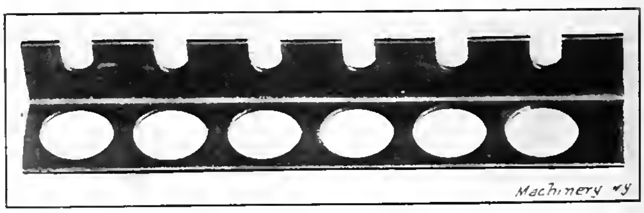

Fig. 2. View showing the Condition of the Anguler Strip after Piercing

through on one side of the die and then reversed and pushed through the opposite side, thus punching both the holes and the slots. The punches shown at *A* and *B* were found to give perfect satisfaction. The action of these punches is as follows: When the punch descends onto the stock, it gath-

ers the stock to the center as would occur when drawing a cup. This obviates the stretching of the material around the hole which would occur if the holes were pierced with punches such as shown at *C*, *D* and *E*. The shape of the blanks as formed by the punches *A* and *B* is shown at *F* and *G*. The other details of this punch and die are as ordinarily used and will therefore not require description. A stop gage is used which is operated by hand, thus spacing the holes at equal distances. CHARLES WESLOW

Buffalo, N. Y.

CONDENSED PRICE LEAF FOR MACHINERY HOUSES

We show herewith a No. 6 modern price leaf with illustration and full description of a line of punch presses that we expect to handle. This price leaf is one of the cleverest ideas that we have ever seen adapted for the use of salesmen,

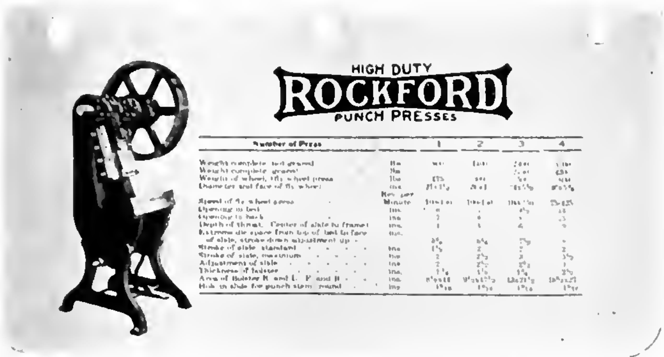

Fig. 1. Condensed Price Leaf for Salesmen

either in the store or on the road. We think it could be profitably adopted by quite a number of machine-tool and

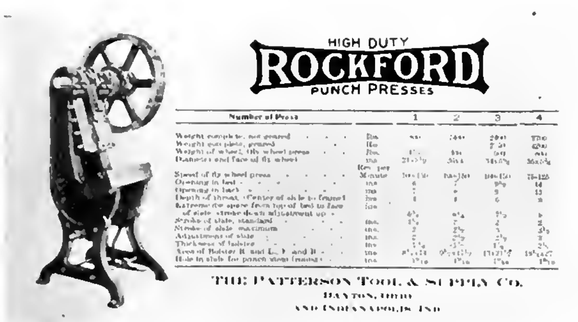

Fig. 2. Condensed Price Card for Mailing

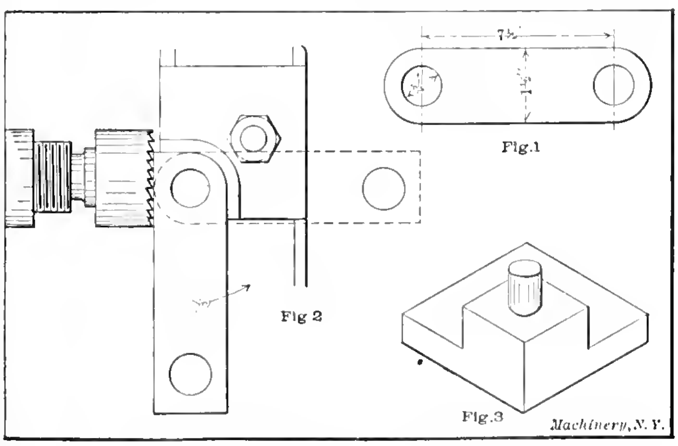
small-tool builders. The same electrotype could be used for printing cards for mailing purposes, and we show a sample herewith in Fig. 2. Both the price leaf and card were gotten up at our suggestion.

THE PATTERSON TOOL & SUPPLY CO.,
Dayton, Ohio. W. B. Patterson, President

ATTACHMENT FOR ROUNDING LINK ENDS

One of our constantly-recurring jobs was rounding the ends of the links shown in Fig. 1. These were of drawn steel ½



Figs. 1, 2 and 3. Link and Attachment for Rounding Ends in a Lathe

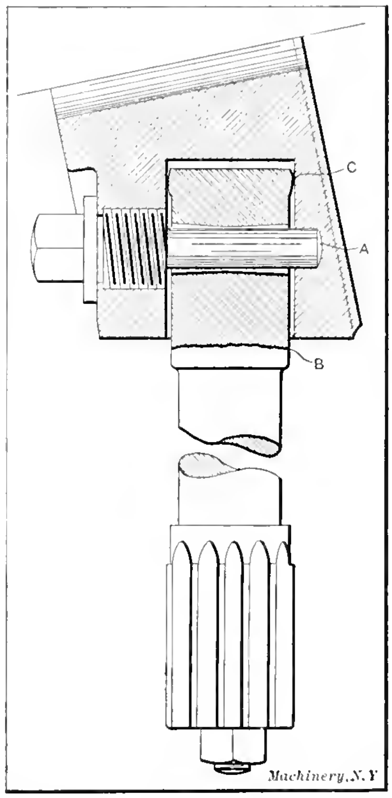
inch thick, and as they were called for in lots of from 2 to 40 at a time, the task of "knocking off" the corners in the shaper and finishing on a grinder was more or less laborious; neither was the finished piece always symmetrical. Something had to be done to put this work on a manufacturing basis both as to time and cost, and how this was done is shown in Figs. 2 and 3. A casting (Fig. 3) was made and fitted with a pin the size of the link holes. This block was then bolted to the lathe toolpost and an end mill fitted to a shank in the lathe spindle, which completed the outfit. Now after the links were cut off, drilled and reamed, they were slipped over the pin and given a quarter turn in a horizontal plane. A piece of pipe 18 inches long served to give the necessary leverage. In Fig. 2 may be seen a link, one corner of which has already been rounded, in position for operating on the second corner. The dotted lines indicate its position when one end has been finished.

This attachment was ridiculously cheap and so simple that a boy could round 50 links an hour and obtain a finish fully up to the requirements. DONALD A. HAMPSON

Middletown, N. Y.

FLOATING REAMER FOR INSURING STRAIGHT HOLES

The turret-head on a boring mill had become worn a little so as to throw it out of line, which caused the reamer to cut the holes cone-shaped; that is, they were larger at the top than at the bottom. The machine was used mostly for pulleys and couplings and the holes had to be straight and true with the turned part. This defect was overcome with very little expense and loss of time in the following manner:



Method of Holding a Reamer in a Turret so that it will follow the Bored Hole

First the turret head was removed from the machine and a threaded bushing having a ¾-inch hole was fitted to the screw hole. The reamer shanks were each placed in a hole in the turret and a ¾-inch hole was drilled through each shank and in the turret to a depth of 1 inch. The holes in the reamer shanks were then re-drilled 1/16 inch larger and taper reamed from each end, as shown in the accompanying engraving, which is a sectional view of one hole in the turret to which all the reamer shanks were fitted. The ends *B* of the shanks were then turned 1/16 inch smaller than the turret hole diameter to within ½ inch of the end. The end *C* was next turned spherical in shape, the diameter of the sphere being the same as the hole in the turret, so as to give a bearing on the end, and at the same time allow full play. A screw *A* was then made with a pilot pin ¾ inch in diameter. As will be seen, this screws fits the tightening screw hole and the back part of turret, but it is a loose fit in the reamer shank.

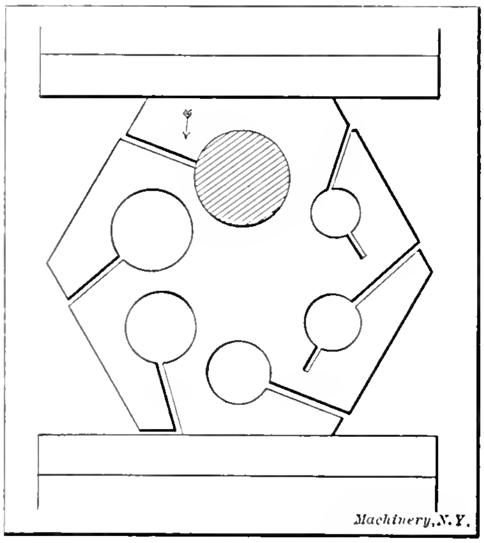
We have had no more trouble from large holes, the holes now being straight and to size. Before using, all the reamer shanks were tested to see that they had a free movement in every direction, because, if from some cause the holes are not drilled true and the reamer will not "float," a taper hole will result.

This method of holding a reamer can be applied with equal success to all forms of machines that finish holes with a

reamer, such as turret and engine lathes and drill presses that have become worn and are not true. JOHN BRANDLE
Jackson, Tenn.

A SPRING VISE-CLAMP

When finished or polished rods, spindles, tubes, etc., have to be held in the bench-vise, it is not always judicious to use ordinary flat clamps, because these do not afford a good grip, and in the case of thin pipes, they are likely to squeeze the



Spring Block for Holding Round Work in the Vise

metal out of shape. Some form of split block is better, in which the work rests in a bored hole and is gripped by the elasticity of the metal, the block being split so that the pressure of the jaws closes it in slightly. Some blocks are made of oblong form, with a series of holes and a longitudinal saw-cut to allow of the necessary elasticity. The illustration shows a neat form of block which is more compact than the oblong type. There are six holes of standard sizes, such as 1 inch, 7/8 inch, 3/4 inch, etc., and the block is hexagon in shape, and about an inch in thickness. The holes and the saw cuts are so arranged that the effect of squeezing the block in the jaws, is to close in the holes on opposite sides, thus clamping any work that may be put in them. The block is therefore turned around to suit the particular size of hole that is wanted. The same kind of block might be made octagonal in form and have eight holes, but I have not attempted to devise anything beyond the hexagon, as it seems better to have another block for the next range of sizes. FRED HORNER
Bath, Eng.

HARDENING HIGH-SPEED STEEL

There have been a number of articles reproduced in MACHINERY from time to time on methods of hardening high-speed steel, but I have never seen published the formula here given, which I have used for three years with good results. It is a well-known fact that high-speed steel made up into small and delicate tools such as taps, cutters, etc., should not be blistered or pitted, as this would spoil the cutting edges. It is generally a problem to harden high-speed steel successfully where the necessary equipment, the chloride barium bath, is not available. One of the principal precautions necessary, in hardening high-speed steel, to prevent blistering, is to keep it from the air while the steel is hot. A powder which is composed of corn meal, salt, and prussiate of potash mixed in equal parts has been found a very satisfactory composition. To harden the piece, heat it to a dull red and lay it in the powder. Then return the piece to the fire and heat to a bright red. Dip again in the powder and return once more to the fire and heat to almost a yellow color. Then quench the piece or pieces in cotton-seed or linseed oil. Pieces hardened in this powder will be found free from pitting and scaling and the sharp edges will be maintained. It will be noted that the hardening heat is a great deal lower than that recommended by the makers of various high-speed steels. W. C. BETZ
New Britain, Conn.

AUXILIARY SCALES ON THE TRIANGLE

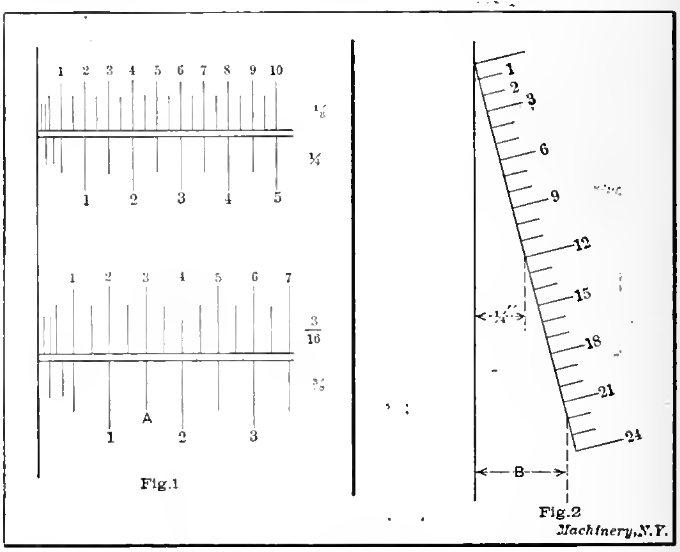
When working on small-scale drawings in which much detail is to be shown, such as the drawings of pipe connections, valves, fittings, etc., the auxiliary scales described in the following will be found of great convenience:

Fig. 1 represents a portion of a celluloid triangle with four scales lined on it. These are reproduced from those upon a draftsman's scale being 1/8, 1/4, 3/16, and 3/8 inch to one foot, respectively. The lines are made by scratching the triangle with a fine prick-point. After this is done, a little india ink rubbed over the marked surface will make the scales more visible. The triangle should then have the figures scratched upon the reverse surface.

To illustrate the use of the instrument, suppose it is desired to draw a vertical line 18 inches to the left of a center-line, to a 3/8-inch scale. The division marked *A* is placed over the center-line and the desired line is then ruled in. That is, the desired line is drawn without other measurement than that involved in the use of the triangle. Thus is accomplished a saving of the labor of removing the triangle for the purpose of measurement with a separate scale, the marking of the position of the desired line, and the replacing of the triangle that it may be drawn—a saving that will be found considerable on certain classes of work.

The scales on the triangle may readily be applied in a vertical direction if it is used in conjunction with another triangle. The surface of the triangle marked with the scales should always be placed next to the drawing paper, as otherwise an error of parallax may result.

Fig. 2 represents a different way of graduating the triangle, by which finer graduations may be made with less care in laying them out. The scale shown consists of twenty-four equal divisions and it is located so that the division 12 is 1/4



Figs. 1 and 2. Auxiliary Scales for Drawing the Details of Small-scale Drawings

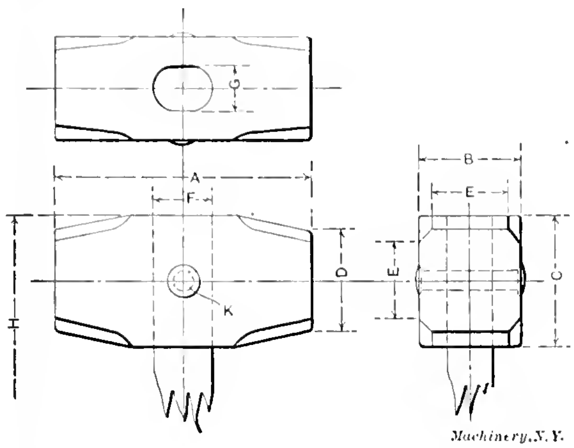
inch from the edge of the triangle and the zero division at its edge. With this arrangement a 1/4-inch scale is obtained. It will be seen that the edge of the triangle is 22 inches, to this scale, from the line *B*. This illustrates its application in use.

If desired, the lined scale may be made on a thin piece of celluloid instead of on the triangle. It may then be used for a variety of scales by simply changing its inclination to the edge of the triangle. For instance, if the 12 division is placed 3/8 inch from the edge of the triangle, a 3/8-inch scale results, and so on. An arrangement may readily be made by which the thin celluloid piece may be tacked temporarily in the position on the triangle corresponding to any desired scale.
Philadelphia, Pa. JULIAN C. SMALLWOOD

MACHINE ASSEMBLING HAMMERS

The machine assembling hammer shown in Fig. 1 is intended for the use of assemblers in the machine shop, where soft hammers are an absolute necessity. The table shown in connection with Fig. 1 gives the dimensions for four different sizes, and a convenient form of mold for casting these hammers is illustrated in Fig. 2. The heads are made of scrap lead or babbitt, which when heated to a molten state is

poured into the cast-iron mold. The handles are held in the heads by pins riveted at each end. The mold, as shown in Fig. 2, is made in two sections S and T which are hinged at Y in two places. The lug W is for holding the mold in the jaws of a bench vise while the metal is being poured. By means of pins V which pass through lugs in front, the upper half is held down when the mold is in use. It is well to have



No.	A	B	C	D	E	F	G	H	K
I	4	$1\frac{1}{2}$	$1\frac{3}{4}$	$1\frac{1}{2}$	1	1	$\frac{5}{8}$	14	$\frac{1}{4}$
II	$3\frac{1}{4}$	$1\frac{1}{4}$	$1\frac{1}{2}$	$1\frac{1}{4}$	$\frac{7}{8}$	1	$\frac{5}{8}$	12	$\frac{1}{4}$
III	$2\frac{1}{2}$	1	$1\frac{1}{4}$	1	$\frac{3}{4}$	$\frac{9}{16}$	$\frac{9}{16}$	10	$\frac{3}{16}$
IV	$1\frac{3}{4}$	$\frac{3}{4}$	1	$\frac{3}{4}$	$\frac{11}{16}$	$\frac{1}{2}$	$\frac{3}{8}$	8	$\frac{1}{8}$

Fig. 1. Dimensions of Machine Assembling Hammers

these pins permanently fastened to the lower half of the mold by small chains to prevent their loss. The steel core X for the handle, is shouldered at one end to prevent it from slipping out of the mold. The metal is poured in through the

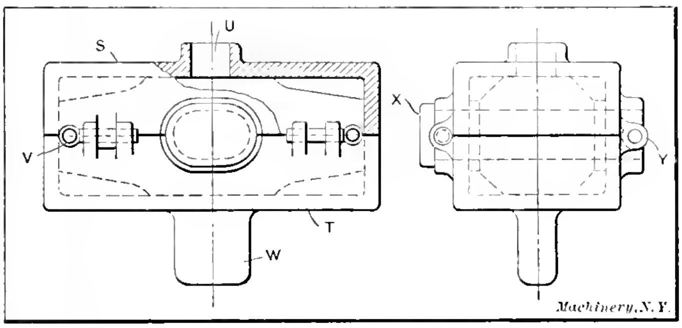


Fig. 2. Mold in which Hammers are cast

inlet U. By the use of these molds, soft hammers may be made with little trouble and they will also be neat in appearance.

L. H. GEORGER

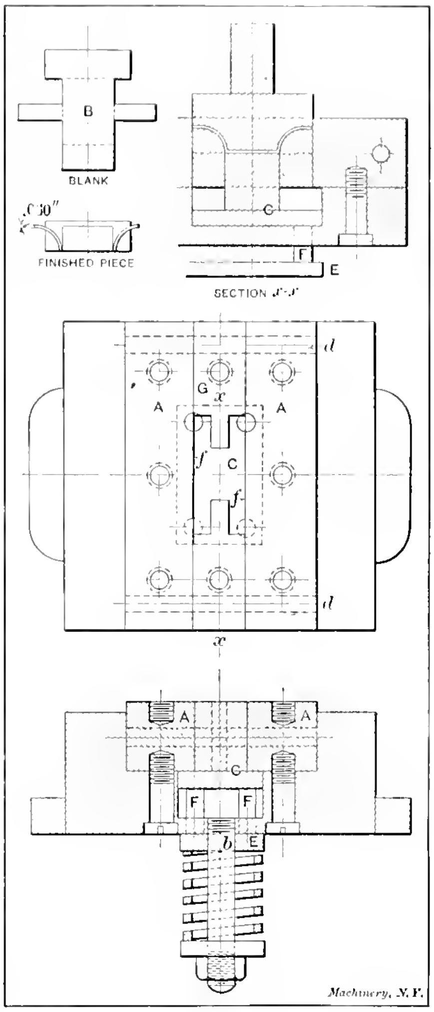
Buffalo, N. Y.

BUILT-UP REVERSIBLE-SECTION BENDING DIE

The die illustrated herewith is for bending the brass blanks B to the finished shape shown, the pieces being bent on the dotted lines. This die replaces a solid one which was continually wearing out on the inside flat faces and which could not be repaired without making a new block. The new die is so made that its sections are reversible; thus when the faces f are worn, the opposite side may be turned inward. When this becomes worn the block may be turned over and the lower half of the face becomes the wearing surface, making four positions which each block can assume to compensate for wear.

The die is made of the pieces A which are reversible, and the sections G which fit between the parts A. The alignment is secured by dowels d in each end, which pass through the three pieces. The four pieces are set into a base-block which is a steel casting, and are held to it by eight screws, three in each long piece and one in each of the small pieces. This makes a very solid construction and will stand any amount of strain without danger of breaking. All the sections were made of non-shrinking steel and were hardened very carefully, all holes being plugged with asbestos. After hardening, they were ground on a surface grinder, care being taken not to disturb the alignment of the holes.

As there was not room for the stripper springs in the base-block, a heavy coil spring of one-quarter inch square stock was wound and tempered. Plate E is loose on the shank of the bolt b and the pins F work through reamed holes in the base-block and bear on the bottom of stripper C. The spring passes through a hole in the bed of the press when the die is in use. The stripper is made in two pieces as shown, one of which passes through the die, the other being a bottom plate which acts as a stop.



Reversible-section Bending Die and Piece which it forms

The forming punch for the die has a round shank by which it is held in the press and which serves to hold it while machining the faces. It was held in a fixture on a lathe faceplate and the slots for bending the side projections on the blank were formed to a templet. The sides were slotted in order to bend the projections without a side-twist. Section x—x gives a good idea of the action of the die. The punch is shown at its full depth, leaving the thickness of the stock between it and the stripper.

The locating plate for the blank is not shown but it is fastened on the top of the die by screws which fit the same holes that are used to hold the die to the base.

PRINTS WITH BLUE LINES ON WHITE GROUND

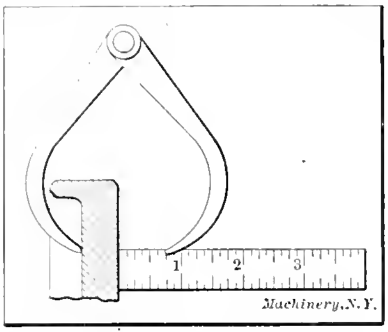
The process of making blueprints with blue lines on a white ground, described in the May number of MACHINERY is rather too complicated to be convenient. The thing may be done much more readily if one has the misfortune to be in a country where most of the carbon paper sold for typewriting is so bad that the first time it is used, the entire black surface is removed, leaving the paper practically transparent. To take advantage of this defect, one has only to place some of this paper with the smutty side up, cover it with a piece of copying paper (tissue paper), and draw or write with the stylus or even with a hard lead-pencil having a well-rounded point, whatever it is desired to print. The result will be two copies; a black or an opaque one on a white ground, and a white or transparent one on a black ground.

The carbon paper, when used as a negative with the ordinary iron paper, will give blue lines on a white ground; and the tissue paper, white lines on a blue ground.

Dresden, Germany. ROBERT GRIMSHAW

CALIPERING OVER FLANGES

A simple method and one which is as accurate as the one described in the July number of MACHINERY by Fred Horner to measure a web behind a flange is to set your calipers to some fixed distance which will clear the thickest portion, say 1 1/4 inch. Then, by the use of a steel scale, as shown in the accompanying illustration, held against the side of the part to be measured, read off the distance that the calipers extend on the scale, and deduct this amount from the distance at which the calipers are set. This will give the thickness of the web.

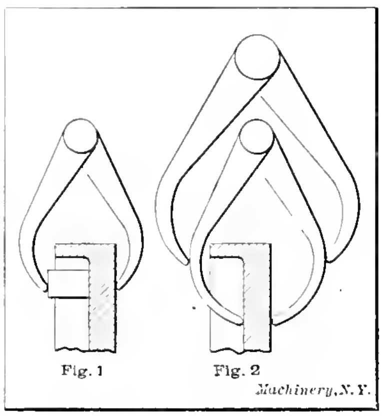


Method of Calipering over a Flange

Pawtucket, R. I. FRED G. KENYON

[A similar method was described in MACHINERY, February, 1904.—EDITOR.]

In the July number of MACHINERY was shown a method of calipering over a flange by making a prick-punch on each leg of the calipers, and measuring the points with a pair of dividers. It would not be possible to replace the calipers very closely by this means. The following methods here shown are quicker and more accurate, and also enable measurements to be taken closer to the corner under the flange. To get the thickness of the flange, simply use a block as shown in Fig. 1. Then subtract the thickness of the block from the opening of the calipers. This method can also be used for measuring a chambered recess. If a block is not handy, use a second pair of calipers as shown in Fig. 2. After removing the first pair of calipers from the work, replace them to size by means of a second pair.



Other Methods of Calipering over a Flange

Dayton, Ohio. JAMES DANGERFIELD

BOLLINCKX'S SCRAP-BOOK

In the machine shops of H. Bollinckx, Brussels, there is a very wonderful and useful scrap-book in several volumes. It consists of a series of sheets of blueprints of standard size, on which are reproduced in sketch form, hundreds of shop kinks from the various mechanical papers, with suitable inscriptions and reference to the date and page of the paper, in which, if desired, further particulars may be obtained. Copies of this scrap-book are placed at the disposal of those who may need them. This is a custom which other establishments would find well worth copying. The sketches can be made by an apprentice in the drafting-room, and in making them he will absorb a great deal of information. ROBERT GRIMSHAW

Dresden, Germany

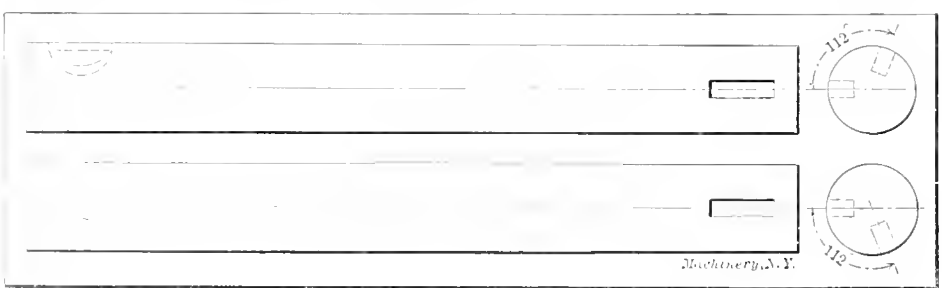


Fig. 1. Shafts with Woodruff Keyseats cut 112 degrees apart

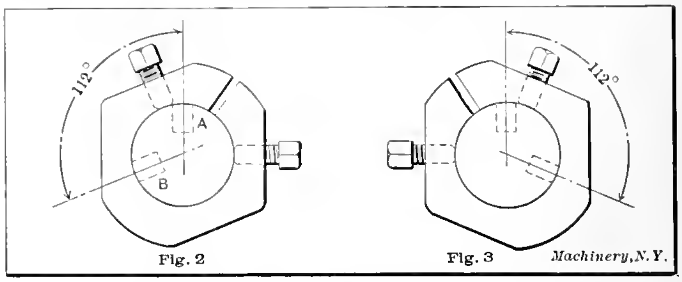
FIXTURE FOR HOLDING SHAFT WHEN KEYSEATING

A number of cold-rolled shafts 7/8 inch in diameter and 9 inches long had to have Woodruff keyseats milled in each end, so that they were 112 degrees apart in pairs of lefts and rights, as illustrated in Fig. 1. The distance from the ends of the shafts to the center of the keyseats was 5/8 inch, and as the shafts were too short to reach through the dividing head, it was impossible to cut a keyseat in one end and use a level on it to get the position for the keyseat on the other end. The fixture in which these shafts were held while the keyseats were being milled is illustrated in Fig. 2. This fixture was first bored to a sliding fit for the shafts. Two sides were then milled parallel with each other, after which the work was indexed 112 degrees and two other surfaces were milled as shown. A 5/32-inch slot was next cut through the block and holes were drilled and tapped for set-screws to secure the fixture to the shaft. The keyseats were milled by placing the shaft in this block, which was held in the milling machine vise. The keyseat *A* was first milled at one end, after which the block was turned over, thus bringing the second keyway *B* 112 degrees from the first. This block was used in a similar manner for milling shafts with keyseats cut to the opposite hand, as illustrated in Fig. 3.



Figs. 2 and 3 Fixture for Holding and Locating Shafts shown in Fig. 1 while cutting Keyseats

In Fig. 4 a method of holding a long shaft when keyseating is shown. Two blocks are placed on the ends of the shaft to be keyseated, as illustrated, and a surface-plate or other smooth surface is used to bring the blocks into the same plane. By holding first one block and then the other in a vise while the keyseats are being milled, the latter are cut in alignment with each other. By cutting a single finished block in two, these two blocks may be made exactly alike without any difficulty. ARTHUR Z. WOLGAMOT

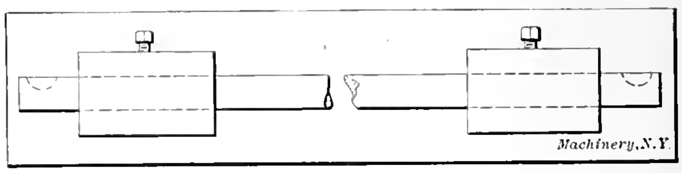


Fig. 4 Blocks for Aligning Long Shafts when Keyseating the Ends

Peoria, Ill.

IRREGULAR SPACING OF THE CUTTING EDGES OF REAMERS

After reading an article in the May issue of MACHINERY by "A," I see no reason for spacing reamers irregularly to prevent chattering and thus make accurate measurement difficult; for the chattering effect may be overcome by simply giving the cutting edges a slight spiral. A. NIELSEN

Cleveland, Ohio.

[Cutting the teeth on a helix, or spiral as commonly expressed, increases cost of production and grinding considerably, and the advantage of the spiral tooth action is doubtful. Is there a common angle best suited to steel, cast iron and brass, and if so what is it? Should the helix be right- or left-hand, and in what respect should the practice vary for machine and hand reamers? The opinions of readers are solicited for publication.—EDITOR.]

IMPROVED HYDRAULIC CYLINDER LINER

In Fig. 1 is shown a new design of hydraulic cylinder liner which does away with the troublesome features common to the ordinary cylinder liner which is shown in Fig. 2. This design shows clearly how to make feed connections to the cylinders without going through the liner. The greatest trouble as experienced with the ordinary cylinder liner shown in Fig. 2, is the making of a good joint at the heads.

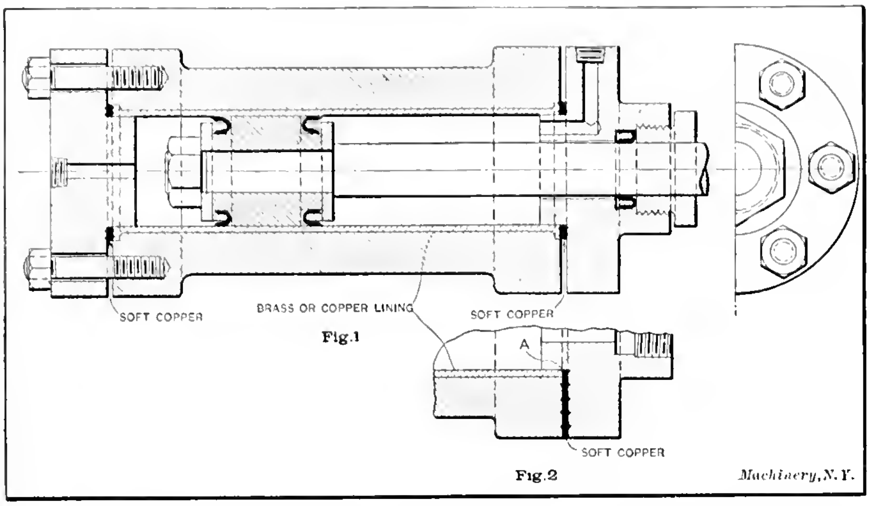

Fig. 1. Hydraulic Cylinder with Overlapping Ends. Fig. 2. Cylinder Liner of the Ordinary Type

Therefore, the reason for the failure of this joint at high pressure is easily explained. The ends and heads of this cylinder are scored or grooved and are put together with a soft copper gasket between the surfaces, which is compressed by the tension of the studs. As will be seen, this tension is not uniform over the whole surface of the gasket. Consequently the pressure of the water acting on the cylinder walls and against the head causes the former to stretch and become larger in diameter, and the latter to bulge and loosen at the gasket *A*. This stretching and bulging, though very slight, is yet enough to make a passage for the water under high pressure to reach the gasket *A*. When the water has once reached the gasket at *A* it soon makes its way between the gasket and cylinder and from there creeps in between the cylinder walls and the liner. It is very difficult to make a perfect fit between the surface of the liner and the cylinder wall and, of course, this is not improved after the cylinder has been used a while. When the water gets in between the cylinder walls and the liner the trouble begins because the water cannot get out, and with each time the pressure is put on and off there is a slight movement between the liner and cylinder. This movement causes the water to spread and make room for more water every time the cylinder is under pressure. The accumulated water soon distorts the liner and hinders the working of the piston, which, in turn, soon ruins the liner.

The design of liner shown in Fig. 1 overcomes this difficulty, and also makes a better joint which can easily be seen. The ends of the cylinder are counterbored as shown, and the liner inserted in the usual way. The ends of the liner are then lapped over into the counterbore, faced and scored or grooved, after which the heads are put on with a soft copper gasket between the joints, and the nuts shown, tightened.

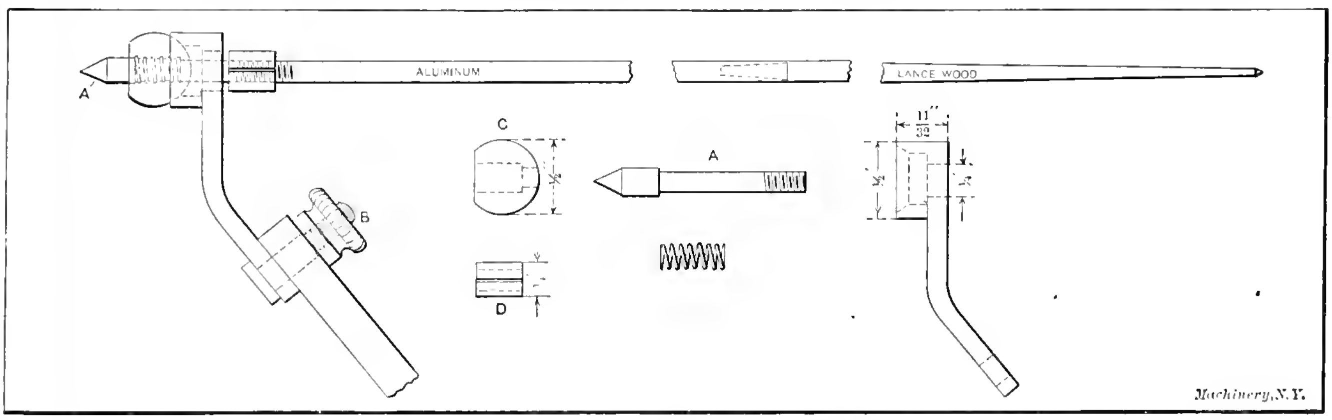
To illustrate that a greater pressure is exerted on the gasket shown in Fig. 1, we will compute the difference in the area between these two joints. For convenience we will call the joint and its parts as shown in Fig. 1 *X*, and those shown in Fig. 2, *Y*. Then to prove that the pressure per square inch of area on gaskets *X* is greater than the pressure per square inch of area on gasket *Y*, assuming, of course, that the total pressure produced by the tension of the studs would be the same in both joints, let the bore of the cylinder equal 4 inches. Let the outside diameter of gasket *X* equal 5 inches. Then the area of gasket *X* equals 7.0686 square inches. Let the outside diameter of gasket *Y* equal 9 inches. Then the area of gasket *Y* equals 51.05 square inches. $\frac{51.05}{7.0686} = 7.22$. Therefore, the pressure per square inch on gasket *X* is 7.22 times the pressure per square inch on gasket *Y*. Hence, the joint as shown in Fig. 1 is far superior to that in Fig. 2. The extra amount necessary for the lapping over of the liner as used in Fig. 1 should be from two to three times the thickness of the liner for each joint.

BENJAMIN BROWNSTEIN

CENTER INDICATOR FOR THE BENCH LATHE

Those who have spare time on their hands may use it to good advantage by making the center indicator shown in the accompanying illustration. The ball-and-socket bearing and the light needle are the good features of this tool.

When centering a point in the lathe, the point *A* is pushed back through the ball and against the spring, the spring pushing the ball against the socket, thus eliminating all play and vibration. After setting the indicator in the tool-holder, loosen the knurled nut *B* and raise or lower the point of the tool to the desired position; then tighten the nut.



Simple Form of Test Indicator for Precision Work

If, in making the needle, it is difficult to get a good piece of wood, the handle of a paint brush may be worked to shape. When making the spherical piece *C*, use a half-inch ball bearing and grind the hole carefully. The point *A* should be hardened and ground, care being taken that it is made a good fit in the part *C*. The bushing *D* keeps the ball and needle in position when the tool is not in use, and plays no part in the working of the tool.

This indicator may, of course, be attached to a larger holder for use in a bigger lathe. I have found it superior to those on the market.

GUSTAVE REMACLE, JR.

Newark, N. J.

* * *

Charcoal should never be used on aluminum while melting, as it cannot be completely removed in skimming and black spots will be found on the castings which are made from it.—*Brass World*.

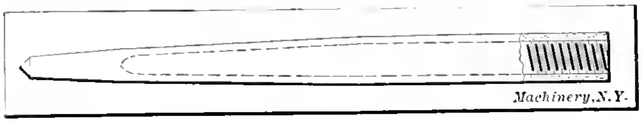
SHOP KINKS

PRACTICAL IDEAS FOR THE SHOP AND DRAFTING-ROOM

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary

HOLDER FOR SHORT PENCIL

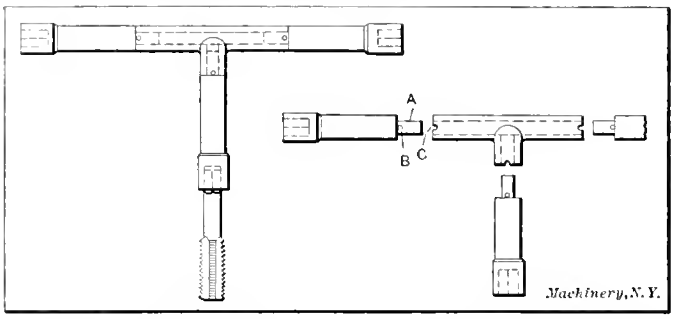
The short pencils which are thrown away by draftsmen can be conveniently used by means of the holder shown in the sketch. This holder was made from a hard rubber pen-



holder, which had been broken at the pen socket. About one inch of the solid end was cut away and the hollow part was tapped with a 5/16-inch tap. By inserting a short pencil in this threaded hole, it is rigidly held, and practically the entire pencil can be used. C. G.

TAP WRENCH WITH INTERCHANGEABLE SOCKETS

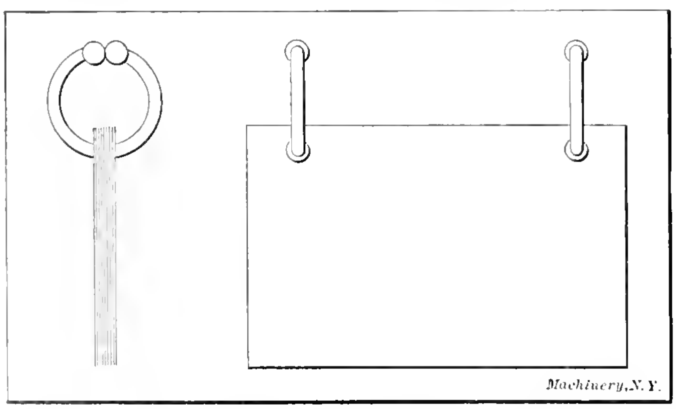
When tapping out holes by hand on heavy machine parts, such as beds, frames, etc., where several size taps are used, it is inconvenient to handle, several times, the different tap wrenches and tap extensions that must be used in operations of this kind. It also requires time to first find the various wrenches and extensions wanted. By combining three extensions to a tee, as shown in the accompanying engraving, a



tap wrench is formed having interchangeable ends of three different sizes. The changing of the extensions in the tee is the work of a second. This tee is a forging in which holes are drilled to fit the reduced ends *A* of the extensions. Small pins *B* which fit into slots *C* prevent the extensions from turning with relation to the tee. Two of these sets in a shop will meet any condition. There should be a small set having extensions for ¼-, 5/16- and ⅜-inch taps, and a larger set for 7/16-, ½- and 9/16-inch taps. J. E. C.

LOOSE-LEAF CARD INDEX FILE

The simple form of loose-leaf book or card index file shown in the engraving, is made of suitable cards held together with two key-rings, that may be obtained in any hardware store for ten cents. I find this file very convenient, as it can be

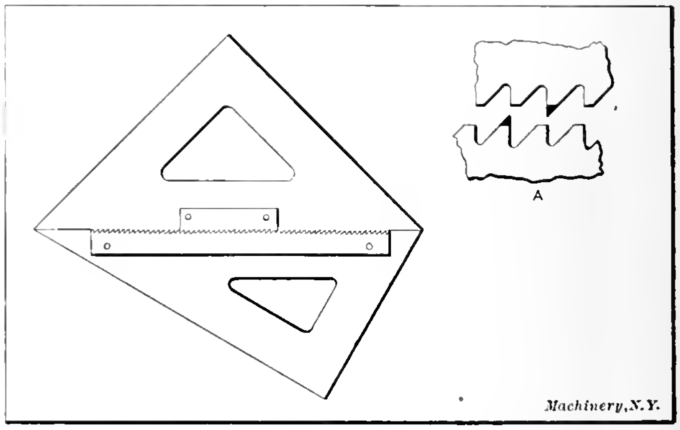


opened at any page and will not occupy more room on the desk than a single sheet or card. It has the additional advantage that a page can be taken from or added to it with little difficulty. D. F. Huddle, Jr.

Wilkinsburg, Pa.

SECTION LINER

A sectional liner, which works very satisfactorily, can be made by attaching pieces of a hack-saw blade to two triangles, as illustrated herewith. I made a section liner in this way by using an old saw blade. The blade was first annealed, after which the sides were ground and also the points of the teeth (as shown in the enlarged view at *A*) so that they would not bear in the fillets. Two pieces of blade, one 6 inches long and the other 2 inches, were then cut and drilled for pins. By using these two pieces as jigs, the triangles were drilled and the pieces attached by pins so that the long one was flush with the edge of one triangle and the short one was in mesh with the other as illustrated. When using this section liner, either one, two or three teeth can be used for

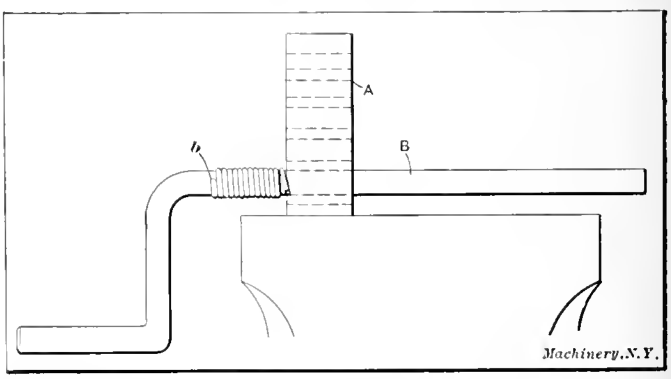


spacing. If a fine sectioning is desired, lines can first be drawn with single-tooth spacing, after which a second set can be drawn with the same spacing but with the triangles so adjusted that the last lines drawn come between the first set of lines. This attachment is easily made, and it does not prevent the ordinary use of the triangles, for when the blades are not required for sectioning, they can be removed.

Milwaukee, Wis. H. Blount

DEVICE FOR WINDING LIGHT SPRINGS

A very simple device that may be used for winding light springs is illustrated herewith. This tool will often save much time when a spring is wanted in a hurry, as springs of a variety of sizes and pitches can be made at a moment's notice. This apparatus is inexpensive and is easily made. The part *A* is made of a piece of ¾-inch square steel about 12



inches long. In this steel piece a series of holes are drilled about one-half inch apart and ranging from ⅛ to ½ inch in diameter. The mandrel *B*, on which the springs are wound, is made of wire or round stock of the size required. It has a handle formed on one end and a small hole is drilled at *b* to hold the end of the wire when starting the spring. To wind a spring, an arbor having a diameter equal to the inside diameter of the spring is selected and inserted in a hole of corresponding size in the piece *A*, which has been clamped in an upright position in the vise as indicated. One end of the wire is caught in hole *b* and, while the arbor is turned with the left hand, the right is used to hold and guide the wire. With a little practice a well-formed spring can be wound with this tool. H. B. Comstock

NEW MACHINERY AND TOOLS

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP

Comprising the description and illustration of new designs and improvements in American metal-working machinery and tools, published without expense to the manufacturer, and forming the most complete record of new tool developments for the previous month.

AUTOMATIC TWIST DRILL GRINDER

As is well known, twist drills, to give efficient service, must be kept sharp and be ground correctly, which means that the cutting edges, in addition to being of the same length, have a proper and uniform angle, that the clearance is so shaped as to give good support to the cutting edges and at the same time permit a free cutting action. In order to simplify the operation of drill grinding, A. Mill, M. E., Cincinnati, O., has designed the twist drill grinder, front and rear views of which are shown in Figs. 1 and 2, respectively. This machine is automatic in its operation and grinds drills ranging from 3/16 inch to 3 inches in diameter.

The drill, while being ground, revolves continuously at a uniform speed, and the ordinary two-lip drill oscillates twice in one revolution about a center which exactly coincides with the axis of the drill and which is more or less away from the drill point. This oscillation, which produces the required amount and form of clearance for the drill lip, is caused by a cam *C*, Fig. 3, which works against a stationary roller *B*, that

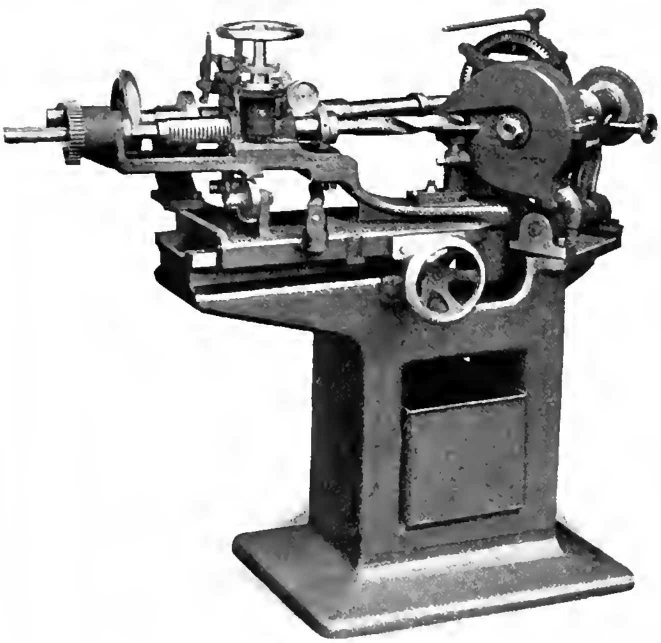

Fig. 1. The Mill Automatic Twist Drill Grinder

is attached to the carriage containing the drill-holding spindle and the feeding mechanism. The back shaft on which the cam *C* is mounted, is driven by means of a universal joint connection, and it revolves at twice the speed of the drill spindle. The drill, in addition to having this oscillating movement, is reciprocated to and from the emery wheel twice during each revolution by face cam *A*, which, through a lever, operates block *D*, Fig. 4, in which the drill spindle is mounted. The point of the drill is, of course, in contact with the wheel while the clearance for one lip is being ground; it is then withdrawn from the wheel by the face cam *A*, an amount sufficient to bring the opposite lip in the correct position for grinding. This reciprocating or longitudinal motion of the drill spindle also affects the automatic feed of the drill. The spindle in which the drill is held, revolves in a rack-sleeve or quill, which is engaged with a pinion as shown. The shaft on which this pinion is mounted, carries a handwheel *F* for the rapid traverse of the spindle and also a worm-wheel which is always in engagement with a worm. This worm-wheel is loose on the shaft, but it can be secured to it by a friction disk and hand-nut for the automatic feed. The small handwheel, shown at the front of the worm-shaft, is for feeding by hand, while the ratchet wheel at the other end furnishes the automatic feed when its pawl is released from the catch. This feed is effected, as before stated, when slide *D* is reciprocated; as this movement takes place, the pawl *H* moves with relation to its ratchet wheel, so that on the return of *D*,

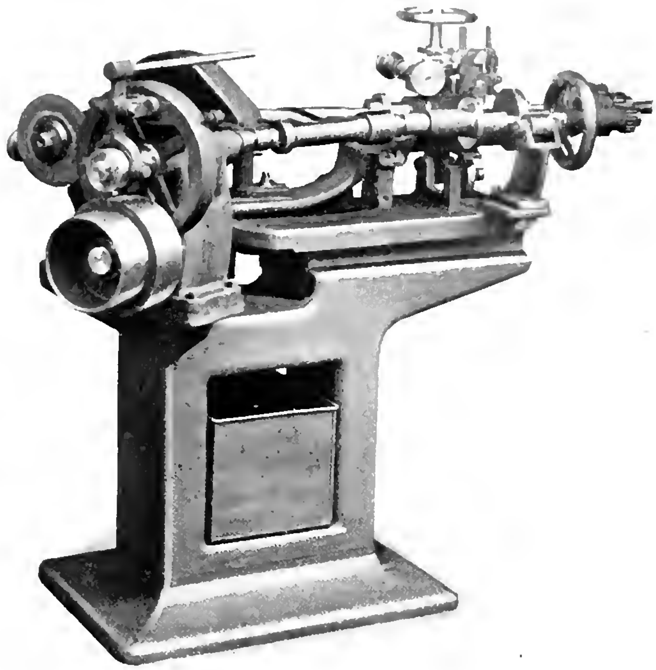

Fig. 2. Rear View of Automatic Drill Grinder

the spindle sleeve containing the drill is fed forward through the worm gearing and pinion connection. This automatic feed can be instantly released by simply disengaging the pawl from its wheel. An automatic stop can also be arranged by having an adjustable pin on the drill spindle sleeve, so located as to strike the lower part of the trip-lever and disengage the pawl.

The emery wheel frame is made oscillating to prevent the cutting face of the wheel from clogging up and also to insure uniform wear. This oscillating movement is effected by an

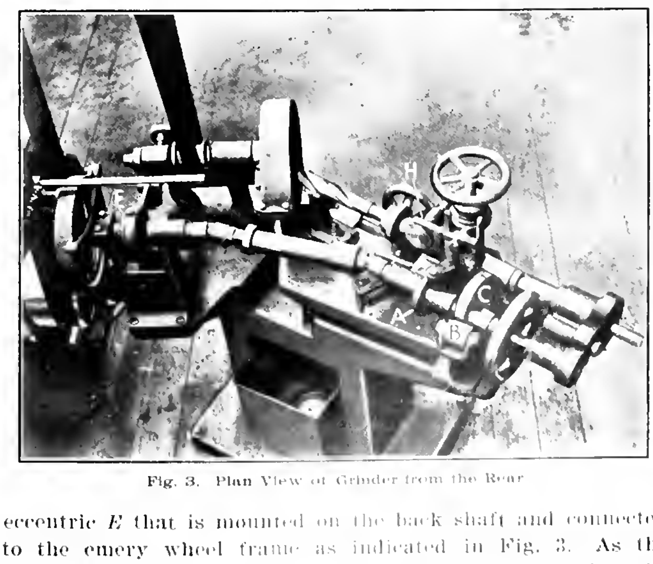

Fig. 3. Plan View of Grinder from the Rear

eccentric *E* that is mounted on the back shaft and connected to the emery wheel frame as indicated in Fig. 3. As the wheel is thus given a continuous movement to and fro, the drill will receive a smooth grinding and the wheel itself will always remain sharp. An adjusting screw is provided to lengthen or shorten the connection with the eccentric so that the entire face of the cup wheel may be used, thus keeping the

wear uniform. The emery wheel is 9 inches in diameter and has a grinding face 1¾ inch in width.

Before inserting a drill in the spindle, the latter is moved to the end of its oscillating stroke by turning a handwheel on the back shaft until an arrow point on the spindle hearing coincides with a mark on the spindle collar. A threaded hand-nut with a conical bore serves to close the slotted spindle end around the drill shank, thus securely locking it in place after the lip of the drill has been set to a gage. These few simple adjustments in connection with the automatic operation, make it possible for a boy to operate several of the machines if necessary.

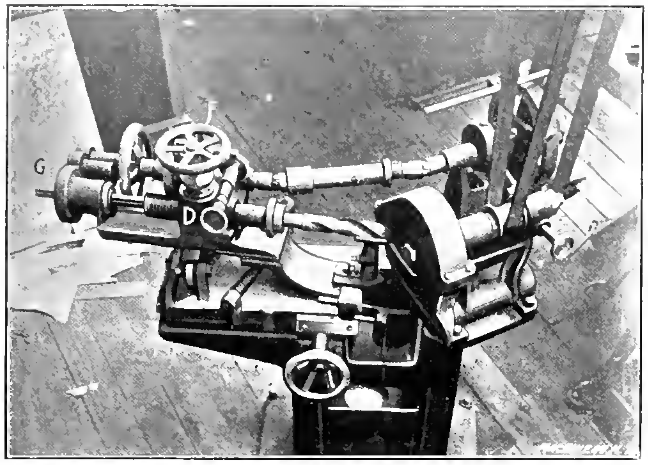

Fig. 4. Plan View from the Front

For different sizes of drills, the distance to the center of oscillation is changed according to a graduated scale by means of a handwheel at the front of the machine, which adjusts the carriage along the bed by a rack and pinion movement. As the engravings show, a small, narrow wheel is mounted at the outer end of the emery wheel spindle. This small wheel is for reducing (by hand) the thickness of the drill web at the point, when this becomes necessary. A rotary pump (not shown in the illustration) is attached to the machine for wet grinding. This grinder can be used for sharpening either right- or left-hand drills, and by the use of change gears *G*, drills having any number of lips, can be ground.

IMPROVED TOLEDO PRESSES

The two presses shown in Figs. 1 and 2 are improved patterns which have been recently designed by the Toledo Machine & Tool Co., Toledo, O. The machine shown in Fig. 1, which is designated as No. 96 C, is a double-crank press so constructed that the press operators or attendants can work on the right- or left-hand ends and on the front and rear sides of the machine. This press is double back-geared and it is operated by a friction clutch (not shown) which is located on the lower of two pinion shafts on the right-hand side in the rear. This friction clutch is operated by the hand-lever seen on the right side of the machine, which gives the operator complete control for starting and stopping at any position of the stroke or slide motion. The two pinion shafts in the rear have been elevated above the gear centers, which gives a clearance or free space from the floor line to the lower pulleys of 7 feet, so that the operators are not subjected to danger because of the driving mechanism. Large openings are provided in each of the two housings, which will permit material being passed through from one side to the other when it is necessary to form parts of greater length than the width between the housings would permit without this construction. As the illustration shows, the press frame is built up of four pieces and is reinforced by a similar number of powerful steel tie-rods. The outboard pedestal bearing is eliminated in this type of machine so that a minimum of floor space is required. The weight of the machine is 65,000 pounds; the distance between the housings, 73 inches. The stroke and the distance from the bed to the slide are made to suit specifications.

Fig. 2 illustrates the No. 59 single-crank forging-trimming press which is a new type developed for trimming drop forgings. In this machine the detached outboard pedestal bearing has also been eliminated, which reduces the floor space and prevents any disalignment of the flywheel or pulley shafts. This press is operated by a powerful block clutch with gravity release or controlling mechanism. It has an unusually heavy balance wheel which, though small in diameter, provides sufficient power or momentum for obtaining the maximum output. The press is double back-geared, and it is intended for trimming long forgings for crankshafts and for similar work. The stroke of this machine is 9 inches; the distance from the

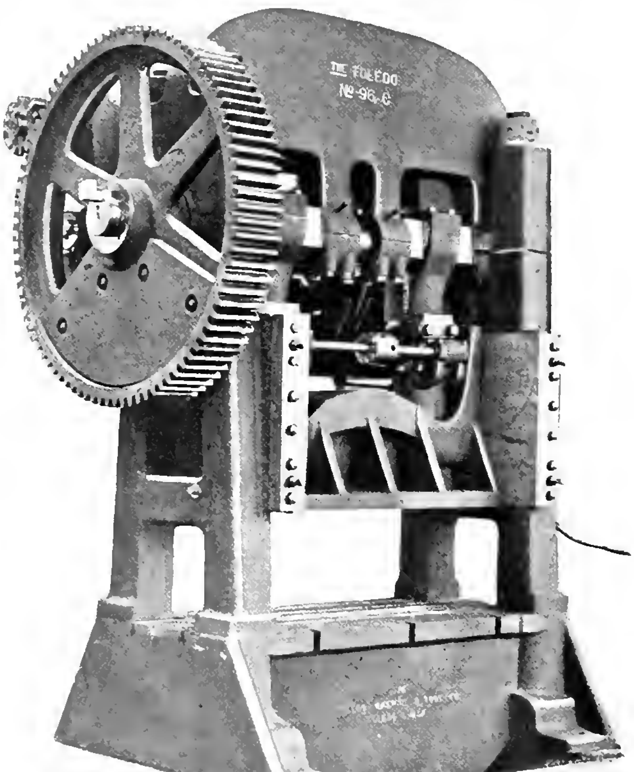

Fig. 1. No 96 C Toledo Double-crank Press

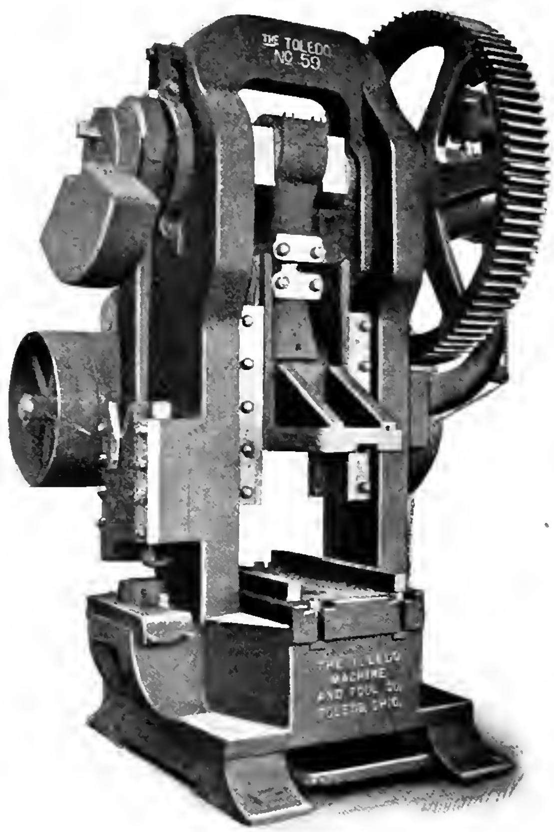

Fig. 2. No. 59 Toledo Single-crank Trimming Press for Forgings

bed to the floor, 24 inches; distance from the bed to the slide, 29 inches; width between the housings, 30 inches; length of bed, 56 inches. The stroke of the outer trimmer is $3\frac{1}{2}$ inches, and the bed measures 14 by 20 inches. The weight of this machine is about 12,500 pounds.

YOUNG MACHINE AND TOOL CO.'S LATHE MILLING ATTACHMENT

A lathe milling attachment that is particularly adapted for small shops and garages where there is not enough milling work to warrant the purchase of a regular milling machine, has been put on the market by the Young Machine and Tool Co., Worcester, Mass. This attachment is capable of a wide range of work and it has the commendable feature of being easily attached to or removed from a lathe. Its general construction is clearly illustrated in Fig. 1, which also shows the dividing-head, tailstock, vise, etc., while the other views, Figs. 2 to 6 inclusive, show the way it is fastened to the lathe carriage and also some of the milling operations which may be performed.

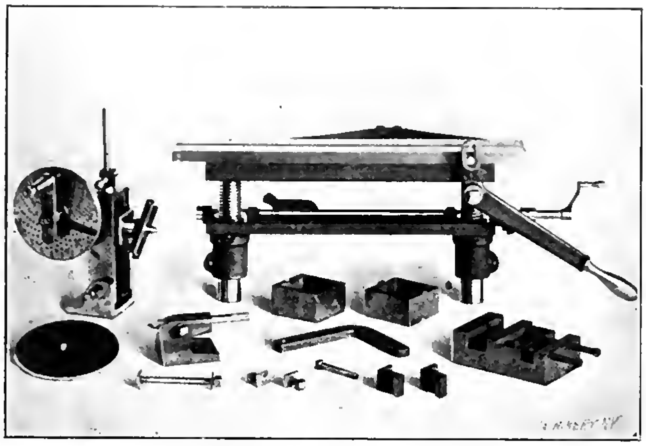

Fig. 1. Lathe Milling Attachment built by the Young Machine & Tool Co.

The attachment consists principally of a work-table that is supported by two square-threaded screws passing through nuts located in a base that is attached to the lathe carriage by two brackets, one of which is bolted to the front and the other to the rear. Meshing with these nuts, which have teeth cut in their peripheries, is a worm-shaft that may be operated by a crank at the front of the lathe to effect a vertical adjustment of the table, the nuts revolving about the screws which are rigidly fixed to the work-table. The attachment, in addition to being bolted to the carriage, is further steadied by two angle-pieces, located inside the ways on each side, one of which is adjustable, thus insuring a close sliding fit.

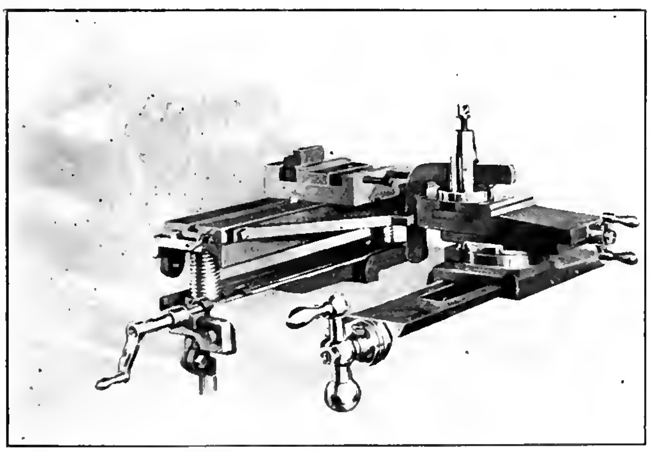

Fig. 2. Attachment set up for End Milling

Either hand or power cross-feed is available, the power feed being obtained from the lathe itself by connecting the table of the attachment with the lathe cross-slide. This connection is made by simply inserting an angle-piece in the tool-post (as in Fig. 2) and clamping it in such a position that engagement is made with a slotted side-piece bolted to the table. By this simple arrangement, a range of feeds is obtained equal to that available on the lathe. When a hand feed can be used to better advantage, the cross slide and table are disengaged by removing the angle-piece, which places the cross movement of the table under the control of the hand-lever seen on the left side of the attachment. This lever is in the form of a bell-crank and it has a slotted end which engages a pin attached to the table.

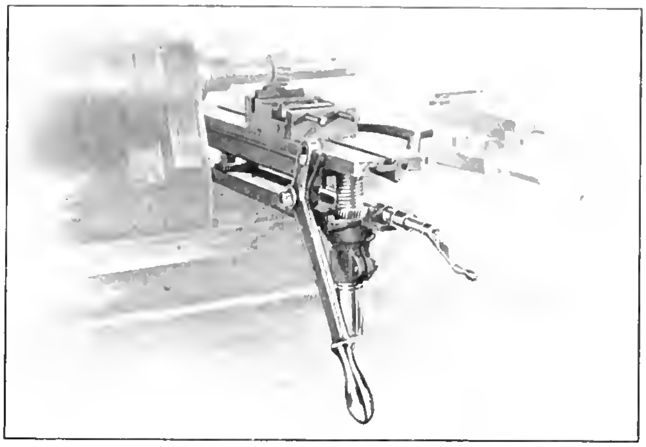

Fig. 3. Milling Light Work by using Lever Feed

By means of the dividing head furnished with this attachment, 133 divisions can be obtained which are as follows: Any number from 1 to 50, every other number from 50 to 100, and beyond that irregular divisions. This head is so attached to its base that it can be swiveled to a maximum angle of 55 degrees from the vertical, and graduations are provided indicating its position. Provision is made for taking up any wear which may occur between the worm and wheel of the dividing head, and a taper gib is used to eliminate play between the table and the slide.

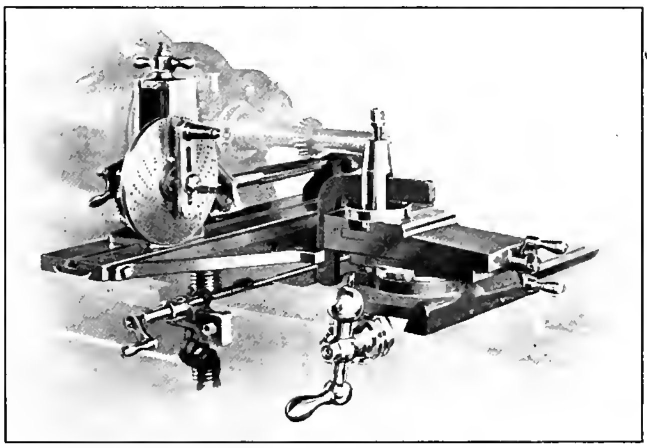

Fig. 4. Fluting a Taper Reamer

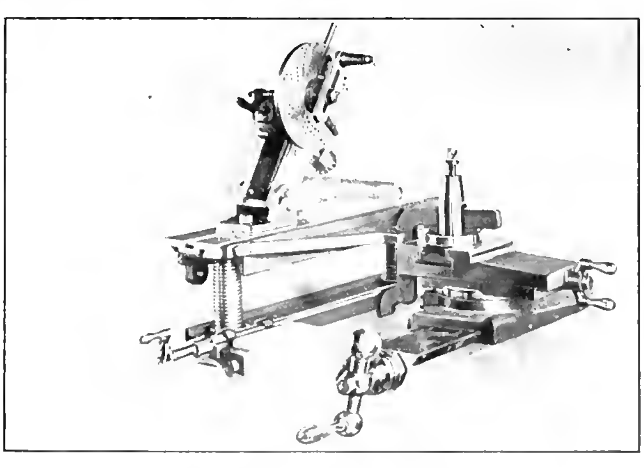

Fig. 5. Cutting a Bevel Gear

In Fig. 2 the attachment is shown set up for an end milling operation with the power feed in use, while Fig. 3 illustrates

the method of milling small parts with the lever feed, the work in both cases being held in the vise, which is part of the regular equipment. In Fig. 4 the method of fluting a taper reamer is indicated, the proper setting for the taper being obtained by the vertical adjustment of the dividing-head center. Fig. 5 shows the way the attachment is arranged for cutting a miter or bevel gear, the work being held in the spindle of the dividing-head, which is set over to the required angle. The method of using the attachment for cutting a spur gear is shown in Fig. 6, the work in this case being mounted on a mandrel between the centers. It will be noted that height

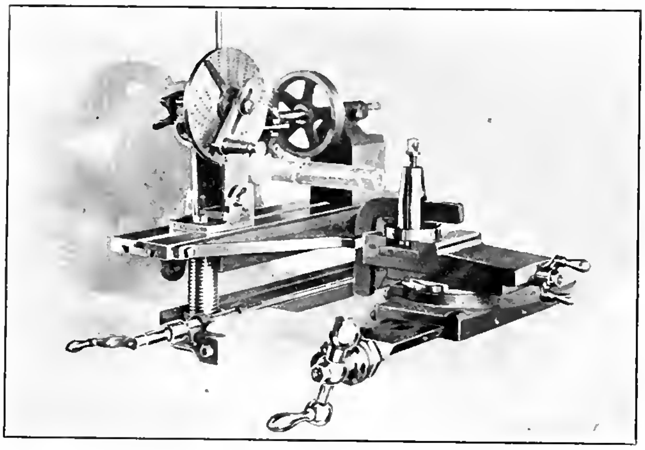

Fig. 6. Cutting a Spur Gear

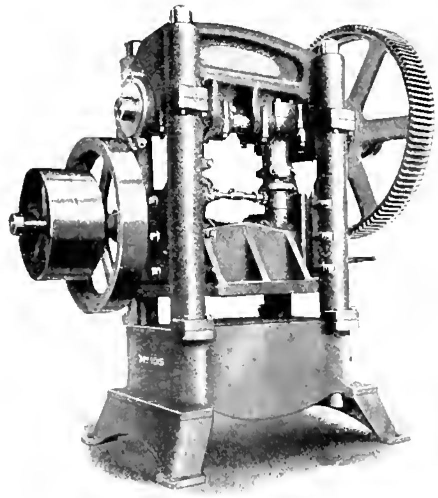
blocks are used beneath the tailstock to bring it to the required elevation.

Of course, much of the work for which this attachment is adapted can be bolted directly to the table, which is provided with a T-slot throughout its entire length, and has a working surface of 4 by 22 inches. The maximum distance between the centers of this attachment is 13 inches, and the dividing-head center can be adjusted vertically to a height of $5\frac{1}{2}$ inches above the table. This vertical adjustment is effected by a hand-nut at the top, which may be locked in any desired position. The spindle will be bored to receive either a No. 1, 2 or 3 Morse taper as desired.



No. 1015 Double Pitman Press built by the Max Ams Machine Co.

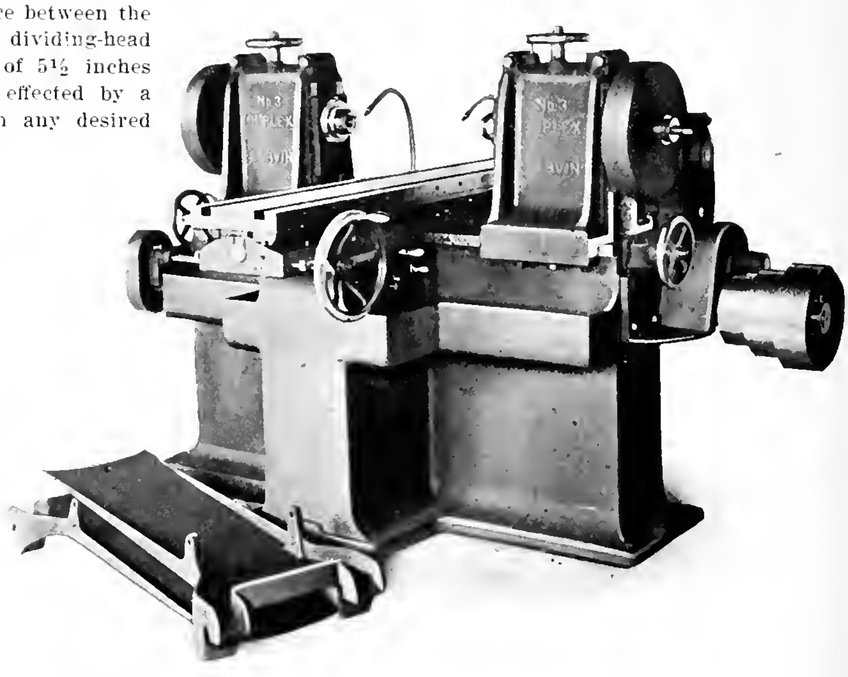
MAX AMS DOUBLE PITMAN PRESS

The Max Ams Machine Co., Mt. Vernon, N. Y., has brought out an interesting design of double pitman press, which is intended for stamping and forming operations of a severe character. The frame of this machine is of the built-up type, the entire working strain being taken by four steel tie-rods, as shown. The slide extends through openings in the uprights at each end, which makes it possible to utilize the entire length of the press bed, so that sheets 20 by 48 inches may be handled, while the distance between the uprights is only 34 inches. A sheet 25 by 25 inches can also be worked when feeding from front to back. The double eccentric shaft on this press is rigidly supported by bearings located on each side of the pitman connections as shown. The eccentrics are solid enlargements of the shaft itself, which gives very large bearings. The strain is taken directly by the main frame instead of the cranks, which prevents springing and eliminates any uneven wear. The clutch is solid with the shaft, and, besides being strong and durable, is practically noiseless. All other features common to this style of press, such as parallel adjustment of the slide, strong pitmans, etc., are embodied in the construction. The driving pulleys of this machine are 28 inches in diameter, and have a 6-inch face. The flywheel weighs 1100 pounds, and the gearing ratio is $8\frac{1}{2}$ to 1. The complete weight of the press is 20,000 pounds.

GARVIN NO. 3 DUPLEX MILLING MACHINE

The Garvin Machine Co., Spring and Varick Sts., New York City, has brought out the duplex milling machine illustrated herewith, which is designed to give a longitudinal table feed of 60 inches without any deflection or cramping action in the slide. The table is 64 inches long and its bearing in the saddle has a length of 60 inches. The feed to the table is by means of a square-threaded steel worm of large diameter and a spiral rack. This spiral rack is cut from the solid on the under side of the slide, and the worm is made in halves for taking up wear. It should be explained that the grooves in the slide illustrated were made for special work, the regular pattern having three standard T-slots.

Particular attention has been given by the makers to the matter of taking care of the chips and the lubricant from the cutters. The two shield castings shown on the floor are bolted to the saddle and serve to drain all the lubricant that drips from the slide when the latter overhangs the saddle, to the oil and chip channels which are cast all around the upper edge of the base, as shown. These channels communicate with one another, and in them there are chip strainers located about half-way in their depth, thus leaving a clear oil space all around from which the pump draws its supply through a fine strainer and delivers it through flexible pipes to the work.



Garvin No. 3 Duplex Milling Machine

The drive to the spindle is from a common splined shaft through spur gearing, back-geared in the ratio of 6 to 1, from a three-step cone pulley, which is driven from an overhead countershaft. The machine has 12 positive feed changes, and 3 speed changes for the spindles. The taper holes in the spindles are No. 11 Brown & Sharpe taper, and they have the positive slot drive. A draw-rod which reaches through from the rear end of each spindle holds the taper shank of the tool firmly in its seat. The threads on the outside of the two spindles are cut right- and left-hand, respectively, and to

the standard Brown & Sharpe size of $3\frac{1}{4}$ inches in diameter by $3\frac{1}{2}$ pitch. The table has a working surface of 12 by 64 inches. The maximum distance between the spindles is 27 inches, and the minimum distance, $4\frac{1}{2}$ inches. The spindles may be adjusted vertically from $1\frac{1}{4}$ inch to 9 inches above the surface of the table.

AUTOMATIC KNIFE ROLLING MACHINE

Over two decades ago it was discovered that table knives could be correctly shaped by grinding them on the face of a cup wheel somewhat beveled inward. This gave the convex cross-section of blade which pleases the eye and backs up the

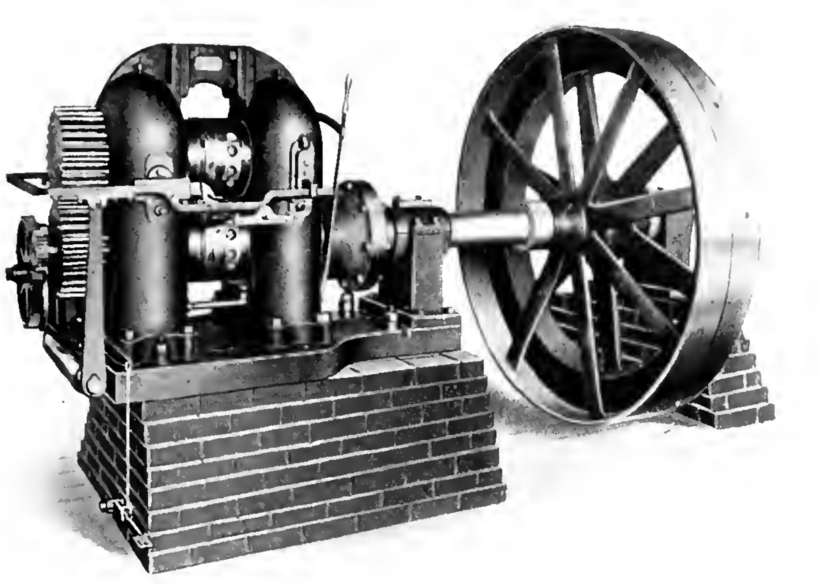


Fig 1. Automatic Knife Rolling Machine built by the New Britain Machine Co

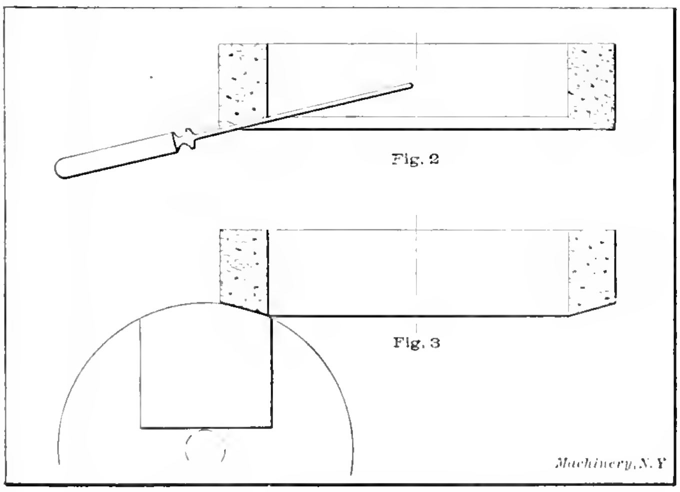
cutting edge. The discovery was important and it formed a foundation upon which automatic knife grinding machines then and since have been built for eliminating the drudgery and uncertainty of hand work.

Singularly enough, the same inventor, but years later, thought out the correlative process of shaping dies for hot-rolling knife blades by grinding these dies concave on the face of a cup wheel beveled in the opposite direction from the knife grinder.

The use of and connection between these two discoveries will be seen from Figs. 2 and 3 considered in connection with the cross-sections of the typical knife blade shown in Fig. 6. These sections show the uniform thickness of the cutting edge,



Figs. 2 and 3. Diagrammatical Views illustrating Use of Cup-wheel to obtain Convex Blade and Correlative Process of Shaping Rolling Dies

the convexity of cross-section and the tapering back, the thickest part being at the bolster.

Previous to rolling, the knife blank appears as shown in Fig. 4, the handle and bolster having been drop-forged and the metal near the bolster spread enough in width to start rolling. It will be noted that the flash need not be removed, and that stock of either round or elliptical section may be used for rolling. Fig. 5 shows the knife as rolled automatically in two passes, and Fig. 6 the knife as finished forged and trimmed with a uniform grinding allowance.

It has been common practice for years to roll blades in interrupted or kidney rolls, running toward the operator, the work held in tongs, being pushed through and the dies forcing it back. Two passes through and back are necessary, owing to the tendency of the first rolling to bow the blade scimitar shape and to leave it rough. The second pass in second dies straightens the blade and leaves a better surface.

In hand rolling, the presentation of the work to the rolls must vary with the workman's skill, and the blank must be held for both rolling operations. In automatic rolling, with the machine illustrated in Fig. 1, the knife is always brought to the same position on the die, and as accurately transferred to the second die without the attention of the operator beyond the initial placing of the heated blank in the gripper. When this has been done, the operator can turn to the fire for a second blank while the first is still in the rolls, and he can easily maintain an output of over four hundred blades an hour—more than twice the hand rolling production. The gripper and the mechanism for transferring the blank from one die to the other are illustrated in Figs. 7 and 8, which show respectively, front and rear views of the rolls.

It has been found advantageous to use alloy steel for the dies, as they hold their shape four or five times longer than do carbon steel die blocks. These dies, which are plainly shown in Figs. 7 and 8, are held in the rolls by wedges, and they are readily removed for grinding or changing. The barring holes shown in the fly-wheel rim (Fig. 1), assist in setting the dies.

The grippers too are readily changed for handling various shapes of bolsters and tangs, a few of which are shown in Fig. 9. Fork blades are similarly rolled and held.

The hand lever with the notched quadrant shown to the

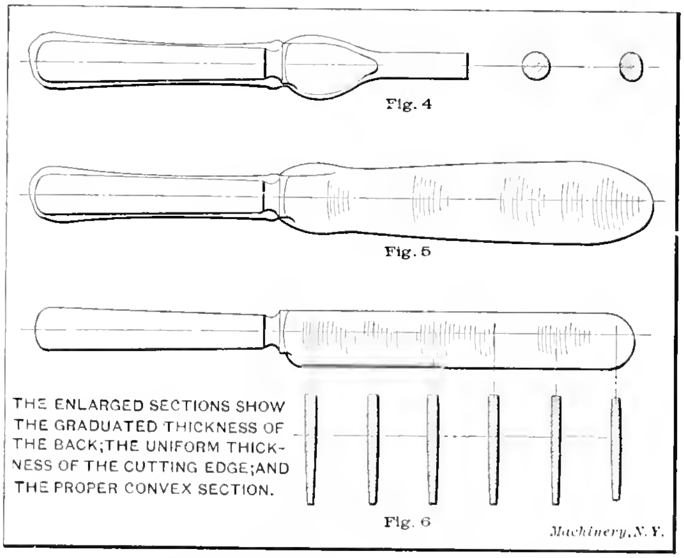


Fig. 4. Blank previous to Rolling. Fig. 5 Knife as rolled in Two Passes
Fig. 6. Knife as finish rolled and trimmed

right of the machine (Fig. 1), controls the thickness of the finished blade; its position may be varied while the machine is running, thus grading the thickness in steps of 0.001 inch. This machine, as illustrated, has the gear guards and belt shipper removed to more clearly show its construction.

Obviously, the closer and more uniformly blades are rolled, the better for the grinding machine, as a small variation in the rolled product means fewer passes by the wheel to bring all blades to a standard. It will be clear then, that a die grinder forms an essential part of the outfit. The grinder shown in Fig. 10 has been designed to produce or duplicate any shape of die desired. The dies are shown in the left foreground with their grinding holders next to them.

Interchangeability in the cup wheels is provided for. The

wheel runs in a safety hood and the spindle in self-oiling boxes. All controlling adjustments are made without recourse to wrenches and without leaving the operating position. The wheel when in use is flooded with water through the piping shown.

These machines are patented and are made by The New Britain Machine Co., which is located at New Britain, Conn., in the immediate proximity of the largest knife concerns in this country.

WATERBURY FARREL AUTOMATIC SCREW SLOTTER

The automatic screw slotting machine illustrated herewith, which is a design recently developed by the Waterbury Farrel Foundry & Machine Co., Waterbury, Conn., embodies a number of new and interesting features which insure accuracy and high quality in the product, as well as economical production. The blanks to be slotted are automatically fed from a hopper

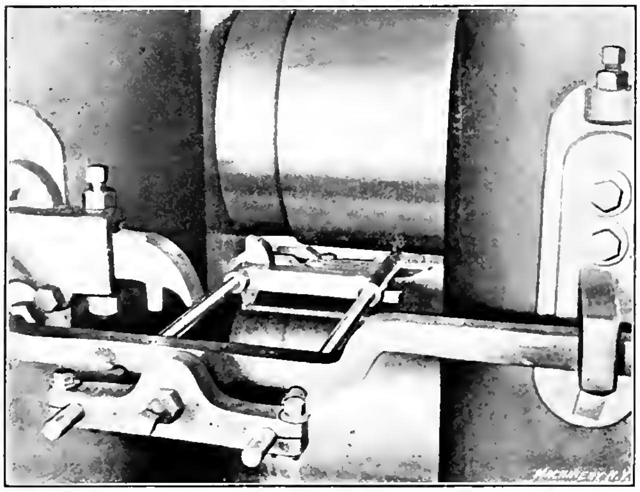

Fig. 7. Front View of the Gripper

to the slotting saw, from which they are delivered to a receptacle without attention on the part of the operator. While the slotting operation is taking place, the screw blank is rigidly held and the frame which carries the saw is also rigidly fixed to avoid chattering. This frame is provided with sensitive lateral and front-to-back adjustments, which accurately locate the position of the saw with respect to the screw-head. The saw also has an adjustment for determining the depth of the slot, which can be operated when the machine is running, and provision is made for allowing the maximum amount of time

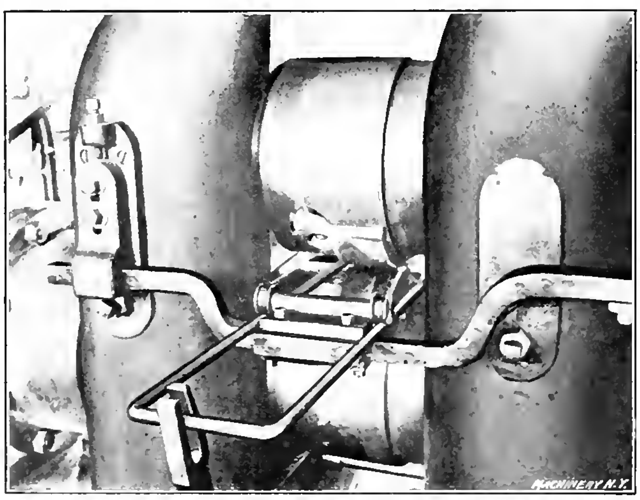

Fig. 8. Rear View of the Gripper

for slotting, even though the slots are of varying depths. The saw is well guarded, not only to protect the operator, but also to prevent the oil and chips from flying. This guard is so constructed that it may be quickly swung out of the way when changing saws.

The machine is arranged so that the chips and finished blanks are delivered into separate receptacles, the chips entering the small removable box seen in the illustration, while the screws are delivered into a pan (not furnished with the machine) placed at the right of the box. Provision is made for supplying the lubricant to the blanks and saw while the slotting is taking place. This lubricant is pumped from a tank (located below the bed), by a small geared pump, which forces it through suitable piping to the operating point, whence it flows with the chips into the chip box, where the chips sink to the bottom and the lubricant flows off the sides and drains back into the tank.

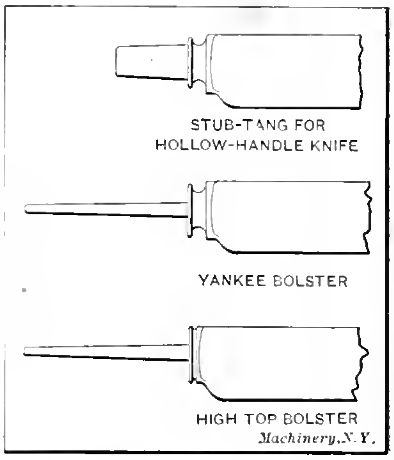

Fig. 9. Bolsters and Tangs of Various Shapes

This machine can be operated at the speed which is most suitable for the particular screw to be slotted. The power for driving the saw is obtained from a countershaft, by belt on a pulley 4 inches in diameter by 1½-inch face, which is geared to the saw spindle in the ratio of 3 to 1 for steel work, while for brass a pulley of the same size is located directly on the spindle. The hopper-feeding mechanism has simple adjustments which adapt the machine not only for work which is done in long runs, but for short runs as well. To shift from

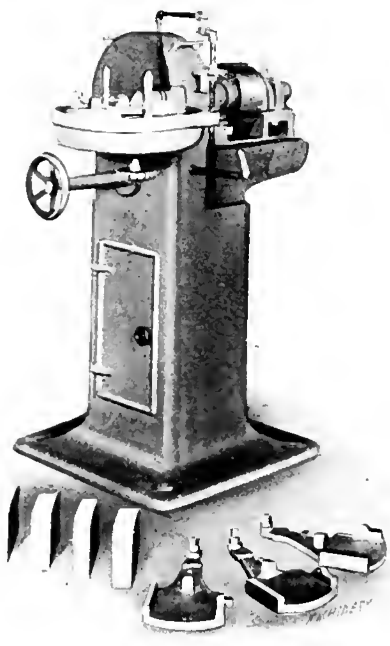

Fig. 10. Machine for Grinding the Diee

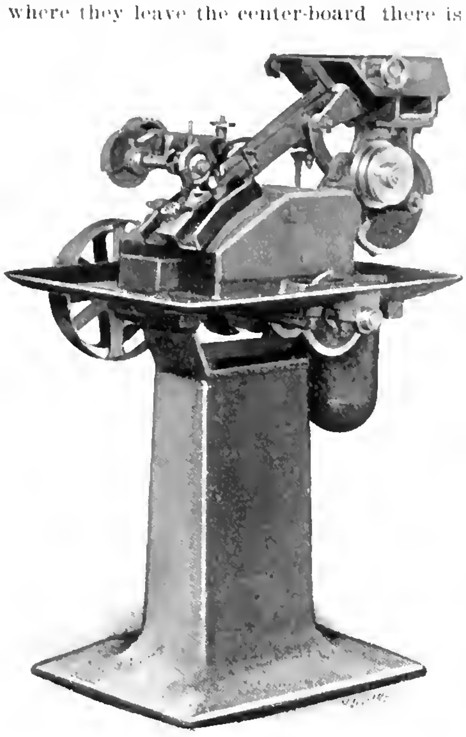
one size blank to another, it is necessary to replace two pieces only. Blanks having short shanks are handled equally as well as those with long ones within the capacity, which is 1½ inch under the head. The maximum diameter of shank for which the machine is adapted is ¼ inch. Blanks having a length of shank equal to one diameter have been successfully fed by the hopper and slotted, but so much depends upon the shape and size of the head that it is difficult to give definite information regarding the minimum lengths allowable. For this reason the builders solicit samples of the blanks to be slotted before recommending this machine. The hopper is driven by a round belt from the machine itself through cone pulleys, which provide means for speeding the hopper to suit the work.

In the operation of this machine, the blanks are placed in the hopper where they are caught by their heads in a blade or center-board, which has a slot along its top a little wider than the diameter of the blank bodies. This center-board, which, at its lower position is parallel with the bottom of

the hopper, swings vertically through the latter; as it is elevated through the mass of blanks, some are caught in the slot by their heads and are carried to the upper position where the center-board acts as an extension to the inclined chute. Here the blanks slide down into the chute, and near the point where they leave the center-board there is a rapidly-



Automatic Hopper-fed Screw Slotting Machine

revolving toothed wheel located and adjusted so that any blanks which enter the chute in an improper position are thrown back into the hopper. This leaves the entrance to the chute clear and prevents clogging. At the foot of the chute, the blocks enter what is called the carrying dial, which is 2 7/16 inches in diameter and ½ inch thick. If a blank should be held so that it was half in the dial and half in the chute, a slight special motion which is given the dial agitates the column of blanks and starts the feed after the loss of only one revolution of the machine and entirely without attention from the operator. This carrying dial has V-notches cut in its periphery in which the blanks are carried from the chute to the point where they are slotted. After this operation has taken place, the blanks are carried a little further and delivered into a receptacle.

The chute cover is hinged so that it can be swung up for removing any blanks that might become lodged. The hopper blade is made with a removable top containing the pick-up slot, which is changed for screws of different sizes. These can be furnished slotted and drilled for fastening them to the hopper slides. The carrying dials can also be furnished ready to put on the machine. The chute is adjustable for different diameters within the limits of the machine, and the design of the latter is such that it can be readily adapted to larger or smaller sizes.

The main drive of the machine is through a two-step cone pulley. The saw is held on its spindle between two clamps by a nut, no key or dowel pin being used. The size of the saws for which the machine is designed is 2¾ inches in diameter. Slightly larger saws can be used, as well as the standard sizes which have grown smaller by grinding. The saw spindle runs in bronze bushings, and the one next to the saw is tapered and split for taking up wear.

A feature to be considered in connection with this machine is the size of the head and slot. For example, a 1/8-inch screw having a very large head might be slotted on this machine, while a ¼-inch screw with a head of extraordinary size might require a larger size machine, whereas if it had an ordinary sized head, the one illustrated would handle it with perfect satisfaction.

Standard stock machines are furnished with a countershaft, a pulley for the saw spindle for brass-work, a set of wrenches, a saw and a dial, all suitable for work similar to the sample which should be furnished so that each machine can be tested on blanks for which it is intended, before shipment.

INTERNATIONAL BELT SHIFTER

A design of combination belt shifter is shown in the accompanying engravings, which, in addition to shifting the belt, retains it when in the off position, thus completely disconnecting the belt from the shaft pulley. The general construction and the method of operation of this shifter are indicated in Figs. 1 and 2, which show the belt on the driving pulley and its position when shifted, respectively.

The apparatus consists of a frame, similar in form to a segment of the pulley rim. Projecting from the curved part of this frame toward the pulley rim there are a number of spindles which carry sleeves or rollers. These rollers form a support for the belt when the latter is shifted, thus performing the function of the ordinary loose or idler pulley. The mechanism employed for shifting the belt consists of front and rear shift-bars, which are mounted in brackets and from which project rollers for engaging the belt. The front shift-bar moves the belt from the driving pulley onto the retaining rollers, and the rear bar shifts it back to the pulley. These shifters, as the engravings show, are operated by pull-chains and they are automatically returned to their original position

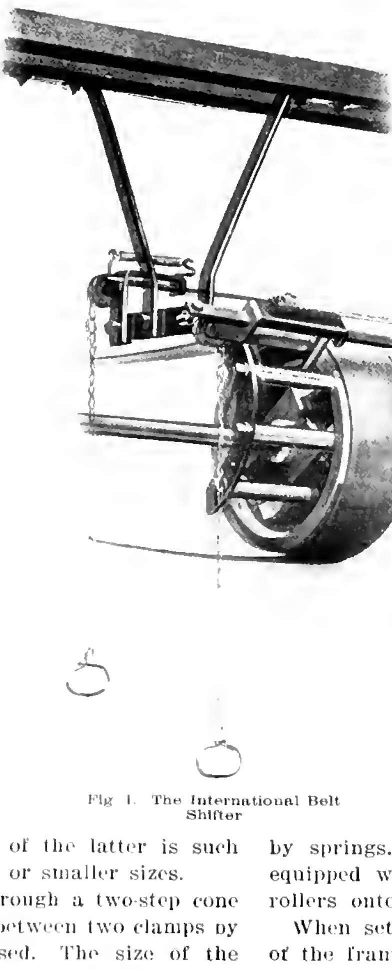


Fig. 1. The International Belt Shifter

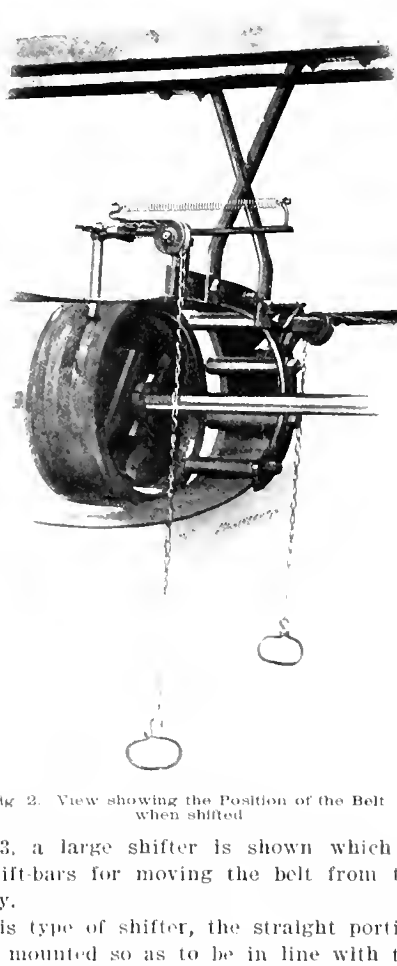

Fig. 2. View showing the Position of the Belt when shifted

by springs. In Fig. 3, a large shifter is shown which is equipped with two shift-bars for moving the belt from the rollers onto the pulley.

When setting up this type of shifter, the straight portion of the frame must be mounted so as to be in line with the belt. The first roll is located at the point where the belt runs onto the pulley, and the first three or four rolls should be 1/8

or 3/4 inch higher than the pulley rim. A sufficient number of holes are drilled in the frame so that the shifter can be bolted to the hangers in any position. It is stated that large, as well as small belts, can be shifted rapidly and without exertion. By the use of this type of belt shifter, particularly in large plants, it will be seen that considerable friction will

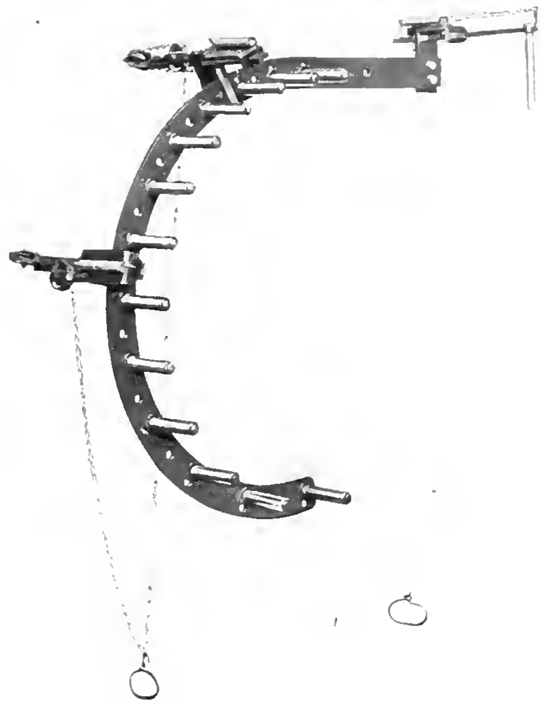

Fig 3. Large Shifter with Two Shift-bars for Transferring the Belt to its Pulley

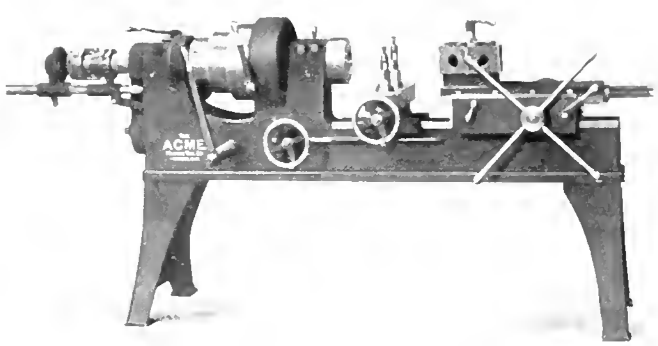
be eliminated and the life of the belts prolonged. It is manufactured by the International Belt Shifter Co., 624 Vance St. Toledo, O.

ACME TURRET LATHE

The Acme Machine Tool Co., Cincinnati, O., has recently brought out a line of turret lathes of the design shown in the accompanying engraving. These machines are especially constructed to withstand the strains incident to the use of high-speed steels. They are furnished with or without a power feed to the turret, and also with or without an extra capacity automatic chuck. The head is of the friction geared type and the back-gears can be thrown in or out without stopping. Two



Turret Lathe built by the Acme Machine Tool Co.

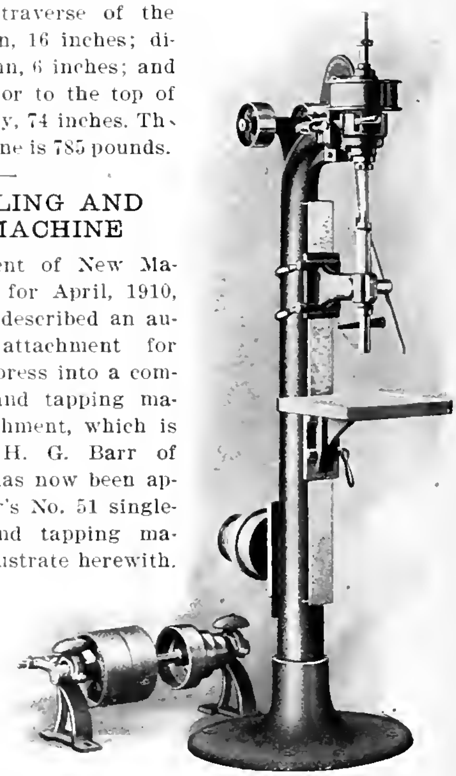
spindle speeds are available for each cone step. The turret, which is of hexagonal form, has a hole through the central stem, of the same diameter as the tool holes. Tapped holes are provided for bolting tools to the turret faces and there are independent adjustable stops for each hole of the turret. The abutment for these stops can be shifted, thus allowing a slight further movement beyond any stop, when this is desired, without disturbing the adjustment. The power feed of the turret is of the geared type, and four rates of feed are instantly obtainable by shifting a lever. The distance from the center of the turret to the top of the slide is sufficient to permit swinging large dies and turret tools. The cut-off has a hand longitudinal adjustment, and it is set low so that work of large diameter will swing over the slide. A double-friction countershaft of improved design accompanies every machine.

SNYDER 20-INCH UPRIGHT DRILL

A new design of 20-inch upright drill has recently been brought out by J. E. Snyder & Son, Worcester, Mass. While the general design of this machine does not differ from the 20-inch size formerly manufactured by this company, it is of somewhat heavier construction, the main column, the arm for supporting the table, and the base, being rigidly designed. The spindle may be fed either by handwheel or lever and the latter is equipped with a ratchet mechanism. The spindle is counterbalanced by a weight inside the column and it has a quick return motion. This machine will drill to the center of a $20\frac{1}{2}$-inch circle, and its general dimensions are as follows: The vertical traverse of the spindle is 9 inches; the greatest distance from the base to the spindle, 41 inches; the greatest distance from the table to the spindle, 26 inches; diameter of the spindle in the sleeve, $1\frac{1}{2}$ inch; traverse of the table on the column, 16 inches; diameter of the column, 6 inches; and height from the floor to the top of the upper cone pulley, 74 inches. The weight of the machine is 785 pounds.

BARR DRILLING AND TAPPING MACHINE

In the department of New Machinery and Tools for April, 1910, we illustrated and described an automatic tapping attachment for converting a drill press into a combination drilling and tapping machine. This attachment, which is manufactured by H. G. Barr of Worcester, Mass., has now been applied to the builder's No. 51 single-spindle drilling and tapping machine, which we illustrate herewith. This machine drills holes up to 3/4 inch in diameter, and has a tapping capacity for holes up to 1/2 inch in diameter in cast iron. All gears are made of machine steel and the clutches and trip pins are of tool steel tempered singly. The general construction of this machine is plainly indicated by the engraving.



Barr Single-spindle Drilling and Tapping Machine

This tapping attachment is also applied to the Barr multiple spindle machines. With this type, the tapping spindles can be arranged in combination with the spindles having lever or power feed, in the way best adapted to meet individual requirements.

MOLINE MULTIPLE SPINDLE DRILL

The Moline Tool Co., Moline, Ill., has recently added to its line of drilling machinery another design of multiple spindle drill, which we show in Fig. 1. This machine is equipped with the company's regular double spiral drive, but it has a spindle feed in place of a table feed. The feed is entirely spur geared, there being no worm reduction, and the feeding mechanism is so arranged that it can be tripped automatically at any point.

By referring to Fig. 1, it will be seen that there is a continuous pinion, or what might be called a pinion shaft, running the entire length of the machine. Meshing with this pinion shaft for each spindle is a combined gear and pinion, so mounted on a swinging stud that the pinion can be brought into or out of mesh with a large gear A, Fig. 2. This gear is mounted on the same shaft as the feed pinion B, which

meshes with a rack cut in the spindle quill. On the lever *C* which carries this swinging gear and pinion, a feed handle is mounted, so that when this handle is pulled down, the feed is thrown in and locked, and when it is pushed up, the feed is unlocked and thrown out of engagement. To the upper end of the spindle quill, a bracket is attached, carrying a stop-rod *D*, which, as it descends, engages with the tail of the feed catch *E*, thus throwing the feed out automatically. As the

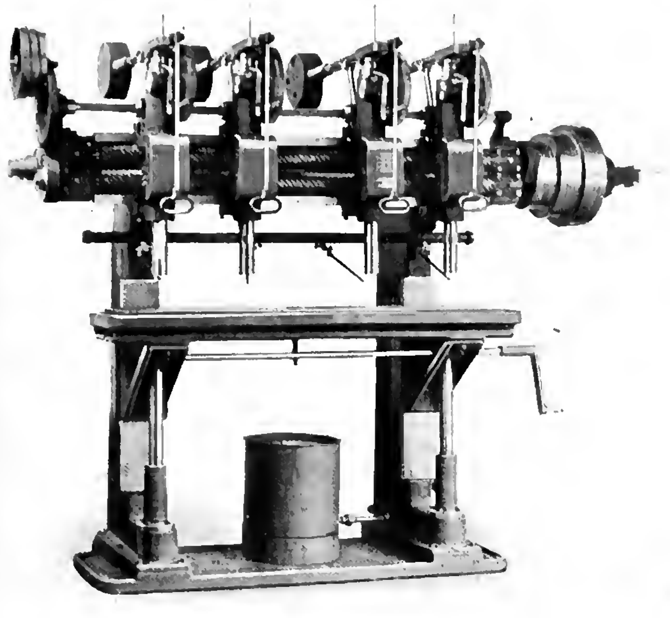


Fig. 1. Moline No 22 D Multiple Spindle Drill with Spindle Feed

engraving indicates, this stop-rod can be adjusted to disengage the feed at any predetermined point. This arrangement of the feeding mechanism gives each spindle, in addition to an automatic stop, independent feed, which is easily controlled.

The spindles are counterbalanced, and they may be rapidly traversed by the handled rods shown. This drill has a capacity for drills up to 2 inches in diameter in steel, with minimum and maximum center-to-center distances of 6 inches

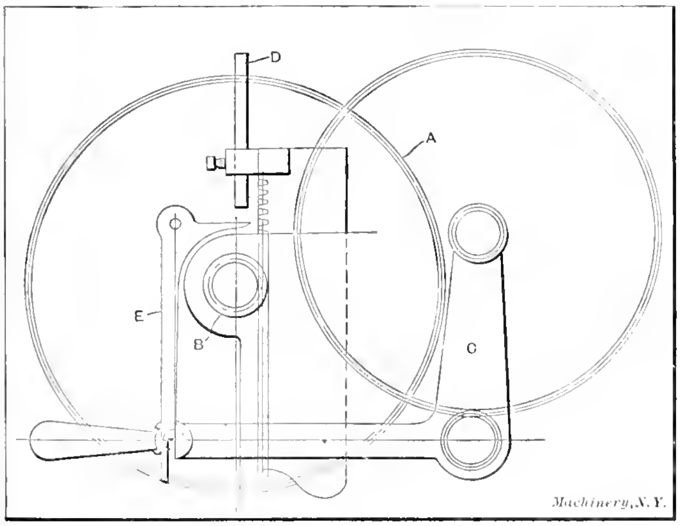

Fig. 2. Arrangement of the Feeding Mechanism

and 5 feet, respectively. The spindles run in bronze bushings and the feed racks are cut from the solid in the steel quills, which are also bronze bushed. The machine has ball thrust bearings and it is back-geared. The table is vertically adjustable by the crank and elevating mechanism shown, and it is provided with a wide channel for catching the lubricant. A pump with tank and piping will be furnished when so ordered.

REINECKER UNIVERSAL TOOL GRINDER

The increasing use of the hobbing machine for producing spur, worm and spiral gears, has created a demand for a tool grinder fitted with a spiral dividing head for grinding spiral-fluted hobs. In Europe, where the practice of hobbing gears has been developed to greater proportions than in the United States, makers of hobs have almost entirely discarded the straight-fluted type in favor of the spiral flute, their experience being that a spirally-gashed hob is more easily driven and cuts more freely than one that is straight-gashed. This has been found particularly true in the case of hobs used for cutting worm-wheels, a marked improvement being noticed when the gash runs at right angles to the thread, especially for hobs of small diameter or those having double or multiple threads. In these cases the spiral gash insures equal cutting angles for both flanks of the tool.

The tool grinder shown in the accompanying engraving, which is the product of J. E. Reinecker, of Chemnitz, Germany, is especially designed for grinding hobs as well as other spiral- and straight-fluted tools. This machine is also adapted for grinding cylindrical and taper work, and for internal grinding as well, by the use of an internal grinding attachment. Besides the uses mentioned, the machine may be employed for grinding milling cutters of all types, cylindrical and taper reamers, taps, etc. It can also be used for surface grinding on such work as dies, small plates, form cutters, etc.

Universal Tool Grinder set up for Grinding a Spirally-fluted Hob

The machine illustrated is the No. 2 size, which has a capacity in length between the centers of 25½ inches, and for diameters up to 7 7/8 inches. The table travel of the grinder shown, is automatic, but it is also built with the hand table traverse. The table is driven from the cone pulley at the base, which is connected with the reciprocating mechanism, through the column of the machine, by gears and shaft connections.

The indexing mechanism of the No. 2 machine is operated by hand, although the makers build a larger machine of the same type with an automatic indexing head, so that the dividing motion, as well as the traverse of the table, takes place automatically. The feed of the table for obtaining the correct lead for the spiral flute to be ground, is obtained by change gears the same as with the milling machine. Twenty change gears are provided, which give leads ranging from 6 to 280 inches. The lead of the spiral flutes in the particular hob shown mounted in the machine, is 172 inches.

The longitudinal and cross-slides are mounted on a base which swivels on the knee, the angular position being indicated by suitable graduations. The knee itself can also be swung about the column and, as the engraving shows, it can be adjusted vertically on the column by a handwheel at the side, which connects through bevel gears with a vertical ele-

vating screw, that passes through a nut supported by a projection on the base. On the back end of the spindle, a fixture

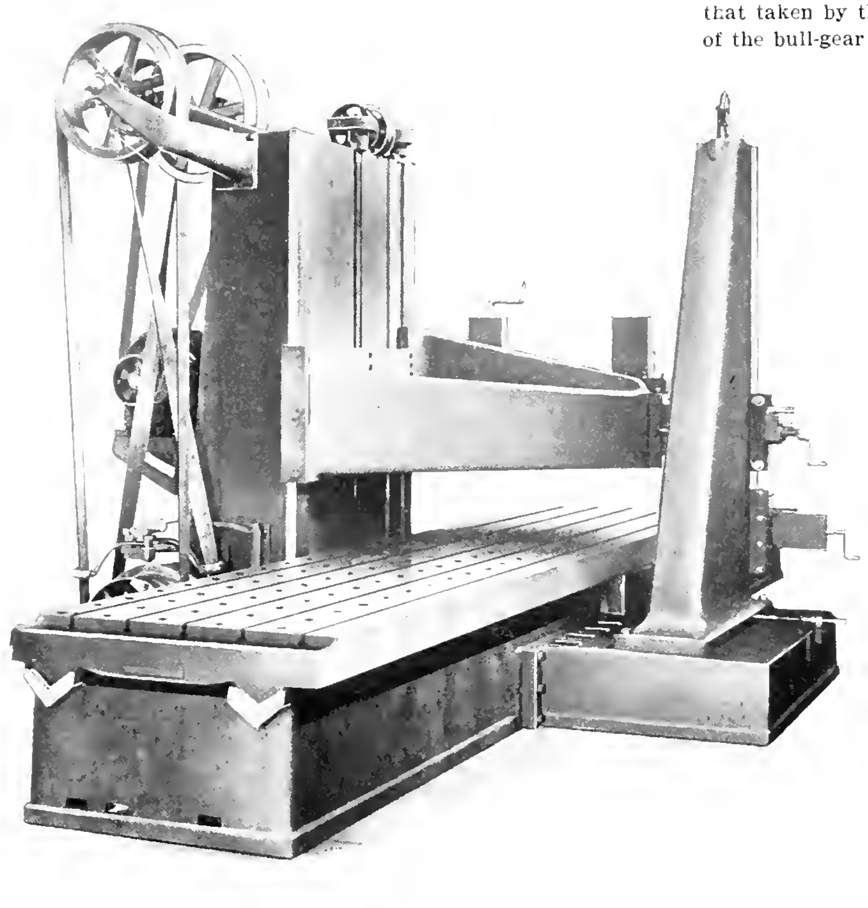

Fig. 1. Cleveland Open-side Planer with Removable Column for Supporting a Fourth Head

is arranged for grinding thin milling cutters and plain tools on a hand-rest.

The Carpenter-Kerlin Gear & Machine Co., 77 White St., New York City, are the American agents for this machine.

CLEVELAND OPEN-SIDE PLANER

The Cleveland Planer Works, 3150-3152 Superior Ave., Cleveland, O., has recently added to its line of open-side planers the 60- by 84-inch machine illustrated herewith. This planer is arranged with an outside column which may be employed to support a fourth head when such an addition can be used to advantage. It should be stated that this is the sole function of the extra column which is not intended as a stiffener for the cross-rail. The bed of this planer, and also the column and cross-rail, are of box section, which gives a stiff and strong construction. The bed is cast closed on the top and it has a number of solid cross-ribs located at frequent intervals. The column is cast solid with the bed up to the table level, at which point the upper section is securely bolted and doweled to it as shown. The cross-rail, which is raised and lowered by power, has an extremely broad bearing on the face of the column, as the engraving shows. It is square-gibbed to the column and can always be drawn up parallel to the table. The heads can be operated from either side of the machine, and automatic feeds are provided in all directions. The side-head has a broad bearing directly on the column and it can be lowered entirely out of the way when it is desired to use the rail-heads close to the table. The table has a depth of $9\frac{1}{2}$ inches, and it is provided with T-slots and holes at frequent intervals which are not bored through. The bull-gear pinion is of forged steel and integral with its shaft. The bearings for the bull-gear are in heavy bosses cast in the sides of the bed and they occupy the entire space between the sides except that taken by the bull-gear hub. All gears with the exception of the bull-gear and its pinion run in oil, and all the bearings are lined with phosphor-bronze. These bushings are pressed in so that they can easily be removed at any time, when worn, without interfering with the alignment of the machine in any way. All the gearing in the running parts can be removed from the sides of the machine, thus making it unnecessary to disassemble the planer if repairs should be needed. The large loose driving pulley runs in a box bushing set in back of the column base, thus relieving the running shaft and stiffening it out to the hub of the double tight pulley.

Some of the principal dimensions of this planer are as follows: Length of the bed over all, 21 feet 8 inches; distance between the V's, 36 inches; angle of the V's, 100 degrees; number of automatic oilers, six. The table has a length over all of 15 feet, and a width of 54 inches. The height of the cross-rail bearings on the face of the column is 36 inches; the width of the cross-rail bearing on the face of the column, 64 inches; and the length of the saddle bearing on the rail, 19 inches. The table has a return of from $2\frac{1}{2}$ to 1 to 3 to 1, and the cutting speed is suited to the requirements of high-speed steels. This planer, as the engraving shows, is electrically driven, the motor being mounted on a bracket attached to the side of the column. The motor is of the variable speed type, and develops 25 horsepower.

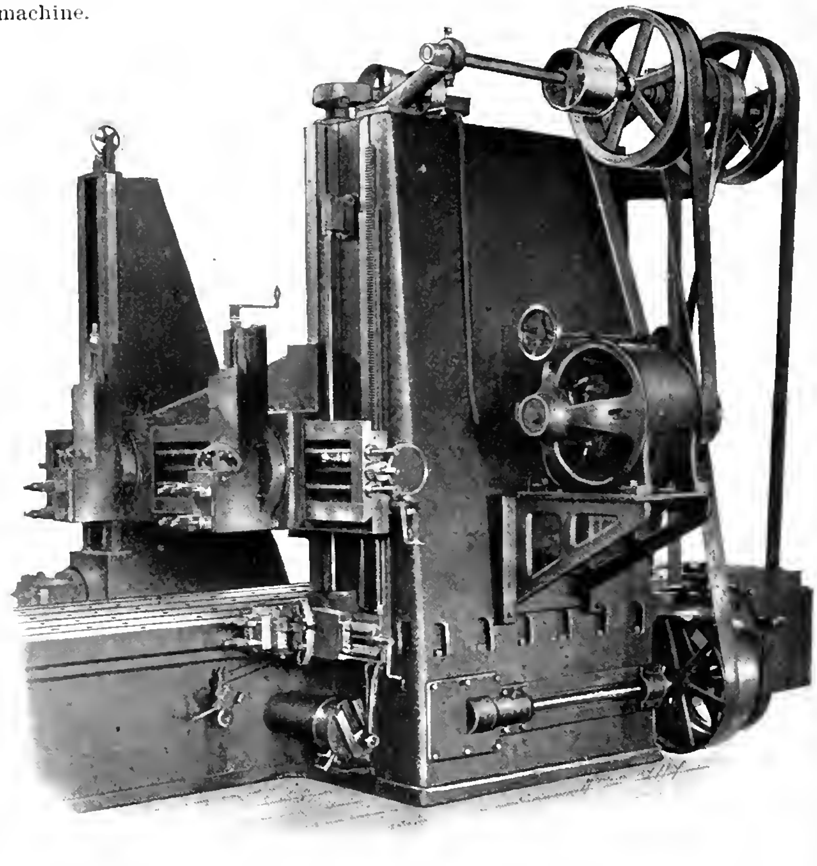

Fig. 2. Front View of the Cleveland Open-side Planer

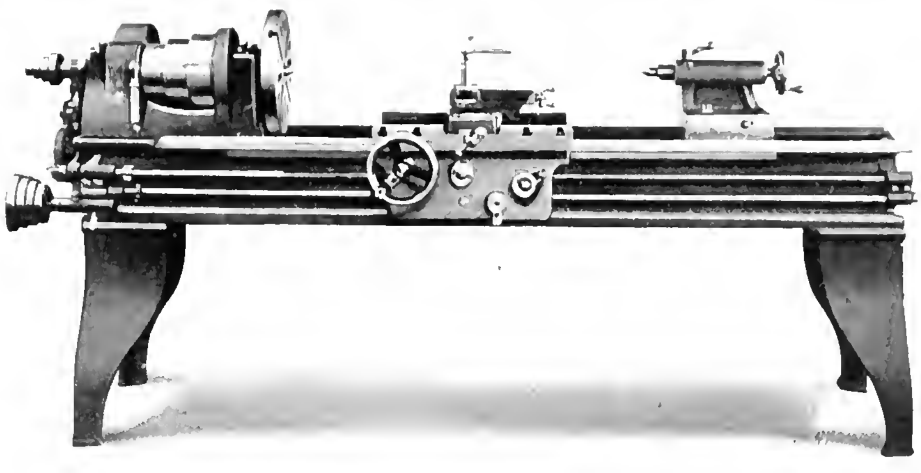
MIAMI VALLEY 16-INCH ENGINE LATHE

The latest design of engine lathe brought out by the Miami Valley Machine Tool Co., 843 Germantown St., Dayton, O., is shown in the accompanying engraving. This machine, which is of the same general design as the single back-geared 16-inch

lathe manufactured by this company, is equipped with a double back-gear and a wide three-step cone, which gives a powerful drive, thus adapting the lathe to heavy duty.

The back-gears are shifted by the hand lever shown at the front of the headstock, and their respective ratios are 5.6 and 9.6 to 1. The carriage of this lathe has a bearing $23\frac{1}{2}$ inches in length, and it is gibbed both front and back. The cross-bridge is heavily ribbed, and the cross-slide and compound rest are of heavy design and well gibbed. The compound rest slide has been lengthened so as to give a feed of 5 inches. The tailstock is of the offset design which allows the compound rest to be set at 90 degrees, or in a position parallel with the bed.



Miami Valley 16-inch by 8-foot Standard Engine Lathe

Either a belt-driven or positively-geared feed can be used on this lathe, a gear on the feed-rod meshing with either a gear on the cone-shaft or one on the screw, thus giving, in addition to the four belt feeds, those obtainable with the change gears. The thread-cutting capacity ranges from 5 to 40 threads, including $11\frac{1}{2}$ threads to the inch. The regular equipment of this lathe includes a full set of change gears, a compound rest, both large and small faceplates, steady- and follow-rests, wrenches and a double-friction countershaft.

HENRY & WRIGHT MULTIPLE SPINDLE DRILL

The eight-spindle ball-bearing drilling machine shown in the accompanying engraving is a new model that is being built by the Henry & Wright Mfg. Co., Hartford, Conn. The

New Model Henry & Wright Eight-spindle Drilling Machine

new features of this design include a new dust-proof thrust bearing; a wider, heavier, and better-balanced base; a new design of idler pulley with bearings twice as large as those formerly used; a new weight chain; different design of belt guide for adjusting idler pulley; a wider table weight, and a much heavier table with oil grooves twice as wide and deep as those of former designs.

The advantages which these improvements give this machine over the older models are a heavier and stiffer construction, and a more serviceable and accurate machine. While the machine illustrated has eight spindles, these new models are built in forty-eight different styles with the spindle heads ranging in number from one to eight. The arms are made to overhang four different sizes—7-inch, $9\frac{1}{2}$-inch, 12-inch, and 15-inch with tables of the correct width to match.

* * *

CORRECTION

In the description of the Colburn Machine Tool Co.'s heavy-duty drill press, which appeared in the July number of MACHINERY, an erroneous figure was given in the reference to experiments made with a 3-inch Celfor drill. It was stated that this drill was driven through cast iron at a cutting speed of 262 feet per minute; the correct speed was 205 feet per minute for the test referred to.

* * *

NEW MACHINERY AND TOOLS NOTES

Hand Vise: Wade Machine Co., Boston, Mass. Small hand vise $7\frac{1}{2}$ inches long with a maximum opening of 2 inches. The parts are casehardened drop-forgings and the vise is neat in appearance and well designed.

Core Molding Machine: Henry E. Pridmore, Chicago, Ill. Machine for molding odd-shaped cores, such as cannot be produced on the usual core-forming machines because of their non-uniformity of section. The rapidity with which the sand can be jolt-rammed, the facility with which the core-box board is clamped and the box rocked over, and the accuracy with which the finished core is released from the box are among the principal advantages claimed for this machine.

Tapping Attachment: J. H. Dorman, 1 Bethune St., New York City. Tapping attachment for the drill press which is built in three sizes with capacities ranging from 0 to $\frac{3}{8}$ inch, $\frac{3}{8}$ to $\frac{3}{4}$ inch, and $\frac{3}{4}$ to 1 inch. The tap is held in a chuck of the floating type, and it centers in a female center in the end of the main spindle. The gears are of steel, and the body of the attachment in which they are enclosed is made of aluminum. The chucks of the two largest sizes are provided with a sliding plate which allows the use of small taps when necessary.

Hand Knurling Tool: Wade Machine Co., Boston, Mass. Knurling tool intended to be held in the hand and adapted for light knurling. It is shaped somewhat like a micrometer, two knurls being located at what might be called the anvil end, and a third central knurl in the spindle or handle, which is adjustable. This handle is hollow and contains an extra set of knurls for finer work. A maximum opening of $\frac{3}{4}$ inch may be obtained between the knurls. The body of the tool is made of a casehardened drop-forging, and its total length when fully open is 7 inches.

Storage Rack: Manufacturing Equipment & Engineering Co., Boston, Mass. Rack with shelves made of No. 16 gage galvanized-iron wire cloth for the storage of wooden patterns. The use of wire cloth tends to eliminate the warping of the patterns as they are exposed equally on both sides to the air. This type of shelves also allows the dirt to fall to the floor. The rack is so constructed that, if desired, sections can be removed, shelves can be adjusted, or new ones added at any time. This rack can also be utilized for the storage of metal patterns simply by using a heavier gage of wire cloth for the shelves.

Electric Radial Drill: United States Electrical Tool Co., Cincinnati, O. Portable electric drill designed particularly for drilling frames and for doing general work in connection with automobile manufacture. Holes may be drilled to a radius of 12 inches on either side of the vertical column, and a hand-feeding movement of 5 inches is available. The drill is made in two sizes for holes from 0 to $\frac{7}{8}$ inch and to $1\frac{1}{4}$ inch, respectively. Either a direct or alternating current may

be used, and two speeds can be obtained. A complete illustrated description of a tool similar in construction was published in the department of New Machinery and Tools, August, 1908.

Planer Elevating Device: Cincinnati Planer Co., Cincinnati, O. Mechanism for elevating or lowering the planer cross-rail by power. It is mounted on top of the tie-piece between the housings, and is so arranged that the cross-rail may be lowered at twice the elevating speed. As the device is only used occasionally, it has been designed so that the gearing does not revolve except when it is in use. It is operated by two small clutches which are mounted on the driving shaft and controlled by a lever at the side of the housing. This lever is provided with a locking handle for holding it in a central or neutral position, so that the clutches cannot be engaged by accident.

Foster Fixed Focus Pyrometer: Taylor Instrument Co., Rochester, N. Y. Pyrometer which may be used by simply pointing the receiver tube at the furnace or other hot body whose temperature is to be measured. It is not necessary to focus the tube, and the instrument does not require accurate leveling. The only rule that must be observed when using this instrument is that the pryometer be placed within a distance equal to ten times the diameter of the hot body or opening. If the pryometer is inside this limit, the reading is not affected, so that accuracy as to distance within the limit is not necessary. The indicator is connected to the receiving tube by a flexible cable. This pyrometer is very rapid in its action, a steady reading being obtained in about 15 seconds.

Tumbling Barrel: Abbott Ball Co., Hartford, Conn. Tumbling barrel designed for burnishing, by the use of steel balls, large quantities of such articles as saddlery, hardware, buckles, etc. The barrel is built in two compartments and its construction is such that the number of compartments may be varied from one to four to suit individual requirements. Each compartment is 30 inches in diameter and 8 inches in width. This comparatively narrow width causes a pressure on articles at the bottom of the barrel, thereby increasing the friction and giving a more rapid burnishing effect because of the long sliding space for the balls which roll in and out around the pieces; at the same time impact in the barrel is eliminated so that there is no danger of denting the work.

Car Wheel Grinder: Norton Grinding Co., Worcester, Mass. Machine for grinding unmounted wheels and intended for the use of manufacturers of car-wheels rather than railroads. The machine is fitted with two faceplates cast integrally with the driving spindle. The loose wheels are attached to these faceplates by a bolt passing through cored holes in the center. The location of work is effected by means of V-supports which are previously adjusted. By simply moving a crank, these supports are moved away from the wheels slightly so that no high spots will come in contact with them when the machine is started. In each faceplate there are three half-round openings, which permit the crank-hook to be admitted to one of the core holes in the casting. By having three of these openings, it is comparatively easy to stop the machine with one of them at the top. The weight of this machine is 16 tons.

Multiple Punch: Cleveland Punch & Shear Works Co., Cleveland, O. Large multiple punch having two rows of adjustable punches, which construction permits the punching of tapering lines of holes which is often desired in punching the stakes for pressed steel freight cars. There are 34 punches in all, divided equally into two rows. The bolster blocks are so arranged that when parallel rows of holes are not desired, they can be diverted. The machine is motor-driven, the motor being connected to the flywheel shaft through cut gears, from which the power is transmitted through an intermediate shaft to the crankshaft. This machine has a 6-inch stroke, and the distance between the housings is 10 feet, 2 inches. The housings are of semi-steel castings, and the shaft of hammered steel. The bolster blocks are cast steel and all the bearings are bushed. The sliding crosshead is counter-balanced with weights hung on levers.

Electric Riveter: Electrical Machinery Sales Co., Milwaukee, Wis. Electrically-driven riveter which will punch the hole, drive and head a rivet with one pressure on the pedal. The mechanism consists of a sliding solid-steel revolving-disk block with three specially-designed striking shoes on its lower surface. These shoes strike a resilient plunger which, in turn, delivers the blow directly upon the work. The riveting operation is controlled by a treadle and the force of the blow is proportional to the amount of pressure applied. When the pressure is released, the blow is stopped instantaneously. This control is one of the advantages of the machine, as it will strike either a light continuous tap, a medium, or a heavy blow as required, and the changes are made instantly. These machines are built in either the bench, pedestal or portable types and each type is made in three sizes. They may be driven by a self-contained motor or by belt, as desired.

Wood Screw Threader: E. J. Manville Machine Co., Waterbury, Conn. High-speed wood screw threader for making wood and machine screws from blanks made by the cold-heading process. This machine has a new type of grooved-blade fan hopper, which is sufficiently rigid to overcome any "snapping" action on the part of the pick-up arm. The hopper blade is operated by a friction device which can slip in case anything gets caught, and by means of a comb or scavenger all oversized or misplaced screws are thrown back into the hopper. The feeding mechanism is self-contained and it can be removed by simply loosening two screws which fasten the bracket to the frame, when the machine is to be changed from one size screw to another. The forming shoe may also be quickly removed or adjusted and it is located where it is easily accessible. This machine is designed throughout to insure against breakage, yielding movements being provided wherever necessary. The gearing is accurately cut and it is well protected by guards.

Internal Grinder: Rivett Lathe Mfg. Co., Boston, Mass. Internal grinder with rated capacity of 3 inches, by 6-inch stroke. The table reciprocating mechanism is so designed that a positive point of reversal is assured, thus enabling the wheel to be run up to shoulders with accuracy. The table has thirty-six speed changes, six being obtained from a change gear box; this number is increased six times by the countershaft which gives six variations for the gear box driving pulley. The spindles of this machine are mounted on ball bearings in quills, and it may be equipped with spindles and quills designed to suit various classes of work. The table has an adjustable positive locating stop which may be disconnected at will for moving the table by hand, without disturbing the original setting. Both the table and wheel-head may be swiveled to any required angle, and their positions are indicated by suitable graduations. The wheel-head has an automatic power cross-feed, which may be adjusted to operate to the fractional part of a thousandth of an inch.

Expansion Boring-bar: Buck Boring Bar Co., Huntington, W. Va. Expansion boring-bar which is intended particularly for the boring of steel and cast-iron car-wheels. It has four cutters, two of which are for finishing, while the remaining two are for roughing. The finishing cutters are adjusted simultaneously by a single expansion screw that is located in the center of the bar, and the roughing cutters have an independent adjustment. The bar has a water attachment by means of which a small stream is applied directly to the point of the cutting tools, thus keeping them cool and making high speeds possible. To adjust the cutters to bore the size of hole wanted, a gage is used that extends the full width of the cutters. This gage is placed over the cutters and the latter are expanded until they come in contact with it. The cutters have a 2-inch range of expansion which enables one bar to be used for two sizes of M. C. B. standard bore. A fifth tool, located near the base of the shank, is used as a chamfering tool for giving the wheel a slightly larger bore, to facilitate starting it on the axle.

Cold Saw Cutting-off Machine: Newton Machine Tool Works, Inc., 24th and Vine Sts., Philadelphia, Pa. Twenty-six inch cold saw cutting-off machine arranged for motor drive and with four positive feed changes. The table and body of the machine, including the saddle slides, are of one solid casting. The different feed changes are engaged instantly by the movement of a single lever. Four changes of feed are provided, ranging from 0.547 to 1.109 inch per minute with a 26-inch saw running at a peripheral speed of 45 feet per minute. The spindle of the machine revolves in brass-bushed cap bearings, and the drive is by a self-contained electric motor. Power quick-return to the spindle saddle is provided which is available in both directions, if a double-throw switch and reversing motor are employed. A Brown & Sharpe geared pump supplies cooling lubricant directly at the point of cutting, and the reservoir for the lubricant is located in the base casting. The machine has a capacity for round stock up to 7½ inches in diameter, square pieces 7 inches on a side, and for 15-inch I-beams on a square or miter-cut in a vertical position.

Embossing Press: Standard Machinery Co., Providence, R. I. Toggle embossing press with extra heavy reinforced uprights and massive proportions throughout. The crankshaft is of forged nickel steel and it drives the main toggle, which is also of forged steel and bronze bushed around the wrist-pin, in a horizontal direction. The two vertical toggles, by means of which pressure is applied, are also of forged steel, and the lower one seats in a phosphor-bronze thrust shoe, which is in the cast steel slide of the press. The driving shaft is fitted with a 1300 pound flywheel which is mounted in close to the frame. The opposite end of the driving shaft is equipped with a forged steel pinion, meshing with a cast steel clutch driving gear. Both pinion and clutch gear have cut teeth, and the gear is fitted with an instantaneous patented roller friction, allowing less than 1/32 inch travel of the flywheel after the clutch is engaged. The machine has both a hand-lever and treadle tripping device, and it is set upon a substantial cast-iron base. The distance between the uprights at the bed of the press is 17½ inches and the minimum distance is 15¾ inches. For special purposes, however, the machine can be made with a minimum space of from 8 to 12 inches between the uprights for small pieces requiring heavy pressure.

Hydraulic Press: United Engineering & Foundry Co., Farmers Bank Building, Pittsburg, Pa. High speed hydraulic forging press which is operated partly by a steam-driven, water-pressure intensifier and partly by steam working in cylinders located on top of the press, which combination gives a rapid action and the required power. This machine is built on the Davy patents, and the principle of its operation was described in an article published in the May, 1907, number of MACHINERY. In order to obtain a practical forging stroke and still keep the proportions of the intensifier within reasonable limits and the steam consumption low, the press ram is operated by steam until the forging part of the stroke is reached. The variation in water supply required for forgings of different thicknesses is obtained from a tank that is partly filled with water under an air pressure of 30 pounds. When the press head is lowered by exhausting steam from the balance cylinders, a check valve connecting this tank with the high-pressure system opens, thus admitting the required amount of water. This press is controlled by a single lever, so that the movement of the hand determines both the speed of the ram and the distance of the traverse. The forging stroke can be repeated as often and as quickly as the hand can be moved, which, in practice, is 150 strokes per minute on small presses and 60 on large ones. Nearly all parts of the press are of steel, and it is so constructed that packings can be renewed without dismantling any part or employing any power outside the machine itself.

* * *

JOINT MEETING OF A. S. M. E. AND INSTITUTION OF MECHANICAL ENGINEERS

About 160 members and guests of the American Society of Mechanical Engineers sailed for Liverpool, July 16 on the *Celtic* to attend the joint convention of the society with the British Institution of Mechanical Engineers that was held at Birmingham and London, July 26-29. Business matters prevented Pres. Westinghouse attending. W. F. M. Goss and Charles W. Baker presided.

An interesting program had been prepared for the entertainment of the members on the voyage. On Monday evening there was a reception by the officers and past presidents of the society; Tuesday evening, illustrated address by W. R. Warner: "What are the Astronomers Doing?"; Wednesday evening, musicale; Thursday evening, illustrated address by John R. Freeman: "Construction of the Panama Canal"; Friday evening, dancing; Saturday evening, conversazione, awarding of prizes for deck games, etc. The party landed July 25 and was joined by other members and guests who had gone before or by other routes. The program of their entertainment arranged for in England was replete with interesting events and is too long to be reproduced. The program of technical papers as prepared is substantially as follows: "English Running-Shed Practice," by Cecil W. Paget, Derby; "Round-house Practice, or the Handling of Locomotives at Terminals to secure Continuous Operation," by Frank Henry Clark, Chicago, Ill.; "Handling of Locomotives at Terminals," by Frederick M. Whyte, New York; "Handling Locomotives," by Henry H. Vaughan, Montreal, Can.; "American Locomotive Terminals," by William Forsyth, Chicago, Ill.; "High-Speed Tools and Machines to Fit Them," by H. I. Brackenbury, Newcastle-on-Tyne; "Tooth Gearing," by J. D. Steven, Birmingham, England; "Involute Gear Tooth Standards," by Wilfred Lewis, Philadelphia, Pa.; Discussion by C. R. Gabriel, New York; Topical Discussion on Rapid Production in Machine Work, by John R. Calder, Ilion, N. Y., Luther D. Burlingame, Providence, R. I., Alexander Taylor, East Pittsburg, Pa., L. P. Alford, New York; "Electrification of Suburban Railways," by F. W. Carter, Rugby; "Cost of Electrically-Propelled Suburban Trains," by H. M. Hobart, London, England; "Electrification of Trunk Lines," by L. R. Pomeroy, New York; "Electrification of Railways," by George Westinghouse, New York.

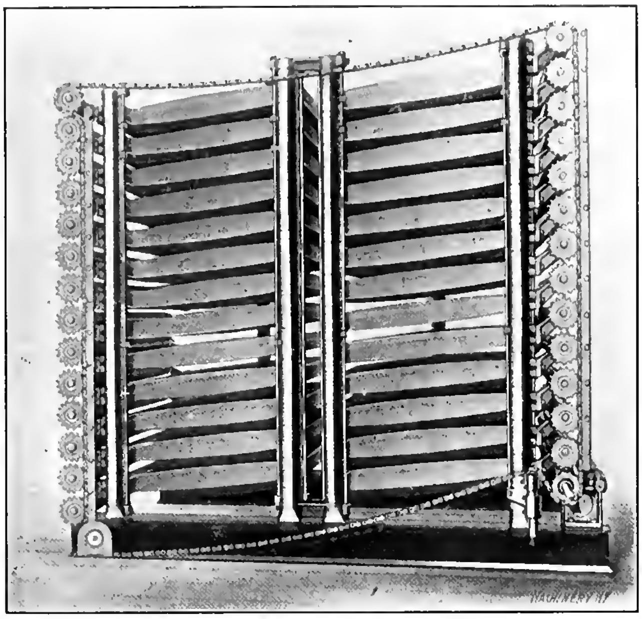
* * *

Aluminum-coated sheet metal has been placed on the market to be used in place of galvanized iron. The sheet metal, however, is not coated with aluminum, as the name would imply, but with a zinc alloy containing but a small percentage of aluminum. The alloy consists of 77 per cent of zinc, 13.5 per cent of tin, 7 per cent of aluminum and 2.5 per cent of copper. The advantage of this coating over the ordinary zinc coating is that it will not peel or strip off when the metal is bent, and a heavier coating than is possible to produce by zinc alone can be obtained.

NEW TYPE OF CHAIN DRIVE

A new method of driving series of parallel shafts or rolls has been recently patented and is now being successfully used on cell driers for drying textiles, pulp, paper, etc. This new drive, which employs a roller chain and sprockets, as shown in the illustration, is said to be much more efficient than the trains of spur gears, and the bevel gear drives formerly used.

Referring to the illustration, the drive has a set of rolls for each tray, the drying unit varying in size from six on the smallest up to forty trays on the largest machines. A single loop of 1 1/2-inch pitch Diamond roller chain made by the Diamond Chain & Mfg. Co., Indianapolis, Ind., runs around the machine and meshes with a sprocket on each roll. The lowest right-hand roll sprocket is the driver on the machine shown, and turns clockwise. The chain is kept in contact with the sprockets by means of two steel guide-rails, one on each



View of a Cell Drier showing Arrangement of Chain Drive for a Series of Parallel Shafts

side of the machine. These rails being slightly narrower than the width of the chain rollers, compel the chain to mesh with the sprockets. The lower strand of the chain runs loose and at the left of the driving sprocket an idler is provided which is adjustable vertically to take up the slack.

The bevel gears and trains of spur gears that formerly drove the rolls consumed considerable power and were noisy at high speeds. The chain is much quieter and absorbs little power in friction load. A 1/2 horsepower motor with a 1-inch belt will easily drive an empty machine of the size shown at high speed, and, as a matter of fact, this is the method used to limber up new machines. The chain drive so far has proved less expensive in initial cost and upkeep and seems to wear less than the gears formerly used.

DETROIT INDUSTRIAL EXPOSITION

The Detroit Industrial Exposition held in Detroit, Mich., opened June 20, and after a successful run attended by good weather conditions, closed July 6. There were 163 exhibitors representing principally manufacturers of mechanical or engineering products. The exposition was managed by Mr. William G. Rose, who was also manager of the Cleveland exposition, and the object of the whole thing is best expressed in the words of the little booklet issued, which are: "To teach Detroit to know itself, to teach the world to know Detroit; to advance the general interests of the city; to show the variety, scope and importance of Detroit industries; to bring benefits to the manufacturers, merchants and citizens in general; to offer the people of the city an entertainment of far greater magnitude and interest than has ever been attempted before and to stimulate civic pride, encourage the citizens to patronize home industries and advance the spirit of: 'One for All and All for Detroit!'"

MANUFACTURING THE SIBLEY HIGH-SPEED DRILL PRESS

In the manufacture of a high-speed drill press, the Sibley Machine Tool Co., South Bend, Indiana, has recently made some radical changes in its manufacturing methods which have resulted in a greatly increased production. A few of the more important of these methods, as well as the machines on which the work is performed, are illustrated herewith.

The high-speed drill press referred to is shown in Fig. 1, which gives a general idea of the work to be done, and of the parts to be bored, milled and drilled. The columns are first centered and turned in a heavy lathe. The finished part of the column is then placed in a V mounted on the table of a universal (horizontal boring machine), as shown in Fig. 2, and the top bracket to receive the gear box is milled. After this operation, the milling cutter is removed from the spindle, and a boring-bar inserted as shown in Fig. 3, and the bearings for the crown gear and spindle sleeve are bored, as well as all other parallel holes. The column is then swung around at right angles, and the hole for the pinion shaft, and other parallel holes are bored; this completes the work on the column.

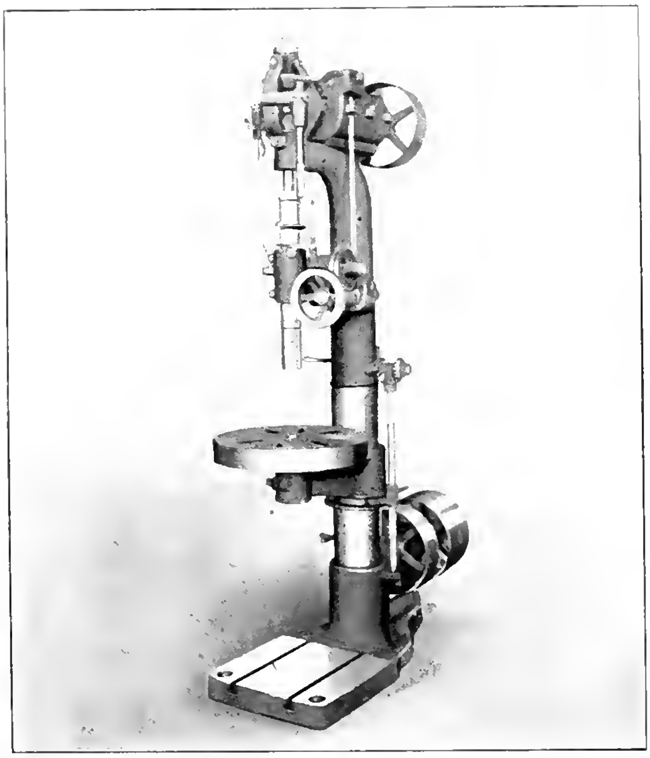

Fig. 1. The Sibley High-speed Drill Press

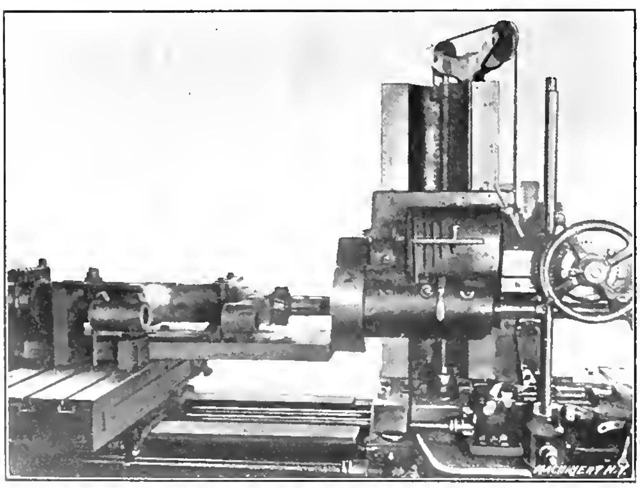

Fig. 2. Milling the Top of a Column for the Gear-box on a Horizontal Boring Machine

The machining of the castings for the speed change box shown in Fig. 4, comes next. This work is also done to the best advantage on the horizontal boring machine. As will be noted from the engraving, the gear case is made in halves. The top and bottom halves are milled together and placed in a jig. The six bearings are then bored. After the gear cases have been machined, they go to the assembling department, where the bronze bearings are fitted and the gears and internal shafts assembled.

In the gear case there are two solid shafts and one hollow shaft on which run the gears for the speed changes. The constant-speed driving pulley may be connected by either of two sets of gearing with the horizontal shaft at the left of the casing (as viewed from the front). The change from one set of gearing to the other is made by the lever in front of the driving pulley at the top of the machine. This shaft, at the left, carries a set of four gears meshing with a corresponding set of four gears on the spindle driving shaft to which the driving bevel gear is connected. By the manipulation of the lever at the front, any of the four ratios provided may be obtained. The combination gives eight speed changes in all.

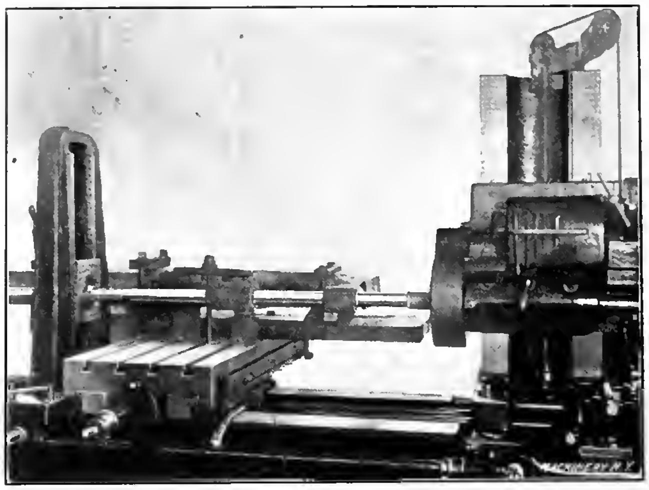

Fig. 3. Bearings for Crown Gear and Spindle Sleeve being bored

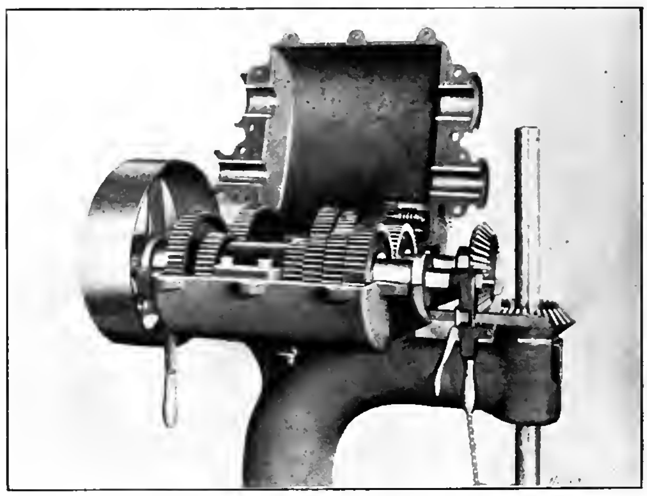

Fig 4 Speed Change Box of Machine shown in Fig. 1

The hollow shaft for the speed change gear box is bored out of solid stock in a turret lathe and the outside is then roughed off. In each end of this hollow shaft sliding keys operate, the hollow shaft being slotted on a miller of the company's own design. After plugs are inserted in each end, the shaft is finished by grinding.

A Pfauter gear-hobbing machine is employed for hobbing the spur gears used in the speed change gear box. That the hobbing principle as applied to gear cutting will result not only in a rapid but accurate production, is now universally acknowledged and appreciated. The spiral hob by which the gear is generated, may be described as a circular rack, the thread of which is a correctly shaped rack tooth. The pitch of the threads being as the pitch of the required gear, such a hob, rotating in conjunction with a gear blank on the generating machine, produces an ideal shape of tooth, for it removes only the parts of the blank that interfere with its free

rotation. Between the straight line of a rack tooth, which would be an exact copy of the hob itself, and the curved shape of a small pinion tooth, there are as many different tooth-curves as there are numbers of teeth. The generating principle, as employed on this machine, automatically forms the correct curve required by any gear within the capacity of the machine. One hob only is required to generate gears with any number of teeth of the same pitch, from small pinions to wheels of a diameter equal to the full capacity of the machine. Prior to the hobbing operation, the rough casting blanks are bored and faced in a chucking attachment in a turret machine; they are then placed on the hobbing machine and the teeth cut, as shown in Fig. 5. After this, three keyways are cut in the loose gears. All the spur gears of the feed mechanism are cut by the hobbing process.

The hubs of the spindles are electrically welded to their shanks; they are then roughed out in a lathe, a Morse taper socket bored, and the drift hole milled on a two-spindle miller of the company's own design. The spindles are then placed in a grinder and the bearings as well as the hub and shank are

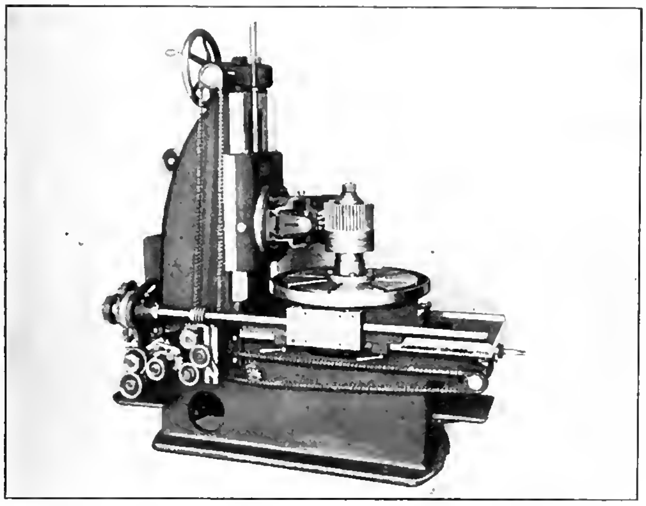

Fig. 5. Pfauter Gear-hobbing Machine generating the Teeth on a Stack of Spur Gears

ground to a finish. All shafts on this machine are ground, after first being roughed out on a lathe. The spindle sleeves, when received from the foundry, are first bored and reamed, then placed in a grinder and ground to a finish after having been graduated.

The engraving Fig. 6 shows the base of the Sibley drill being milled off in the horizontal boring machine. As will be seen, the base is bolted to an angle-plate mounted on the table. With the base still in position on the angle-plate, the hub is

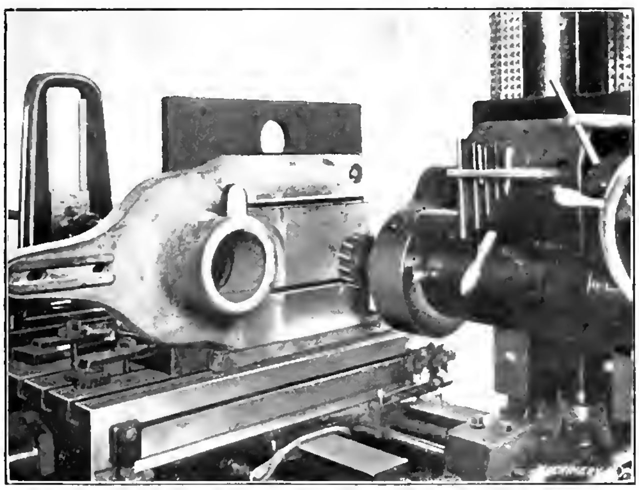

Fig. 6 Milling the Drill Press Base in a Horizontal Boring Machine

bored out and also the bearings for the table screw, as shown in Fig. 7, all three operations being done with but one setting of the casting. This method eliminates the necessity of setting up the base on a boring mill for the boring job, and then re-setting the work on a planer to finish.

The four pulleys are bored and the hubs faced in a turret lathe; they are then placed in a pulley turning lathe, and the faces turned and ground.

All the castings used in the construction of this machine are of the very best grade of iron. After several years of experience in the company's own foundry, a mixture has been selected which gives the proper toughness, as well as the re-

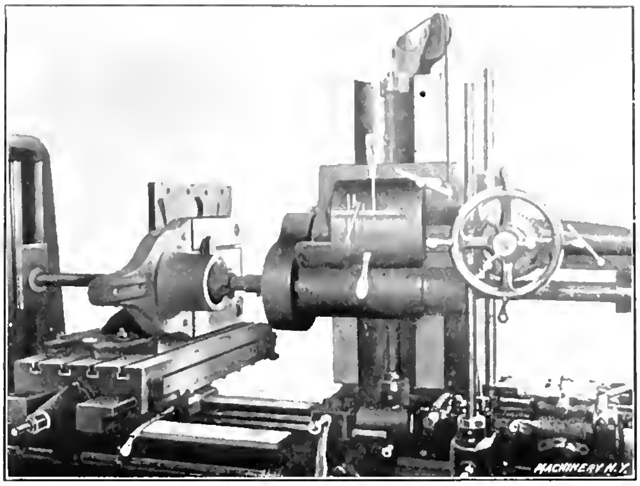

Fig. 7. Boring the Hub of the Drill Press Base

quisite softness for easy machining. Before being sent to the machine shop, all castings are put through exhaust mills which remove all core and molding sand, as well as fins and other rough surfaces.

Practically all the manufacturing on this drill press is done in one department, whence it passes into the inspector's hands. All parts that pass inspection go into stock and are drawn out by the assembling department as required. After the machines are completely assembled, they are run for forty-eight hours, and then tested. One of the tests is drilling through a hammered steel block 4 inches thick, as well as boring out the table arm to insure perfect alignment of the table with the spindle. After thorough inspection, the machines are painted, a sufficient length of time being taken to give a very nice finish. From the paint department, they pass into the shipping room ready for delivery.

A CHROMIUM ALLOY FOR EDGE TOOLS

As chromium hardens copper and its alloys to such a degree that it will take a cutting edge, James Naulty and John Scanlin of Philadelphia, Pa., have proposed the use of a copper, nickel-zinc and chromium alloy for edge tools (U. S. Patent 959,156, May 24, 1910). The alloy is as follows:

Copper	45 per cent.
Nickel	25 per cent.
Zinc	25 per cent.
Chromium	5 per cent

The method of making the alloy, the inventors say, is to melt the copper and the chromium separately and then mix, after which the nickel and zinc are introduced. It is claimed that the alloy will work hot and will take an edge good enough for edge tools, and at the same time is non-corrosive.—*Brass World.*

* * *

It is common practice to mount the motor of a motor-driven planer on the housings, this position in most respects being admirably suited for the purpose. The motor takes up no additional floor space, and though out of the way it is "get-at-able" whenever anything goes wrong. It is conceded, however, to be an objectionable position for the motor where highly-finished planed surfaces are required. Some concerns have so highly developed their planer practice that planed work is turned out of extraordinary smoothness of finish. If the motor is mounted on the housings the vibrations and jar due to defective balance and gear tooth action will show in the work. The inaccuracy resulting is so small as to be impossible of measurement, but the appearance cannot be tolerated on the class of work referred to, and when such work is to be produced it is probably best to mount the motor on the floor or on a separate support so that the vibrations will not be communicated to the planer housings.

ATTACHMENT FOR TURNING SPHERICAL WORK

In the July number of MACHINERY, an interesting taper turning attachment designed by W. Z. Bean, West Medford, Mass., was illustrated and described, and mention was also made of an auxiliary attachment to be used in connection with it for turning spherical work. The spherical turning attachment *A* is shown attached to the swiveling part *B* of the taper turning attachment by the adjusting screw *E*, in the accompanying illustration. The sleeve *F* containing the spindle *G* and its operating handle *H*, which was described in connection with the taper turning attachment in the previous article as mentioned above, has been removed and the spherical attachment substituted as shown. The method of operating this attachment is as follows:

After the sleeve and spindle have been removed, the adjusting screw *E* is secured in the part *A*, and is screwed into a threaded sleeve located in the part *B*, the tool-holder *D* being slotted at its lower end to clear the adjusting screw *E*. The tool-holder *D* is then adjusted to approximately the required height and held in position by cap-screws *b*. The turning tool *d* is then inserted and held in position by set-screw *c*, and it is brought to the desired position either by adjusting the part *A* by means of the screw *E* or by bringing the tool further out of the part *D*. The radius required is obtained by measuring the distance in a horizontal line between the point of the tool *d* and the face *a* of the swiveling part *B*, the face *a* being in line with the center of the plug on which the part *B* swivels. When the tool *d* is set to the desired radius the work can be turned by rotating the handle *C* in either direction as required.

WRECK OF AIRSHIP ZEPPELIN VII.

The world's first airship line was inaugurated in Germany by the Aerial Transportation Co., June 22, when the third large Zeppelin airship, *Deutschland VII*, started from Friedrichshafen, on Lake Constance, to Dusseldorf. The distance of 250 miles was made in about nine hours, the average speed being about 28 miles an hour. The project came to a disastrous end on the third trip, June 28, when a party of twenty journalists was taken for a special trip. The vessel was wrecked in the Teutoburg forest by a gale which forced a descent with thirty-three persons aboard, including the crew. Tree tops pierced the silk envelope and twisted the aluminum frame, and the wind completed the total wreck of the finest of the Zeppelins, 485 feet long and costing $137,000. The passengers and crew descended by rope ladders, and no one was injured. It is said that, notwithstanding his many disasters, Count Zeppelin will build another airship.

* * *

PERSONALS

W. H. Kinsel, formerly with the Thompson-Bassett Co., has taken charge of the toolroom at the plant of the Detroit Radiator Co., Detroit, Mich.

C. L. Smith has succeeded Mr. Hall as Cincinnati editorial representative of the *Iron Age*. Mr. Smith is located at 612 Second National Bank Building.

V. M. Palmer, chief engineer of the Selden Motor Vehicle Co., Rochester, N. Y., has resigned his position to take a similar position with the Sheldon Axle Co., Wilkesbarre, Pa.

B. M. Switzer, for the past five years superintendent of the Brattleboro Machine Works, Brattleboro, Vt., has taken a lease of the works and will continue the business along the established lines.

Sylvester S. Howell has become associated with Paul Chamberlain, Marquette Building, Chicago, Ill., under the firm name of Chamberlain & Howell. The firm will carry on the designing and consulting engineering practice established by Mr. Chamberlain.

William Lodge, of the Lodge & Shipley Machine Tool Co., Cincinnati, Ohio, sailed July 16 on the *Celtic* to attend the joint meeting of the American Society of Mechanical Engineers and the British Institution of Mechanical Engineers, held in Birmingham and London, England, July 26-29.

George Cherrington, formerly with the Lodge & Shipley Machine Tool Co., Cincinnati, Ohio, and lately salesman with Brown & Zortman Machinery Co., Pittsburg, Pa., has opened an office in the First National Bank Building, Cincinnati, Ohio, where he will act as manufacturers' representative for high-speed steel specialties and machine tools.

* * *

OBITUARIES

Henry C. Clark, senior member of the firm of H. C. Clark & Son, manufacturers of paper machinery, Lee, Mass., died at his home, July 3, aged seventy-two years.

Joseph Thomas, an inventor of note, died at his home in Hoboken, N. J., July 1, aged eighty-eight years. He was born in Paris, France, and came to America at the age of nineteen. He became a machinist's apprentice and early displayed inventive genius. He was employed by Isaac W. Singer when Singer was perfecting his sewing machine in Ann St., New York, and helped perfect the oscillating feed which made the machine a success. Mr. Thomas invented the first machine for the manufacture of sulphur matches, but his principal reputation was made by the invention of the steel wire hoop skirt which was the fashionable rage in the fifties and sixties. Like many other inventive geniuses, Mr. Thomas was not a success as a business man, and did not profit largely by his numerous valuable inventions.

William Henry Brown, late chief engineer of the Pennsylvania R. R., died of heart failure at Belfast, Ireland, June 25, aged sixty-four years. Mr. Brown was assistant engineer on United States military railroads and telegraphs in 1861, in which service he attracted the attention of Col. Thomas A. Scott, then Assistant Secretary of War, and afterwards president of the Pennsylvania R. R. Co. But it was not until Mr. Brown had worked four years in various capacities on railroads, including a brief term of special service with the Pennsylvania R. R., that he made the connection with the latter in 1865, which was destined to continue for the remainder of his active life. The development of the great Pennsylvania system during Mr. Brown's connection therewith is almost unparalleled in the history of railroads. Mr. Brown retired in 1906, after forty-five years of active railroad work.

Edwin T. Marble, president and treasurer of the Curtis & Marble Machine Co., Worcester, Mass., and for nearly half a century a leading figure in the public life of Worcester, died Sunday, July 3, at his home in that city, aged eighty-two years. Mr. Marble was born in Sutton. His education was received in the Worcester County Manual Training School, now known as Worcester Academy. Entering the employ of Albert Curtis as a machinist at eighteen years of age, he worked up until, after holding many responsible positions with other companies, he entered into partnership with his former employer under the name of Curtis & Marble Machine Co. He saw the business grow to be one of Worcester's most thriving concerns, and in 1895 he became sole owner. Aside from his business interests, he served the city in many ways. He was at different times representative, state senator, alderman, member of the common council, school committeeman, besides being associated with many banking institutions and civic organizations.

COMING EVENTS

August 16-18.—Annual convention of the International Railway Master Blacksmiths' Association, Detroit, Mich. A. L. Woodworth, secretary, Lima, Ohio.

August 16-19.—Annual convention of Traveling Engineers' Association, Clifton Hotel, Niagara Falls, Canada. Subjects to be discussed are: "Fuel Economy," "Superheating," "Education of Firemen," "Development of Air Brake Equipment," "Locomotive Lubrication," and "New Valve Gears." W. A. Thompson, secretary, N. Y. C. Car Shops, East Buffalo, New York.

August 19-23.—Exhibition of nut, bolt and forging machinery at Tiffin, Ohio, by the National Machinery Co. A special excursion train will be run from Detroit for the conveyance to the works of the master blacksmiths in attendance to the annual convention of the International Railway Master Blacksmiths' Association.

October 10-14.—Annual convention of the American Street and Interurban Railway Association, Atlantic City, N. J. H. C. Donecker, secretary and treasurer, 29 West 39th St., New York.

NEW BOOKS AND PAMPHLETS

NATIONAL METAL TRADES ASSOCIATION PROCEEDINGS. 12TH ANNUAL CONVENTION, NEW YORK, APRIL 13-14. Published by the Association. Robert Wuest, Commissioner, 605 New England Building, Cleveland, Ohio.

The proceedings include the following technical papers: "The Fitchburg Plan of Industrial Education," by W. B. Hunter; "Growth of the Cooperative System," by Professor Herman Schneider; "A Plea for Continuation Schools," by Dr. Frank B. Dyer; "The Compensation of Workmen," by H. L. Gantt; "Cincinnati's Continuation Schools," by J. Howard Renshaw; "Employers Liability Insurance," by Miles M. Dawson; "Modern Methods of Shop Management," by Frederick A. Waldron; "Labor Bureaus," by Joseph A. Holland; "Industrial Education," by Prof. Dexter S. Kimball. The proceedings will be found of much interest by all concerned with the problems of industrial education.

WORK, WAGES AND PROFITS. By H. L. Gantt. 194 pages, 4¾ x 7¼ inches. Published by the *Engineering Magazine*, New York. Price $2.

This work is a re-issue in book form of a series of articles, "Compensation of Workmen and Efficiency of Operation," published in the *Engineering Magazine*, to which have been added three of Mr. Gantt's most important preceding contributions, revised and brought up to date. The work, as a whole, is a complete statement of Mr. Gantt's ideas on methods of works management and compensating workmen. The contents by chapters are: The application of scientific methods to the labor problem, utilization of labor, compensation of workmen, day work, piece work, task work with bonus, training workmen in habits of industry and cooperation, fixing habits of industry, profits and their influence on the cost of living. The work is one that can be read with interest by those not directly connected with the problems of manufacture.

TESTS OF TIMBER BEAMS. By Arthur N. Talbot. Bulletin No. 41. 77 pages, 6 x 9 inches. Published by the University of Illinois Engineering Experiment Station, Urbana, Ill.

The investigations were undertaken to obtain information on the structural properties of full-sized timber beams such as are used in bridge practice, but of course, the results are applicable to timbers wherever employed in all forms for building construction. The tests include 112 full-sized stringers and several hundred smaller test pieces cut from large beams. The woods tested were long-leaf pine, short-leaf pine and Douglas fir. The fiber stresses developed in beams not shearing horizontally is generally low, averaging, on untreated timber tested, from 3690 in Old Douglas fir to 5300 pounds per square inch in the long-leaf pine. The results disclose the very interesting fact that timbers having knots and cross grains are generally less stiff than clear timber. From this fact it is obvious that when strong sticks and defective sticks are placed side by side in a structure, the weaker stick usually takes less than its share of the load.

A PATHFINDER—DISCOVERY, INVENTION AND INDUSTRY: Subject, Edward G. Acheson. 143 pages, 6 x 9 inches. Published by the Press Scrap Book, 209 Broadway, New York.

We are indebted to the International Acheson Graphite Co., Niagara Falls, N. Y., for this beautiful example of bookmaking, of which company Dr. Acheson is the president. The world knows vaguely that Dr. Acheson is a renowned discoverer and inventor, but few know just what remarkable things he has accomplished. Originally written for the benefit of his family and friends, it has been secured from Dr. Acheson and published to give the youth and young men of the country a life story that is an incentive to ambition. It records his early struggles, his experience with Edison at Menlo Park, travels in Europe, discovery and development of carborundum, graphite, Egyptianized clay, direct reduction of aluminum and silicon, production of siloxicon, aquadag and oildag. Dr. Acheson has read many important and valuable papers before scientific societies and has had many honors conferred on him. The work is one that should interest all who are attracted to advanced and original scientific work.

ENGINEERING CHEMISTRY. By Thomas B. Stillman. 755 pages, 6 x 9 inches, 174 illustrations. Published by the Chemical Publishing Co., Easton, Pa. Price $5.

This work, which now appears in the fourth edition, is a manual of quantitative chemical analysis for the use of students, chemists, and engineers. Much of it has been re-written by the author, who was formerly professor of engineering chemistry at Stevens Institute of Technology. It describes the proximate analysis of coal and coke, analysis of limestone, iron ores, manganese ores, blast furnace slag, copper, lead and zinc, boiler waters, chimney gases, etc. It also describes the construction and use of the Uehling gas compositemeter and Junker's gas calorimeter. A chapter is devoted to practical photometry. A partial list of contents will give an idea of the scope of the work: Manufacture of water gas, composition of natural gas, natural gas under steam boilers, liquid fuel, the blast furnace as a power plant, method of the United States Steel Corporation for commercial sampling of iron ores, foundry chemistry, carbon compounds of iron, analysis of tin plate, analysis of clay, fire sand, composition of natural cement, the chemical and physical examination of Portland cement, testing of brick, saline efflorescence of brick, asphalt, soap analysis, examination of lubricating oil, oils used for illumination, paint analysis, etc.

WORK-ACCIDENTS AND THE LAW. By Crystal Eastman, edited by Paul Underwood Kellogg. 345 pages, 6 x 9 inches. Illustrated. Published by the Charities Publication Committee, New York, under the Russell Sage Foundation. Price $1.50, postage 15 cents extra.

This remarkable and absorbingly interesting work treats of the industrial problem in its relation to the laboring classes, without gloves. It is a terrible indictment of conditions with some phase of which most of us are familiar, but of which very few realize the monstrous proportions in the country as a whole. One reads with pity, horror and indignation of accidents that have crippled men, bereaved wives and parents, and thrown dependent children upon charity which could have been prevented if the simplest precautions had been observed. "Man's inhumanity to man makes countless thousands mourn" takes on a new significance after having read the chapters on the railroaders and steel workers. On the other hand, a large proportion of work-accidents are the result of individual carelessness or deliberate disobedience to rules. A great deal of educational work has to be done with employes to bring about a general sense of the need of always being careful in the use of machinery, the piling and handling of material, etc. Space will not permit giving this great work the thorough review that it merits. It should be in the hands of all manufacturers and others employing labor, especially in hazardous occupations. It treats of the causes of work-accidents, economic cost of work-accidents and employers' liability. Those who believe that every large industry should bear the burden of caring for its employes killed, maimed or injured and their families, will read this book with heartfelt approval and be moved, we hope, to promote the movement to secure such state legislation as shall be just and equitable to all concerned.

CATALOGUES AND CIRCULARS

CLINTON EDWARDS, 27 East 22nd St., New York. Bulletin on industrial engineering.

BROWN INSTRUMENT CO., 311 Walnut St., Philadelphia, Pa. Circular No. 5 of Brown thermometers.

ASSOCIATION OF AUTOMOBILE ENGINEERS, 1451 Broadway, New York. List of members of the association.

INGERSOLL-RAND CO., 11 Broadway, New York. Bulletin No. 8108 on "Crown" bench and floor sand rammers.

AMERICAN BLOWER CO., Detroit, Mich. Bulletins Nos. 267 and 273 on "Detroit" steam traps and the "A B C" heater.

HILL CLUTCH CO., Cleveland, Ohio. Catalogue No. 8 on friction clutches for general power transmission purposes.

SPRAGUE ELECTRIC CO., 527-531 West 34th St., New York. Bulletin No. 600 on single-phase and polyphase induction motors.

HAMMACHER SCHLEMMER & CO., 4th Ave. and 13th St., New York. Catalogue 400 on hand screws and clamps of all kinds, comprising practically everything in this line.

T. R. ALMOND MFG. CO., Ashburnham, Mass. Circular of Almond right-angle coupling for power transmission, built in four sizes, 5, 10, 20 and 40 horsepower, respectively.

ROCKFORD LATHE & DRILL CO., Rockford, Ill. Descriptive circular of 13-inch floor drill having a drilling capacity up to ¾-inch hole and to the center of a 13-inch circle.

C. W. HUNT CO., West New Brighton, N. Y. General catalogue 102 of coal-handling and hoisting machinery, conveyors, industrial railways, electric locomotives, steam hoists, etc.

RUSSELL JENNINGS MFG. CO., Port Chester, N. Y., has published an illustrated booklet entitled: "How to Sharpen Auger Bits, and How to Care for Them." Copies will be sent free on request.

CUTLER-HAMMER MFG. CO., Milwaukee, Wis. Bulletin of 48 pages entitled "Battery Charging Rheostats," which illustrates and describes the company's entire line of battery charging rheostats.

CINCINNATI IRON & STEEL CO., Cincinnati, Ohio. Booklet entitled "Pointers on Machinery." The company carries a complete line of machinery for automobile, carriage, wagon, sheet-metal and structural shops.

INGERSOLL-RAND CO., 11 Broadway, New York. Bulletin No. 8803 on "Imperial" high-duty pneumatic-hammers, comprising scaling hammers, chipping hammers, riveting hammers, chisel and rivet shanks, duplicate parts, etc.

HUTHER BROS. SAW MFG. CO., INC., Rochester, N. Y. Catalogue of patent dado heads, milling saws, box board matcher cutters, lock corner cutters, concave saws, saw fitting machinery and all kinds of special grooving saws for wood working.

MIAMI VALLEY MACHINE TOOL CO., Dayton, Ohio. Descriptive circular of the Miami Valley No. 1 universal tool and cutter grinder having a capacity of 16 inches between centers and swing of 8 inches. See description in MACHINERY, March, 1910.

INGERSOLL MILLING MACHINE CO., Rockford, Ill. Bulletins Nos. 18 C and 19 C, illustrating and describing the design and application of fixed rail automobile multiple-spindle milling machine designed especially for builders of automobile gasoline motors.

FIDELITY & CASUALTY CO., 92 Liberty St., New York. Rules for operating low-pressure steam pumps, and rules for operating high-pressure steam power boilers. These rules should be placed in the hands of engineers and firemen of steam plants generally.

RICHARD DUDGEON, 24-26 Columbia St., New York. Booklets 9 and 11 on the Dudgeon universal hydraulic jack, printed in Spanish and French, respectively. The pamphlets illustrate the construction of the Dudgeon hydraulic jacks and contain directions for use. Copies are sent free on request.

NEW YORK BELTING & PACKING CO., 91-93 Chambers St., N. Y. Engineers' catalogue showing high-grade packings for all conditions of service, comprising piston-rod packings, valve-stem packings, high-pressure steam packings, waterproof packings, hydraulic packings, sheet packings, gaskets, pump valves, pump diaphragms, valve disks, asbestos wicks, etc.

BRISTOL CO., Waterbury, Conn. Illustrated index of Bristol recording instruments for pressure, temperature and electricity, and Bristol electric pyrometers for high temperatures. This attractive pamphlet should interest all shop managers, central station engineers, and others desiring accurate and reliable records of temperatures, machine operations, pressures, etc.

AMERICAN CHAMBER OF COMMERCE, 3 Rue Scribe, Paris, France, has issued bulletin No. 82 on the Franco-American tariff agreement which contains a synopsis of the new French tariff on American products. Manufacturers, exporters, and others doing business with France will find this synopsis of value. It is printed in French and English, in parallel columns, on opposite pages.

INTERNATIONAL ENGINEERING CO., 1779 Broadway, New York. Price list of Lemoine springs for motor cars. The price list includes useful data for engineers and designers such as load, length, width and camber for front, semi-elliptic rear and three-fourths-elliptic springs; also tables showing distances springs may be deflected without taking permanent set, the material being mangano-silicon, premiere qualite steel, qualite courante steel, etc.

ANDERSON FORGE & MACHINE CO., Detroit, Mich. Folder briefly describing the company's new drop forge plant which occupies thirteen acres located on Jefferson Ave. The folder illustrates a 7500-pound steam drop-hammer that will be installed. The hammer takes a die weighing five tons, and delivers a blow of 12,000,000 foot-pounds. The equipment of the plant will be of the most advanced type. Oil will be used as fuel throughout. The plant is expected to be ready for occupancy September 1.

INGERSOLL-RAND CO., 11 Broadway, New York. Pamphlet 9001 on the Davis "Calyx Diamondless" core drill. One form of the Davis "Calyx" drill employs a cutter of the hollow mill variety, the teeth being made of steel. The cutter does not cut the rock, but chips it away, which is doubtless the secret of its ability to stand up in hard rock. Another form of cutter employs chilled shot. The advantages of the "diamondless" drill, of course, are lessened first cost and reduced cost of up-keep.

AETNA LIFE INSURANCE CO., Hartford, Conn. Pamphlet on the care and operation of elevators, published with a view of preventing accidents. The purpose of the pamphlet is to call attention to certain matters in the care and operation of elevators which should never be overlooked or neglected if accidents are to be prevented. It treats of general considerations affecting elevator installation, investigation, the attitude of the owner, agent, the engineer, operator, passenger, safety of equipment, careful operation, useful information, elevator warning signs, etc. The pamphlet will be sent free to those interested.

BROWN INSTRUMENT CO., 311 Walnut St., Philadelphia, Pa. Catalogue No. 3 containing 48 pages on electric pyrometers. The Brown pyrometers are made with nickel-chrome alloy couples for use at temperatures up to 2200 degrees F. and for intermittent use up to 2400 degrees F. For temperatures up to 3000 degrees F. they are supplied with platinum-rhodium couples and horizontal indicators. Electric recording pyrometers and methods of installing the various parts of pyrometers in furnaces, etc., are shown. The catalogue also illustrates the Brown radiation pyrometers for measuring the highest temperatures. This instrument is similar to a telescope with a tripod, the

CONTENTS FOR AUGUST

The first column of page numbers applies to the Engineering and Railway Editions; the Second to the Shop Edition

part corresponding to the eye-piece in the ordinary telescope being directed to the flame whose temperature is to be measured.

ASSOCIATION OF AUTOMOBILE ENGINEERS, 1451 Broadway, New York, has issued a list of material specifications, published under the direction of Mr. Henry Souther, metallurgist, with complete instructions on the method of purchasing, inspecting and handling materials used in motor car construction. The materials include low- and high-carbon steel, carbon spring steel, screw stock and high-carbon nickel steel, chrome-nickel steel, chrome vanadium steel, chrome vanadium spring steel, silicon spring steel, alloy steel, steel castings, gray iron castings, malleable iron, babbitt metals, white brass, phosphor-bronze bearing metal, aluminum alloys and automobile engine lubricating oil. A great deal of attention is given to the heat treatment of steel. The work will be issued only to the members of the society.

TRADE NOTES

GILBERT & BARKER MFG. CO., Springfield, Mass., manufacturer of gas machines, and gas and oil furnaces, is building an addition to its factory.

WAGNER ELECTRIC MFG. CO., St. Louis, Mo., has changed the location of its Denver office from the Ideal Building to the Gas and Electric Building.

BURROUGHS ADDING MACHINE CO., Detroit, Mich., is building a four-story concrete-fenestra building that will add 80,000 square feet to its floor space.

WINKLEY CO., Detroit, Mich., has more than doubled its capacity by the building of a large one-story concrete and steel addition in which the installation of machinery has been practically completed.

UNION MACHINE CO., INC., 164 University Ave., St. Paul, Minn., has been appointed general manufacturing and selling agent for the products of the Plunger Plastic Packing Co., Inc., St. Paul, Minn.

BRIGHTWOOD MOTOR MFG. CO., Springfield, Mass., has bought the plant and equipment of the Bailey Automobile Co., and is adding considerable machinery for the manufacture of a new line of automobiles.

C. W. HUNT CO., West New Brighton, New York, has made arrangements with the San Francisco Bridge Co., San Francisco, Cal., to handle the company's Pacific coast business in coal handling, conveying, and hoisting machinery.

MIAMI VALLEY MACHINE TOOL CO., Dayton, Ohio, has recently completed an addition to its building, greatly increasing its floor space, for assembling purposes. The addition will enable the company to considerably increase its output of engine lathes, universal cutter and plain tool grinders and drills.

LAPOINTE MACHINE TOOL CO., Hudson, Mass., gave its employes their first annual outing Saturday, June 25, at Treaty Elm Grove, Stow, Mass. About 150 attended. Sports were provided and prizes given to the successful competitors. Music was furnished by the Hudson Band. The event was a great success.

BROWN & SHARPE MFG. CO., Providence, R. I., announces that its works will be closed from August 5 to 22 for the annual vacation. During that period the offices will be opened as usual and orders for machine tools, machinists' tools and measuring tools will receive attention as at other periods of the year.

INVINCIBLE ELECTRIC BANK PROTECTION CO., Munroe, Wis., manufacturer of double steel electrified vaults, linings and complete electric alarm systems, has added to its output a line of improved safe-deposit boxes, filing cases, roller shelving, omnibuses, desks, tables, etc. The capacity of the company has been more than doubled during the last three months.

BAUSH MACHINE TOOL CO., 200 Wason Ave., Springfield, Mass., has begun the publication of a house-organ entitled *The Driller*. The second number is attractively printed in black and red and, besides the advertising and argument for the Baush multiple-spindle drill, contains interesting shop notes and miscellany. It will be sent on request to those interested.

CINCINNATI PLANER CO., Cincinnati, Ohio, reports an improvement in foreign business during the month of June. The company booked orders for planers from Siberia, Germany, Holland, Italy, Mexico, Cuba, South America and Canada. It also booked some large orders from prominent concerns in the United States, and the prospects for a big year's business are good.

BANTAM ANTI-FRICTION CO., Bantam, Conn., through its president, Mr. W. S. Rogers, who is spending the summer in Europe, has secured sole representation in America for the well-known steel balls made by Heller Bros., Marienthal, Germany, and DKF ball bearings made in Leipsig. It is the intention of the company to open branch offices in Philadelphia and Detroit in the Autumn.

ST. LOUIS STEEL FOUNDRY, St. Louis, Mo., owned and operated by Curtis & Co. Mfg. Co., has increased its capacity about 100 per cent as a result of the success the company has made in the manufacture of manganese steel crossings, frogs, switches, etc., for steam and electric roads, and miscellaneous manganese steel castings. The addition has been completed and additional crane and grinding equipment has been installed.

T. R. ALMOND MFG. CO., Ashburnham, Mass., is distributing copies of tests recently made at the Orswell Mills, Fitchburg, Mass., showing the horsepower required to drive spinning mules. The tests demonstrate the desirability of using flywheels of about 30 inches diameter, weighing about 600 pounds, to reduce the power fluctuations, and it is expected that a No. 3 Almond right-angle transmission will drive two mules satisfactorily.

ELECTRIC WELDING PRODUCTS CO., Cleveland, Ohio, has moved into its new factory addition 94 x 100 feet, three stories high. New machinery has been installed and offices have been fitted out on the second floor of the new building. The number of men now employed is about 350. The company solicits business particularly from automobile and parts manufacturers, manufacturers of machinery, electric apparatus, and stationary engines.

INTERNATIONAL ACHESON GRAPHITE CO., Niagara Falls, N. Y., will erect a large addition to its works on the lands of the Niagara Falls Power Co. in that city. The addition will be a furnace room having a capacity for ten or twelve new furnaces. The building will be of brick and steel construction. The additional furnaces will largely increase the output of graphite which is used in the manufacture of electrodes, paint pigment, lead pencils, electroplaters, molding and polishing leads, lubricants, etc.

ACHESON OILDAG CO., Niagara Falls, N. Y., has purchased a factory site of thirty acres at Port Huron, Mich., where it will erect a building for the manufacture of oildag. The price of oildag has been reduced to approximately 60 per cent of that recently quoted, which brings it down to a price, when bought in quantities, considerably less per gallon than that of the oil with which it is mixed. It is claimed that the presence of deflocculated graphite in the oil makes each gallon equal to from two to four gallons of plain oil.

WAGNER ELECTRIC MFG. CO., St. Louis, Mo., has removed its Charlotte, N. C., office to the Woodward Building, Birmingham, Ala., where it will be in charge of Mr. J. F. Jones. The Birmingham office will serve that part of Tennessee east of the Tennessee River and all of the states of Mississippi, Alabama, Georgia and Florida. North and South Carolina, which have hitherto been handled from the Charlotte office, will now be served by the Philadelphia office, which is located in the Real Estate Trust Building, in charge of Mr. John Mustard.

WAGNER ELECTRIC MFG. CO., St. Louis, Mo., has opened an office in the Woodward Building, Birmingham, Ala., which will be in charge of Mr. J. F. Jones. Mr. Jones, who is a Southerner, graduated from the Alabama Polytechnic Institute in 1901, when he entered the employ of the General Electric Co., working in its testing department, inspection department and finally becoming transformer salesman. In 1905 he became transformer sales engineer for the Fort Wayne Electric Works, and in 1909 joined the home office force of the Wagner Electric Mfg. Co.

TAFT-PEIRCE MFG. CO., Woonsocket, Mass., has opened an office at 1311 Majestic Building, Detroit, Mich., where competent mechanics will be located for the express purpose of looking after the company's interests in the Middle West. The increasing demand for prompt and high-grade service in the designing and construction of special tools

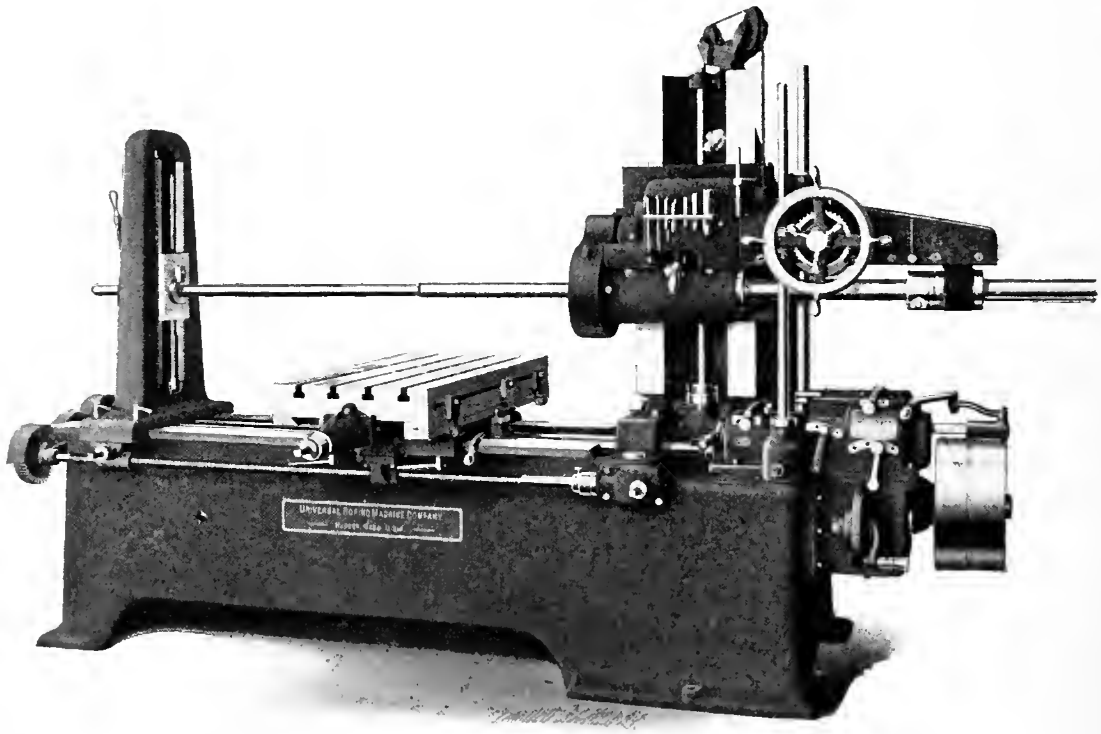
such as jigs, fixtures, gages, etc., has required the Western office. The company now has, in its Woonsocket plant, one of the most completely equipped tool-rooms in the country, with ample facilities for at least 250 workmen.

JOSEPH T. RYERSON & SON, Chicago, Ill., have removed their New York office to the seventh floor of the Hudson Terminal Building. The office will be maintained in connection with the machinery display rooms and warehouses immediately adjacent to the Jersey City terminal of the Hudson-Manhattan tunnel. A complete stock of boiler, structural and machine shop fittings and specialties, Morison corrugated furnaces, Glyco bearings, tool steel, metal-working specialties and shop supplies and equipment will be carried. The shipping facilities are unexcelled.

B. F. STURTEVANT Co., Hyde Park, Mass., manufacturer of fans, blowers, fuel economizers, and mechanical draft apparatus, held a salesman convention June 15-18. The company's branch office managers and principal salesmen from all over the country assembled at the works and general office of the company at Hyde Park, and spent four busy days in going over general business. The evenings were enlivened by banquets and other social features. The last day of the convention closed with a delightful sail down the harbor and an afternoon and evening at the Cohasset home of Mr. E. N. Foss, treasurer of the company.

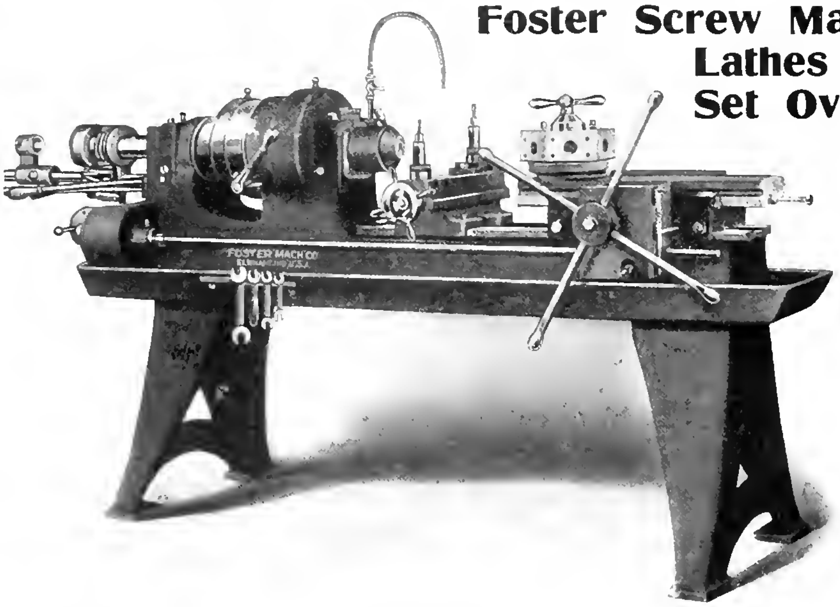
KEUFFEL & ESSER Co., Hoboken, N. J., manufacturer of drawing materials and engineering supplies, celebrated the forty-third anniversary of the founding of the house Tuesday evening, July 19, by a banquet to its employes at Grand View Park, Jersey City Heights, N. J. Interest was added by the fact that four employes this year complete their twenty-fifth year of service with the company. Appropriate gifts were presented to them by the company and some very handsome testimonials were given them by their fellow workmen. Twelve employes, who have completed a quarter of a century of service with the company, occupied places of honor with the officers. The evening proved to be so great a success in cementing the interest of all concerned that the banquet no doubt will be made an annual institution.

AGNEW ELECTRIC WELDING Co., 868 Military Ave., Detroit, Mich., has issued a statement regarding its activities and business control. The control and management of the company recently changed hands. A party of Cleveland men, active in the management of the Electric Welding Products Co., Cleveland, Ohio, has bought out the Agnew interests. The officers of the company are: C. E. Thompson, president; J. A. Krider, vice-president; R. K. Loofburrow, secretary and treasurer. The company will immediately add to its facilities, and expects to move from 868 Military Ave. to a better location in Detroit. Application has been made to change the name of the company to the Michigan Electric Welding Co. The company makes a specialty of welding automobile work such as the forging of rod yoke ends assemblings complete, drag links, fore-and-aft connections, propeller shafts, and in short the welding of any sort of forgings and parts that can be successfully welded to rods, shafts, tubes, etc.



Foster Features that are Financial Factors

in the rapid production of duplicate machine parts and are incorporated in



Foster Screw Machines, Foster Turret Lathes and Foster Universal Set Over Turret Lathes

are as follows:

Independent stops for each hole in the turret.

Quick Change Gears to the power feed.

Adjustability in all directions—allowing re-alignment when worn out of true, and in all Foster Universal Machines, Independent stops to the turret slide—an advantage not found in any similar machine.

You can save money, insure accuracy and handle a wider range of work with Foster Machines.

Screw Machines have capacity from ¾" to 4½"—Turret Lathes take work from 10" to 24" swing and Set Over Lathes 16" to 18" swing.

Ask us for estimates on your line of work.

Foster Machine Co., 1100 Beardsley Ave., Elkhart, Ind.

AMERICAN AGENTS—The H. A. Stocker Machinery Co., Chicago, Ill C. C. Wormer Machinery Co., Detroit, Mich. Manning, Maxwell & Moore, New York, Philadelphia, Pittsburg, Syracuse, Buffalo, Cleveland, St. Louis, Atlanta, Ga., Milwaukee, Wis., Portland, Ore., Seattle, Wash., Boston, Mass., Chicago.

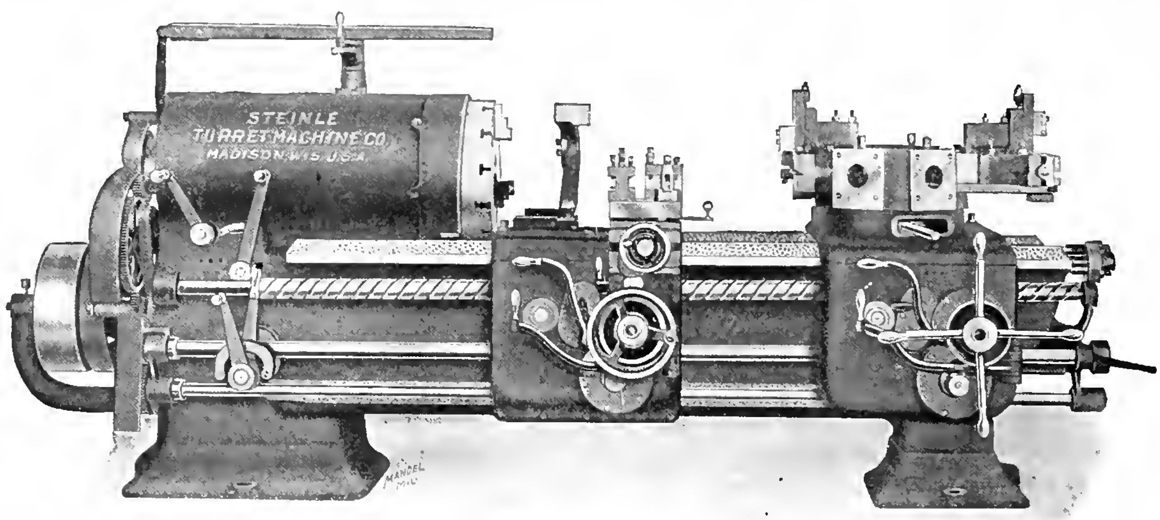
Steinle Full Swing Side Carriage Turret Lathe



Pre-eminently a manufacturing machine with every advantage for the economical production of duplicate machine parts, it has strength, rigidity, all operating conveniences and is built for the heaviest service. Tools have practically no overhang. Tool post carriage is arranged to run past the chuck. Both carriages are operated by power. Single drive. Thirty changes of speed all under immediate control. We shall be glad to send further description on request.

It has never been our custom to forward our interests by discrediting others

Lincoln-Williams High Speed Twist Drills

meet all competitors fairly and squarely and stand on their own individual merit.

We have centered all our forces and energies on making the best twist drill that could be offered—

Lincoln-Williams High Speed Twist Drills

made from the finest materials, after improved patterns and under the supervision of trained mechanics are "The Perfection of Mechanical Art".

The staying qualities of these high grade, high speed drills have been so well demonstrated that their economy is firmly established. They meet the highest speeds of which modern drilling machines are capable, stand heavy feeds and do their full duty under all conditions.

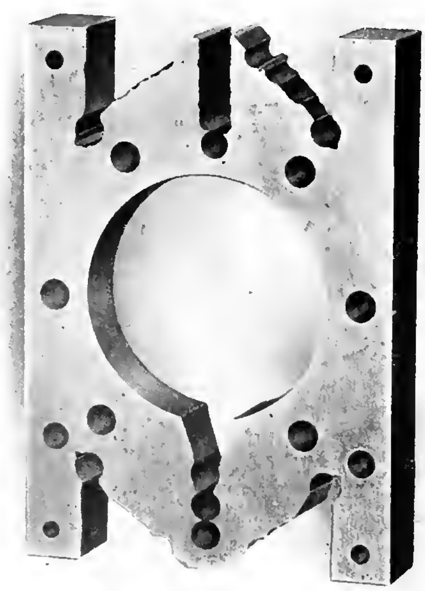
We can lessen your drilling costs by a considerable amount if you will use Lincoln-Williams High Speed Drills—full line of styles and sizes.

Catalogue on request.

Lincoln-Williams Twist Drill Co.

Taunton, Mass., U.S.A.

Steel for High Grade Dies



The making and working of high class dies is one of the tests that brings out the good qualities of the steel or shows up its deficiencies.

The die, here shown, made by a manufacturer of extremely fine and expensive dies, did not vary 1-10000" in the hardening, notwithstanding the unusual difficulties offered by reason of the many angles, holes and thin sections.

No change in hardening.

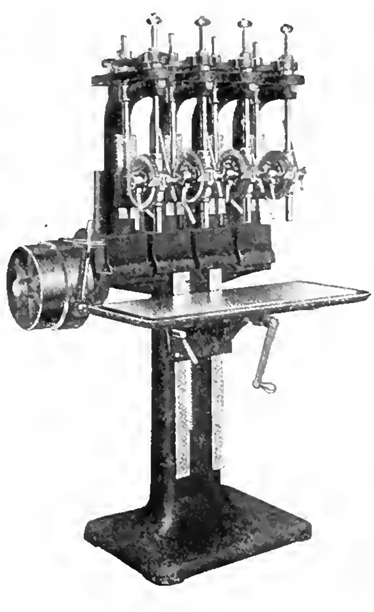
Our steels are particularly well adapted for die making—write us your requirements and give us a trial.

Cammell Laird & Co., Ltd., (Sheffield)

25 Cliff Street, NEW YORK CITY

Manufacturing Drills

Capacity $\frac{1}{4}$-inch to $\frac{3}{4}$-inch Holes



In convenience, speed, adaptability and simple but absolutely up-to-date construction these machines meet and pass all competitors. They are built in a wide range of sizes with five different types of heads, have positive gear drive and silent chain, thus avoiding the annoyances consequent to slipping or broken belts, frictional losses from tight belts and other belt troubles. There is power and rigidity to drive high speed drills to their full limit and a dependable accuracy that counts largely in the days work.

New catalogue showing all sizes will be sent on request.

WHEN THE CENSUS MAN WENT ROUND

If he had kept score of the number of **skilled workers machinists, toolmakers** and others—who are using **American Swiss Files** to the exclusion of other brands, there would have been some **surprising figures.**

Files have come to stay. We are making new friends every day, but what's more to the point, we keep our old friends. You can persuade a man to *try* a new thing, but it must have **quality dependable, ingrained quality**—before he will "tie to it".

We should like to send a few *free* sample files as **"persuaders"**—they will do the rest themselves. Your preference in size, shape and cut written on your *business letter head* will bring the samples.

Address nearest agency below.

Bearing vs. Wearing

The solution to the question, in so far as it concerns High Speed Drilling, is found in the inserted, interchangeable bearings of

Henry & Wright Drilling Machines

Wearing never ceases, yet by this plan it not only decreases but becomes a secondary consideration in the life of our machines.

They allow a **200** to **400** per cent. production increase and speeds that would destroy an ordinary machine. Bearings seldom need replacement and guarantee a new length of life and service with each renewal.

9½", 12", and 15" Overhang.

Office Boy—Impossible.

IS LIFE A GRIND TO YOU?

To the preacher life's a sermon,
To the joker it's a jest;
To the miser life is money,
To the loafer life is rest.
Life is but a long vacation
To the man who loves his work;
Life's an everlasting effort
To shun duty—to the shirk.
To the heaven-blest romancer
Life's a story ever new;
Life is what we try to make it—
Brother, what is life to you?

Away with the pessimist who says the world is growing worse. Working conditions, bad as they seem to-day, are not to be compared with the barbarous olden days.

Even in England, some centuries ago, if an ordinary workman moved from one parish to another without permission, in search of work or better wages, he was branded with a hot iron.

Consider the ever-increasing number of helps on simple operations such as grinding or cleaning castings. Not only is the old-fashioned way pure drudgery, but moving heavy, cumbersome work about is inconveuient, to say the least.

Now, a light, speedy tool which moves freely wherever required does the work more efficiently and in a fraction of the former time. This same outfit has several interchangeable tools which multiply its usefulness.

If life is a grind to you, we recommend a Coates Flexible Shaft Outfit—it shortens the grinding time.

EDITING THE SPOTLIGHT

You say it's a simple matter.

It is (if you only have to read it) but with our foreman at home shot three times, a printer in the jail half-shot, another in the office not worth shooting, the SPOTLIGHT is issued under difficulties this month.

But to come to the point. Some of our readers have had interestiug experiences with Coates Flexible Shafts and Tools. Many users have reduced working time on several operations to one-half or one-third of that formerly necessary.

The Editor would like a few details of these things first-hand. Just drop him a line addressed: "Editor of THE SPOTLIGHT, care Coates Clipper Mfg. Co., Worcester, Mass." It will be promptly acknowledged and possibly published here. Please let us hear from you soon—in time for the next issue if possible.

SUMMER BOARDERS—"Haow do them summer boarders of yourn keep busy?" "They play golf." "What'n Sam Hill's that?" "S near's I kin figger, it's solitaire shinny."

YOU can fool udder peoples some of der time, but you can fool yourself all der time.

NERVE CURE—"Prisoner, are you guilty or not guilty?" "Let my lawyer plead not guilty for me, judge; I ain't got the nerve."

COMPANION WANTED—The absent-minded professor returned home one evening, and, after ringiog his front door bell for some time to no effect, heard the maid's voice from the second-story window, "The professor is not in."

"All right," quietly answered the highly educated man, "I'll call again." And he hobbled down the stone steps.

SOME mens go through dis vorld on der brincible dot der more noise dey make, der more salary dey vas voith py pay day oo.

Please Mention THE SPOTLIGHT Ad.

The COATES Way—1910

200 years ago they cleaned castings by hand. But up-to-date manufacturers cannot afford to use slow, costly methods especially when one

Coates Flexible Shaft Outfit

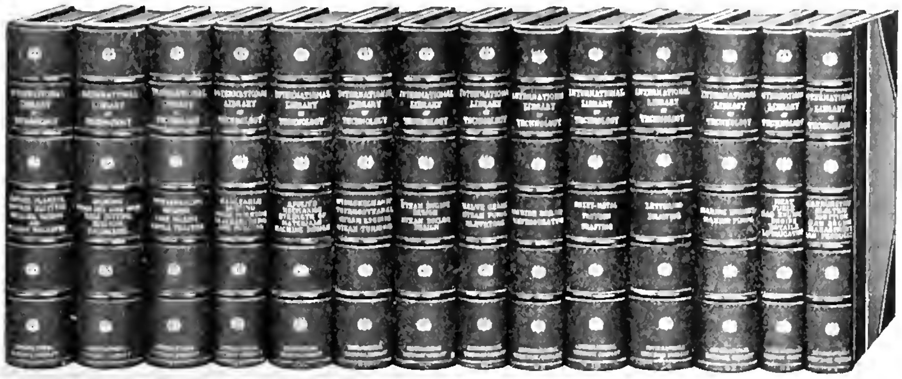
does the work of several different tools and as many men.

Grinding is only one of the possibilities. Drilling, surfacing, snagging, scratching, polishing, chipping, boring, etc., are all within its capacity.

The outfit takes the place of sand blast in removing rust, and for slicking up metal work or preparing castings so the paint will look smooth. It can't be equaled either in point of economy or efficiency.

Catalogue 22 will tell you many things of interest. Have you a copy?

Coates Clipper Mfg. Co.
Worcester, Mass.



The World's Best Mechanical Library

This Library of Mechanical Engineering is part of the 99 volumes of the International Library of Technology that cost over $1,500,000 in its original preparation. They contain the results of years of experience of the best mechanical experts in the country. They contain the best modern practical methods used in every branch of the mechanical profession. The matter has been written by the foremost technical experts and illustrated by a special staff of artists and craftsmen. Not only are they suited for mechanical engineers already well trained in their profession, but they are especially adapted for the use of those learning the profession and desiring to advance to the higher places, and those that wish to acquire in the easiest and most thorough manner the knowledge that will qualify them for such advancement. This Library is the only practical library in existence wherein the subjects treated can be readily understood and practically applied by persons having no knowledge of higher mathematics.

Edwin S. Cramp, vice-president of the William Cramp & Sons Ship and Engine Building Company, of Philadelphia, says: "I have examined the International Library of Technology and have no hesitancy in saying that it is the most complete set of technical books that I have ever had the pleasure of placing in my bookcase. The thoroughness with which you go into the various subjects is marvelous."

You need a work that will explain to you the latest and best practice—not a collection of long-drawn-out, involved theories, but an epitome of the every-day practice of the foremost mechanical experts. No other reference work on machinery so fully merits this description as these volumes of the Mechanical Library. The volumes treat of practical work, starting with the simplest problems and covering in a comprehensive manner the whole subject of mechanical engineering.

The Mechanical Engineering Library contains 14 volumes durably and handsomely bound in three-fourths red morocco, stamped and numbered in gold. The books are printed on a high-grade book paper, and the type is large and easy to read. Each volume is 6 × 9 inches in size. They may be purchased in sets of five or more volumes.

If you will mark and mail the attached coupon we will send to you a circular containing a full description of all the volumes of the International Library of Technology. Every man engaged in mechanical work should know about our Library of Mechanical Engineering. Mark and mail the coupon **NOW.**

Little Giant

TOOL TOPICS—TWO TESTS

All merchandise is subject to TWO general tests—the "eye" test and the "service" test. You have probably found that some tools are only built for LOOKS—in fact, just to SELL. And you know there are other tools that don't look very fine but get the work done.

LITTLE GIANT tools will pass BOTH tests. They are made FIRST to do the work RIGHT, to do a lot of it, to do it for a long time—and THEN we finish them to pass the "eye" test—you'll find them the best looking tools of their class on the market. They ARE right and they LOOK right.

Ask for them at your dealer's or write us direct for quotations. **"Their use becomes a habit."**

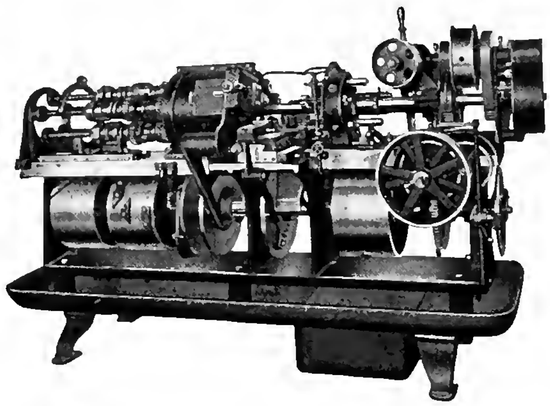
The Universal Automatic Screw Machine

A Money-maker that will Quickly Earn its Cost.

Profitable

for any manufacturer who uses large quantities of metal parts.



Practical

and strong enough for almost every class of work milled from the solid bar.

Do You Want Bigger Profits?

Then the "Universal Automatic" is a necessity. Absolutely simple design and construction, does the work of a score of machines in an almost incredibly short time and bears the strain of the heaviest cuts without spring or binding. We have collected data on economical production of small metal parts, steel, iron or brass—any shape. This information is always at your service. *May we send it?*

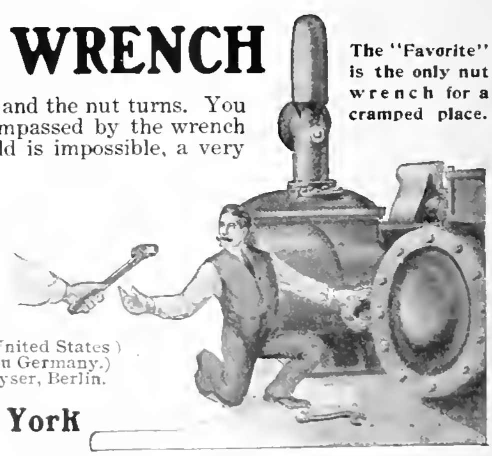
With THE FAVORITE REVERSIBLE RATCHET WRENCH

The "Favorite" is the only nut wrench for a cramped place.

only a slight movement is necessary to enable the ratchet to catch one tooth and the nut turns. You are not bothered to catch a fresh hold at each turn, for the nut being encompassed by the wrench head does not leave it until the nut is seated or removed, slipping the hold is impossible, a very important matter when working in an awkward place. It is not only a trouble saver where other wrenches won't work, but wherever nuts are to be turned it has all ordinary wrenches skinned a mile.



"Favorite" (Registered trade mark in United States)
"Greentweed" (Registered trade mark in Germany.)

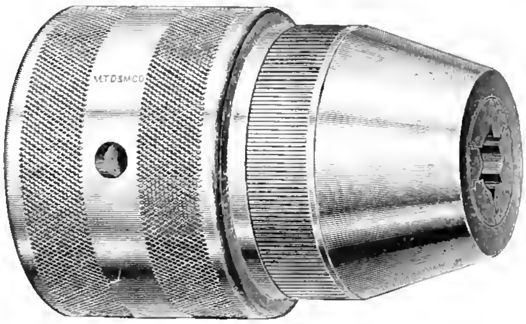
"MORSE CHUCKS"

STETSON PATENT DRILL CHUCK.



This chuck is strong and of heavy construction. The jaws are controlled by separate drivers and are guided in that part of the chuck which is attached to the driving spindle. This arrangement gives increased strength to the chuck.

The threaded and working parts of the Chuck are covered, and thereby protected from injury and dirt.

No. 2 Holds from 0 to $\frac{3}{8}$ inch diameter.
No. 3 Holds from $\frac{1}{16}$ to $\frac{1}{2}$ inch diameter.
No. 4 Holds from $\frac{3}{16}$ to $\frac{5}{8}$ inch diameter.

These Chucks are so designed that a hole can be drilled through the center if desired.

No. 2 will permit of a hole $\frac{1}{4}$ inch in diameter.

Nos. 3 and 4 will permit of a hole $\frac{3}{8}$ inch in diameter.

With Chuck No. 2 is furnished a spanner wrench, illustrated below.

These wrenches are of steel, drop forged, finished and case hardened.

With Chucks Nos. 3 and 4, instead of a spanner wrench there is furnished a special pin used in tightening and for rapid adjustment.

NORTON

THE CUTTING FACE OF A GRINDING WHEEL

has thousands of little tools cutting off little chips. It makes a big difference what these little tools are made of, just as it makes a big difference what quality of steel is used in making steel tools. It makes a big difference as to how each little tool holds its cutting edge.

A Norton wheel gets its good-cutting face from Alundum. Each little grain of Alundum that is working is a tool in perfect condition for good work.

Insist on a grinding wheel made of Alundum, just as you would insist on the best grade of steel for your steel tools.

INDIA OIL STONES

Every user of edged tools should have a list of India Oil Stone shapes and prices. The "India" cutting quality is recognized wherever tools are used. Made in 64 different shapes. Send for list to Pike Manufacturing Company, Pike, N. H., Sole Selling Agents for the India line.

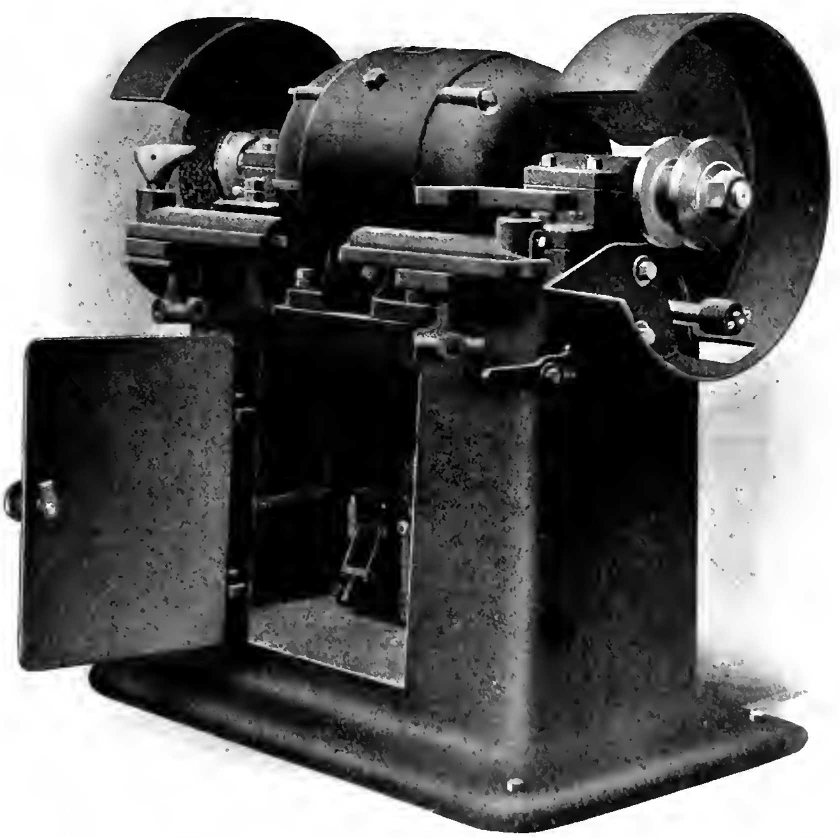
FASTER AND BETTER

IN grinding large steel dies for stamping out buckets and coal hods, Carborundum was tested out in competition with the best grinding wheels that could be found of other makes. Carborundum ground one die every fifteen minutes—It did not heat the die—It held up well on the corners and did not throw chunks or raise dust—

The best of the other wheels took 30 to 40 minutes for each die—It threw chunks and did not hold up on corners—It also raised so much dust that the operator could not finish a die without taking fresh air. Carborundum not only worked twice as fast, but it held up better, lasted longer and was clean. It will do the same thing in your grinding shop.

THE CARBORUNDUM COMPANY, Niagara Falls, N. Y.

The Ransom Patent Speed Controller Applied to Ransom Motor Driven Dry Grinders



Makes an A-1 combination of economy, convenience and efficiency.

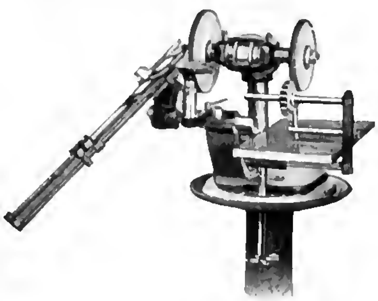
Gives the operator complete control of speed variation. Keeps the machine running at correct speed as the wheel wears down. Assures the maximum production at all times without power losses.

Adapted for any direct current grinder.

Ask us for complete details.

RANSOM MANUFACTURING CO., Oshkosh, Wis.

The Robinson Tool Grinder for Twist Drills and General Work



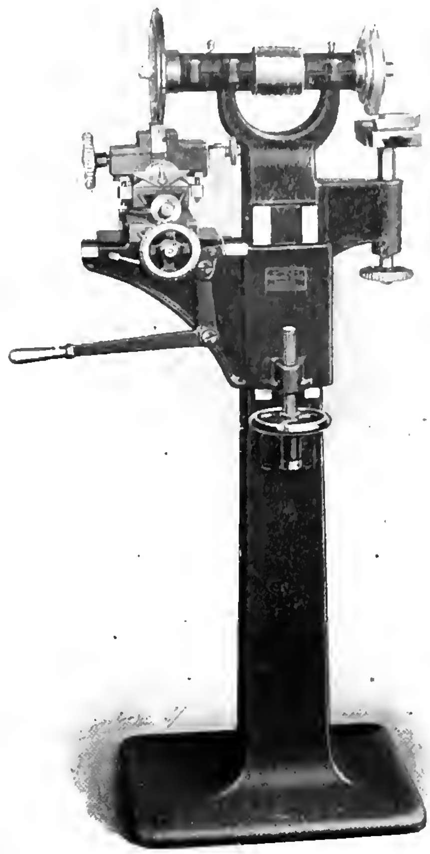
Any mechanic can grind twist drills theoretically correct on the Robinson Improved Grinder. Especially satisfactory on three and four flute drills.

Selected wheels and smooth, steady running insure the efficiency so necessary for fine tool grinding.

Combines many special features of larger, more costly machines. Moderate price. Write for details.

THE ROBINSON TOOL WORKS
Waterbury, Conn., U. S. A.

The New Geometric Chaser or Die Grinder Insures Continued Accuracy.



That's the chief requirement of all screw-cutting tools. Correct grinding by hand is no easy matter and the Geometric Grinder is distinctly designed to overcome these difficulties and secure clean cutting dies quickly and economically, within any desired limit of tolerance.

For "touching up" or complete regrinding all makes of thread chasers, either stock or special, this machine is unequaled and a second wheel provides for ordinary tool grinding.

Universally mounted vise with adjustments for grinding to any radius, right or left hand, is part of the equipment.

Let us send the full description.

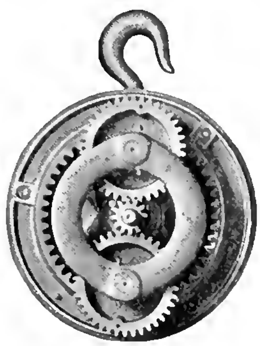
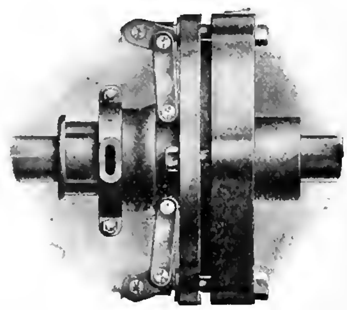
PERFECT CHAIN GUIDE

Simple Mechanism
Interchangeable
Steel Parts



135 No. Second Street
PHILADELPHIA, PA.

The Acme of Simplicity



In Clutch Construction

has been reached in the Latest Improved Worrall Friction Clutch. It is built on the principle of a solid flange coupling with the addition of simple levers to afford a means of connecting and disconnecting instantly. In addition to its simple mechanism, this clutch offers advantages which are not met with in any other make. It has demonstrated its superiority over all other clutches for all purposes, and is the choice of practical men the world over. The almost universal use of the Worrall Clutch under all conditions is its strongest claim for favorable consideration.

We build "A Special Clutch for every Special Purpose". Better let us design a special clutch to meet your requirements and give you the benefit of our long experience.

Send for catalog. It illustrates various improved methods of transmitting power by means of this clutch.

American Twist Drill Co.

Established 1865 — Dept. A, LACONIA, N. H.

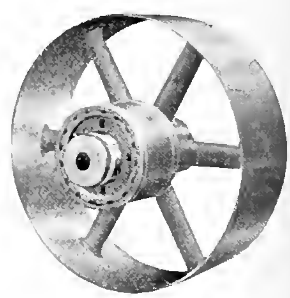
3,000 GRIPS A DAY WITHOUT A SLIP

The perfect control of "AKRON" Friction Clutches in the line of heavy service brought us the following:

> "These clutches must be operated 3,000 times every 24 hours in our work and naturally the service is very severe. Your clutch has stood up to this work in the best possible manner and we have not spent a cent on it for repairs."

The smooth, positive action of "AKRON" clutches is always assured because all pressure is in line with the shaft and, once engaged, all end thrust is eliminated.

If you need a powerful, satisfactory clutch, write for the Akron booklet.



The Williams Foundry & Machine Co., Akron, Ohio, U.S.A.

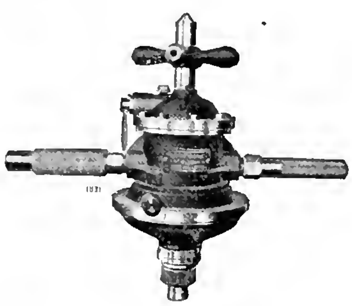
TOOLS THAT NEED NO NURSING

A tool that isn't dependable—that is erratic in its behavior—that must be "nursed" to make it do its work at all—isn't a good tool for your purpose.

The tool you want is always ready for business, and works hard and fast and profitably.

The difference between these two kinds of tools is in the amount of care and "know how" applied in their design and construction.

"CROWN" AND "IMPERIAL" PNEUMATIC HAMMERS AND DRILLS NEED NO NURSING. OPEN THE THROTTLE—AND THEY'RE READY FOR THE DAY'S WORK, AND A VERY GOOD DAY'S WORK, TOO.



We have built them as well as we possibly can, with thirty-nine years of experience to teach us. We know that no tools can be better built.

We offer you "Crown" and "Imperial" Tools with no wildly extravagant claims as to their performance, and with no "extras" thrown in.

We urge them upon you with the firm conviction that you will find them to be steady, reliable, profitable "tools for service."

Your request will bring you our Tool Bulletins.

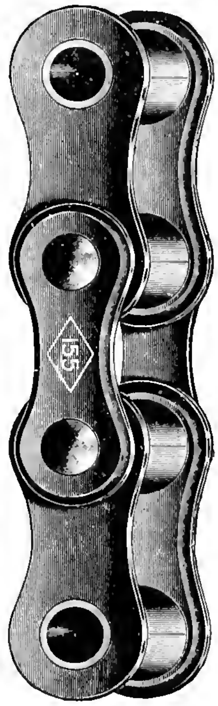
DIAMOND CHAINS ONLY WOULD DO THE WORK HERE



This machine mixes foundry sand, the knives making a cut every half inch from the top to the bottom of the pile. Of course some of the damp sand gets onto the power transmitting mechanism around the knives, and this would knock out belting or gears in no time.

Diamond Chains have long been used to drive both wheels and cutting knives, and do their work well in spite of the dampness and the dirt. In fact, the whole machine is dependent for its success upon durability and satisfactory service from the chains.

That Diamond Chains are honestly good and are able to withstand such rough treatment is emphasized by Mr. George Lorimer, President of the Auto Sand Mixer Co., Piqua, Ohio, makers of the above machine, who comments as follows:

"The chains have given satisfaction and wear remarkably well considering that they are working in sand at all times and one of them at quite high speed. The chains wear longer than the sprockets under very hard conditions."

Let our engineers advise you about your troublesome drives. Ask for book "Chain Transmission of Power."

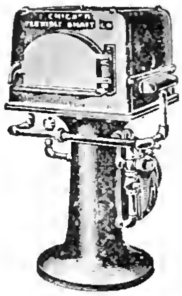
STEWART FURNACES

Adapted for use with any kind of gas, or with crude oil.

Proven efficiency and economy

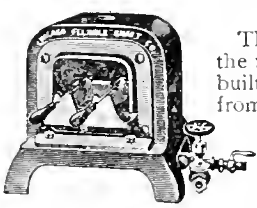
Send for our large catalog. Shows dozens of styles; gives descriptions and prices of each. Free on request.



Muffle and Oven Furnace

For heating dies, milling cutters, tools of all kinds, cutlery, springs, reamers, etc., this furnace is unquestionably the most practical made.

No. 1—Complete, with blower........ $100.00
" " without blower 75.00
No. 2—(as illustration) with blower.. 160.00
" " without blower 120.00



Soldering Iron Heater

For Gas Only

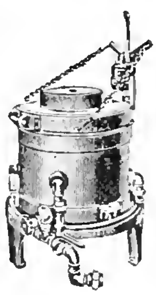
The most efficient of its kind on the market. Compactly and solidly built. Flame is projected upward from the bottom and surrounds the irons, heating them uniformly. Flame may be regulated by valves at right.

Price $8.00

Barium Chloride Furnace

Designed especially for hardening high speed steels. Special analysis fire-clay linings; no useless apparatus. Perfect combustion and absolute control of heat. Allows the life of high speed steel tools to be doubled.

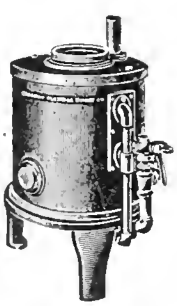
Prices.................. $40.00 to $150.00



Metal Melting Furnace

This is the most satisfactory furnace made for melting brass and other metals. The specifications are similar to those of the Barium Chloride furnace for high speed steels, but is fitted with an automatic device for swinging the cover

Prices...................... $43.00 to $155.00

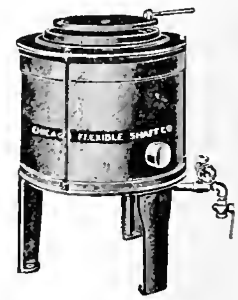


Cyanide Hardening Furnace

Similar to the single crucible furnace, but is more practical for use on cyanide hardening. Allows cyanide to be raised to desired temperature quickly, and retained indefinitely. Very compact and requires little attention.

Price, with blower $75.00
" without blower................ 50.00

SEND FOR CATALOG TODAY

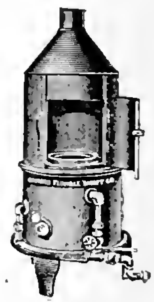


Soft Metal Melting Furnace, No. 3

For Gas Only

Cover is of cast iron and swings easily on a metal pin hinge. This allows all the heat to be retained and expedites the bringing of metal to the melting point. In fact, with this furnace melting point can be reached in 15 minutes after the furnace has been heated.

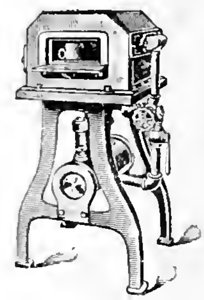
Price, without blower..................... $55.00
" with blower.......................... 80.00



Cyanide Hardening Furnace, No. 10

This furnace allows cyanide to be brought to hardening heat in about 40 minutes (starting with the furnace cold) and can be retained at this heat indefinitely. Burners are so arranged that flame strikes the pot at a tangent, giving a rotary motion to the heat and allowing heat to be evenly distributed.

Price, complete, with blower $100.00
" " without blower 75.00

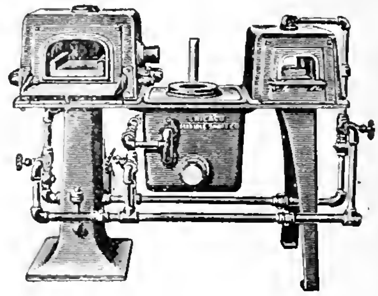


Stewart Forges

(No. 3 Illustrated)

These are ideal for making small forgings for tool dressings, etc. required heat is quickly produced and can be retained for almost any length of time. Takes only one minute to reach a forging temperature.

Price, without blower.................$40.00
" with blower..................... 65.00



Special Combination Furnace

Here's an oven furnace — crucible and forge furnace — all combined on one base for reasons of economy and convenience.

Price,

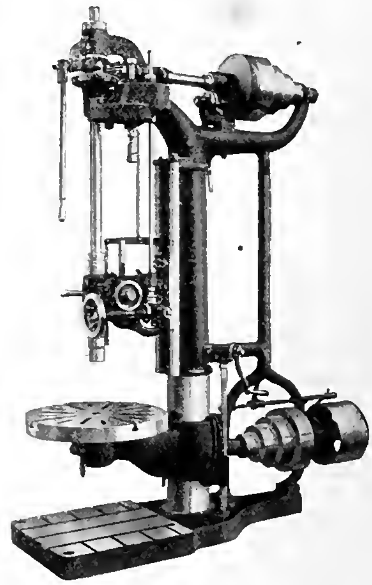
New Upright Drill No. 32

With Tapping Attachment and Geared Feed



The Mechanics line of high grade drills is noted for simple but powerful construction. No operating convenience has been overlooked, strength and rigidity are everywhere apparent, but the entire lack of complicated mechanism brings the manufacturing cost to a very moderate figure.

Write us for particulars, our line includes Standard Drills 32", 26", 24", 20", 14", 12"-B, sizes and No. 1 and 2 Friction Drills. All feeds "Positive." "Positive Feed".

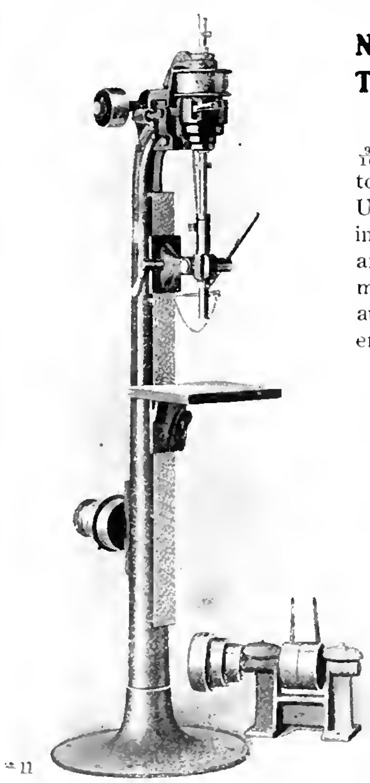
Something Entirely New and Worth Your Attention



No. 11 Drilling and Tapping Machine.

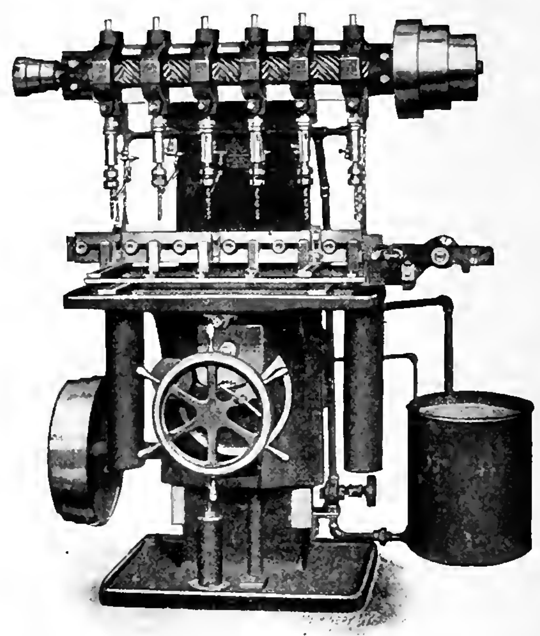
This machine drills $\frac{9}{16}''$ holes and taps up to $\frac{7}{16}''$ holes in cast iron. Used as a drilling machine, all tapping parts are idle. As a tapping machine it reverses automatically at both ends of the stroke. This is a convenience that you cannot afford to be without. We have two styles in single spindle machines, and any combination in multiple spindle drills.

Write for circulars.

H. G. BARR, WORCESTER, MASS.

21 HERMON STREET

Continuous Drilling



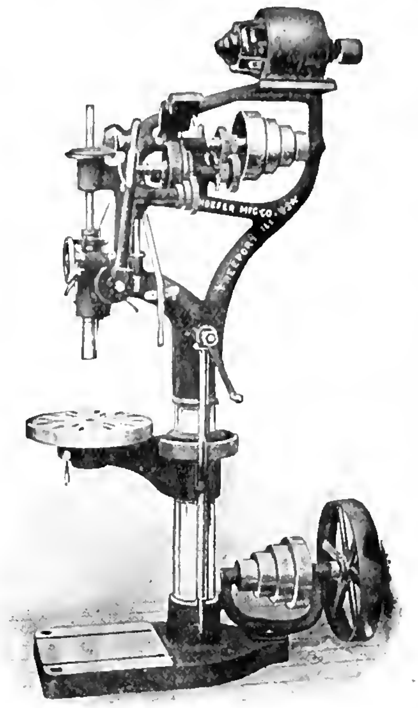
The sliding jig of **Moline Multiple Spindle Pin Drills** allows one set of work to be removed while the other is drilling, so operation is practically continuous.
Adjustment for holding different length and diameter cotter pins and similar work. Ball thrust bearings—vertical adjustment for various drills.

Send for complete details of Multiple Spindle and Gang Drills for every purpose.

MOLINE TOOL COMPANY, Moline, Ill., U.S.A.

AGENTS: Marshall & Huschart Machinery Co., Chicago, Milwaukee, St. Louis and Indianapolis.

A Line on Hoefer Drills is a Straight Line.



They are "straight" goods from the foundation up. We do our full duty when we build the machines spare no time, labor or expense to secure and maintain the most accurate alignment in every part. Grind all sleeves, worms and shafts to accurate standard size and to secure true running fit. Make the machines a little heavier and more rigid than usual to handle the heavier work, use sufficient metal, properly distributed, to provide for working strain. Incorporate all the time-saving devices that practice has proved worthy. We make the Hoefer Drills as near right as a mechanical proposition can be made and shall be glad to send full particulars on request.

Hoefer Mf'g. Co.
120 Jackson St., Freeport, Ill.

CLEVELAND, O., U. S. A.

THREE ESSENTIALS

QUALITY

Too little attention is given the big factor of QUALITY in buying. There are generally as many grades of quality as bidders and the tendency to regard prices only is altogether wrong.

You will find in our products – first of all—the best grade of material for the purpose – a distinctly different method of manufacture is used and the products are actually stronger and of better finish than others on the market.

PRICE

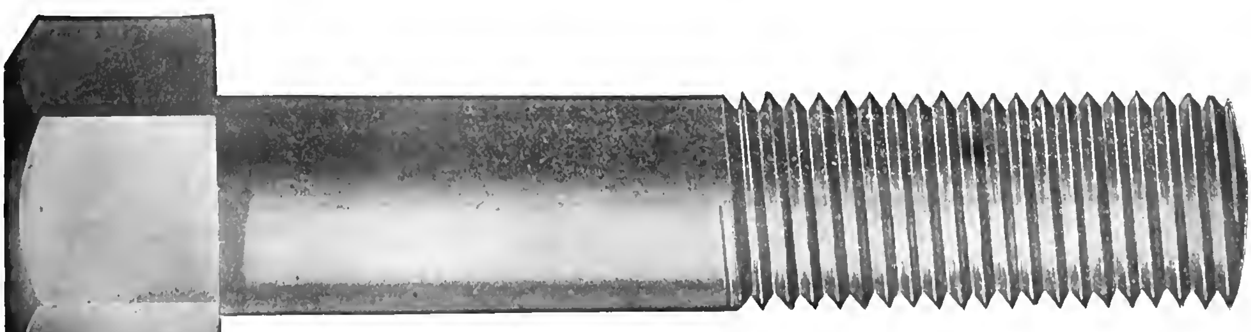
Our large finished steel bolts and screws, drill spindles, vise screw blanks, valve stems, rods and other machine, engine and automobile parts cost less the majority of times than inferior work made by other processes than the electric welding process.

In rare cases the price may be a trifle higher, but the difference in the quality, when considered, far over-balances the difference in prices.

SERVICE

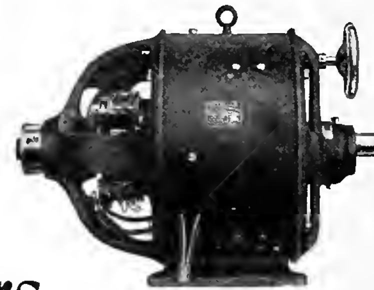
With your co-operation in anticipating your orders as far ahead as practicable, we'll give you the goods when you want them, as we are adding very heavily to our equipment.

You can ask about any other things of importance to you which we may have overlooked when you send in your next order or inquiry.



The Electric Welding Products Co., Cleveland, Ohio

When you install motor drive in your plant—get all the advantages



Why be satisfied with the ordinary type of motor which *almost* gives the desired results when you can get a *real* adjustable speed motor that *does* give the best possible results – the kind you want.

Reliance Adjustable Speed Motors

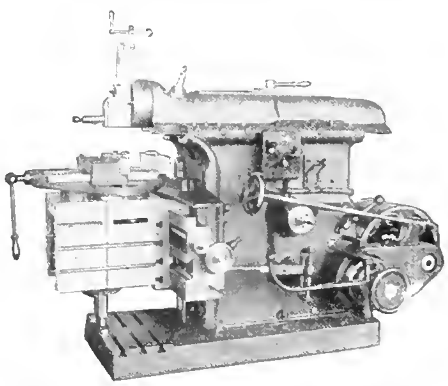
will give you all the usual advantages obtained with ordinary motors, such as greater cleanliness, better light, clear overhead space, flexible arrangement of machines, absence of belt and line shaft accidents, ample power at the cutting tool, and the greatest possible power economy.

What is of added importance on your machine tools is the accurate speed adjustment throughout wide and unbroken ranges in speed. The changes are smooth and gradual—no steps or jumps. You get the right speed for every operation on all kinds of work.

This is all accomplished easily and quickly by a simple mechanical method inside the motor—*no electrical controller is needed.*

The Ideal Drive for Your Machine Tools

Look at the illustration of the motor driven crank shaper. Note the compactness, and the simple and convenient method of speed control. An operator with a spark of energy will get the most out of such a machine.



Every machine in your plant regardless of its make or type is capable of producing certain maximum results. You can get these results all the time if you will provide your machines with the means of meeting the changing conditions which are constantly arising, especially in machine tool work. The power, overload capacity, and really accurate speed adjustment over wide ranges necessary to meet these conditions can be found only in the Reliance Adjustable Speed Motor.

If you have never had a chance to investigate the many merits and advantages of this wonderful motor at first hand, let us tell you of some of your neighbors who are using them. Our motor is its own best advertisement and the more familiar its users become with its efficiency and simplicity of speed control, the surer we are of a hearty recommendation.

If you are inclined to be skeptical when someone attempts to tell you how to increase the efficiency of your machine tools 25 to 100 per cent., we wish that you would read our Bulletin 101, "The Crank Shaper". It contains some real information—facts and figures that are the result of extensive and thorough tests.

Our Folder 10-M is interesting reading for motor users and we will gladly send copies for all of your engineers.

RELIANCE SERVICE

We are not electric motor manufacturers in the ordinary sense of the word but are specialists in complete motor equipments for Machine Shops. We furnish not only the motors but are also prepared to design and manufacture all brackets, gears, etc., for converting your belt driven tools to motor drive.

If you have work on which motors can be used to advantage, our engineers will gladly make a careful investigation of your needs. All we ask is an opportunity to show you what we have to offer as we are confident that sooner or later you will be convinced of the superior merit of Reliance Motors.

We manufacture Reliance Constant Speed Motors for either alternating or direct current service.

Reliance Electric and Engineering Co., 800 Huron Road, Cleveland, Ohio

---

It Is Shop Economy

to have a **Cut-Meter** for every machine tool. With this device at hand there is no excuse for speeds below the standard. It is simple, requires no timing or calculation; adaptable, can be used on any machine; convenient, can be held in any position—and shows the operator instantly and exactly, the cutting speed in feet per minute at which his machine is running.

Built for hard service and will save its cost a hundred times over in a year.

Send for catalogue.

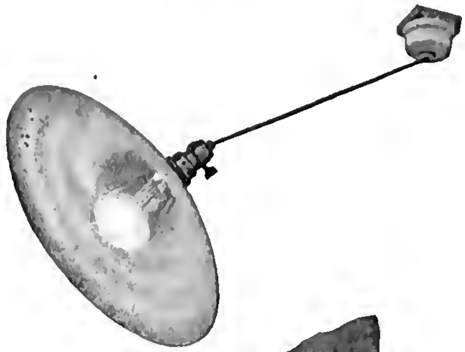
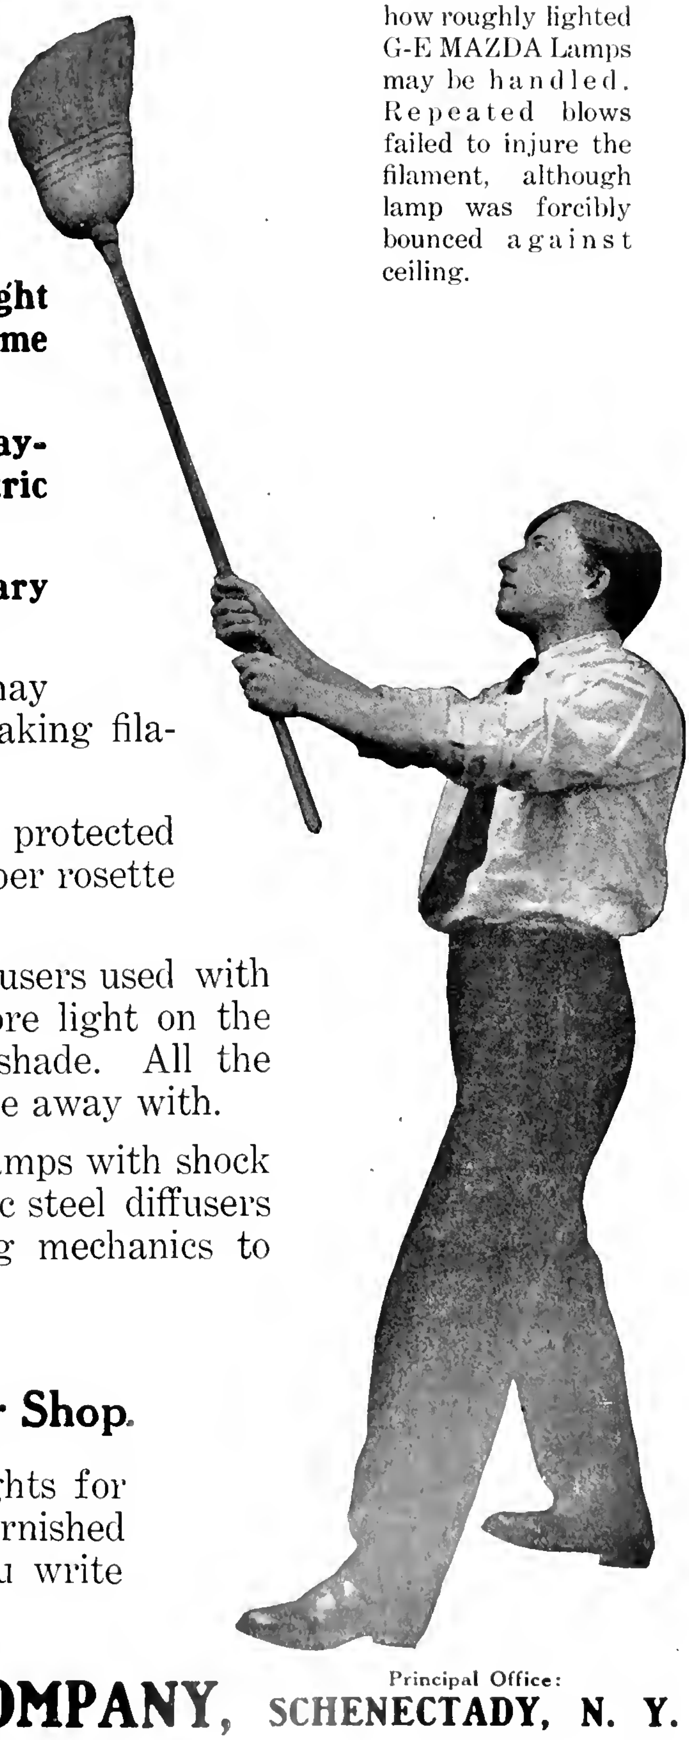
Sturdy G-E Mazda Lamps Stand Rough Treatment



This illustration is made from an actual photograph of a man demonstrating how roughly lighted G-E MAZDA Lamps may be handled. Repeated blows failed to injure the filament, although lamp was forcibly bounced against ceiling.



For shop lighting G-E MAZDA Lamps have three characteristics that place them far ahead of all other illuminants.

1. They give three times as much light as ordinary incandescent lamps of the same current consumption.

2. They show colors nearer to real daylight values than any other type of electric incandescent lamp.

3. They will withstand any ordinary shock without breaking.

When lighted, G-E MAZDA Lamps may be roughly cleaned without fear of breaking filament.

When not lighted, these lamps are protected from vibration by a special shock absorber rosette on the ceiling.

The 16 and 21″ concentric steel diffusers used with these lamps reflect from 15 to 20% more light on the work than is possible with any glass shade. All the light is reflected and black shadows done away with.

The combination of G-E MAZDA Lamps with shock absorbing ceiling rosettes and concentric steel diffusers will increase your output by enabling mechanics to watch their cuts clearly and surely.

A Lighting Plan for Your Shop

showing size and location of lights for most efficient lighting will be furnished promptly without charge if you write at once.

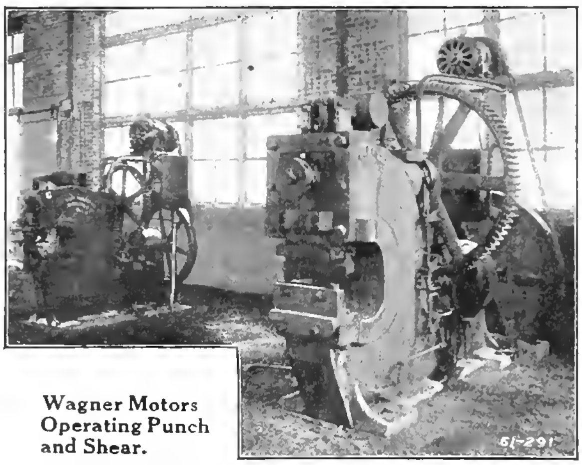
2012

Wagner Electric
Manufacturing Company, St. Louis, Mo.

The Wagner Single-Phase Motor

takes less current per line wire at starting and therefore disturbs less, the single-phase from which it takes **all** its current than a squirrel-cage motor disturbs each of its two or three phases. This is true even though the Wagner Single-Phase motor is thrown directly across the line without the intermediary of **any** starting device, while the demands of the squirrel-cage motor are moderated through an auxiliary auto-transformer.



Wagner Motors Operating Punch and Shear.

There is nothing novel about this statement. It has been advertised before and known for years. Let us send you, however, our Single-Phase bulletin which contains an excerpt from a paper read by the Manager of the Small Motor Department of one of our big competitors. The remarks in question outline clearly the present trend of opinion on the subject of single-phase distribution, particularly the change of sentiment on the part of manufacturers, who, unable to supply commercial single-phase motors have heretofore claimed the single-phased system to be uneconomical.

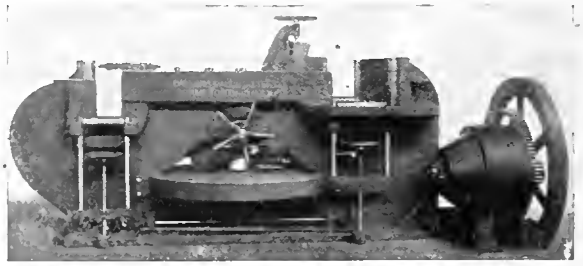
W WESTINGHOUSE ELECTRIC

Type "S" Direct-Current Motors
have stood the test of time



Westinghouse Type "S" Motor driving Horizontal Punch and Bender.

Their reliability under the severest operating conditions, their efficiency, durability, great overload capacity and low operating temperature are some of the reasons for their constantly increasing use. Type "S" Motors are made in standard capacities suitable for almost any possible demand and immediate shipment can be made from stock. The standard ratings range as follows:

2 to 75 horsepower, 110 volts
2 to 150 horsepower, 220 volts
2 to 150 horsepower, 500 volts
6 to 100 horsepower, 600 volts

Special motors for higher voltages up to 650 can be supplied on order.

Full particulars in Circular 1068.

Motor Profits

Before you spend much money for electrical equipment you probably want to know what interest you will make on your investment. This can be determined quite accurately before you spend a cent.

Anything that reduces your unit cost of production means additional profit and here is where

Fort Wayne Motors Prove Their Superiority

We will be glad to furnish you with guarantee performance curves for any of our motors and if you will send us your specifications our engineers will solve your individual problems and recommend sizes, etc.

With this information you can easily figure out how much you will gain by installing electric drive in **your** plant.

There are a great many advantages also on which it is hard to place a **money** value, such as cleanliness, convenience of locating machines regardless of power supply, ease of control, automatic operation, economy of floor space, elimination of belts and pulleys, increased safety and freedom from accidents to employees, more light and less noise.

These points apply in general to almost all motors but there are particular features about Fort Wayne Motors that make them the **best purchase** on the market. Anyway it will pay you to send for our Bulletin "Motor Drives." It's free.

Successors to F. B. McCROSKY MFG. CO.

Duplex

Drawing Paper

has long been recognized by draftsmen throughout the country as the standard for machine drawing. It is tough and hard, and absolutely uniform in quality.

The erasing qualities of Duplex paper are unsurpassed. Successive erasures may be made over the same spot until the thickness of the paper is reduced to that of tissue paper, and it will still take ink and pencil as perfectly as on the original surface.

Another advantage of Duplex is the cream or buff color, which is agreeable to the eye and permits the paper to be handled without soiling.

Send for a free sample of Duplex paper and test its good qualities yourself.

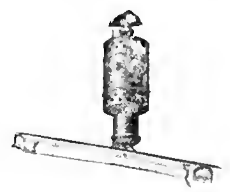
TRADE "BETTER THAN DAYLIGHT" MARK

COOPER HEWITT LAMP

An Array of Facts:



Theories are good for the inventor and the scholar, but facts are what you want when you are estimating on a job. You always give yourself the benefit of the doubt, with a liberal margin of safety.

Here are the facts concerning the Cooper Hewitt Lamp, proven beyond doubt and stated with a hundred per cent margin of safety.

The Cooper Hewitt Lamp gives a light of an entirely different quality from any other light-source, because the light comes from a luminous vapor instead of a luminous solid.

The quality of light from the Cooper Hewitt is such as to enable the eye to distinguish finer details than is possible with any other light, not even excepting daylight.

You can see objects plainly in a much dimmer light from the Cooper Hewitt Lamp than from any other light-source; hence there are no shadows that you cannot see to work in.

The light of the Cooper Hewitt Lamp contains no red rays, which are heat-producing and irritating; hence is the easiest of all lights on the eyes.

The Cooper Hewitt Lamp is the CHEAPEST of all electric lamps to operate and maintain; lamps frequently run two or three years without other attention than an occasional wiping off of the tubes.

Put this array of facts to any test you please,—the harder the better, so far as we are concerned.

SHOP OPERATION SHEET No. 101

Franklin D. Jones — MACHINERY, June, 1909

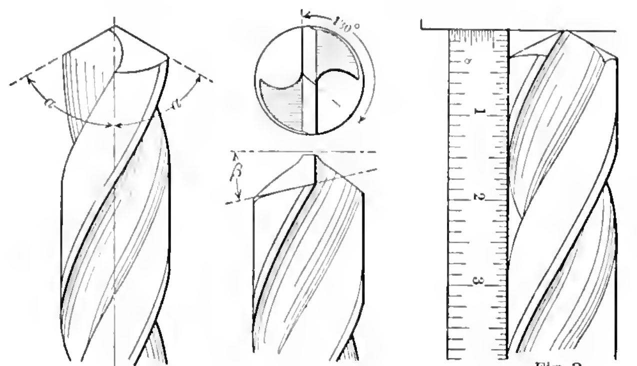

Fig. 1 Fig 2 Fig. 3 *Machinery,N.Y.*

Grinding a Twist Drill

NOTE.—The cutting edges of a twist drill should, as with the flat drill, be equiangular, of the same length, and have the same clearance. When both the cutting edges of the drill are ground to the same angles a, one cutting edge supports or counteracts the tendency of the other to spring from the cut (providing the clearance is also correct), but when the angles a are different, one edge will do more work than the other, thus subjecting the drill to an unbalanced twisting or torsional strain.

1. Grind each cutting edge to an angle a of 59 degrees (see Fig. 1), using the face of a wet emery wheel, and proceeding the same as if a flat drill were being ground, as described in paragraph 2 of the preceding sheet. The end of the drill will then appear as shown in Fig. 2. The clearance angle will be approximately correct when the line joining the cutting edges is at an angle of 130 degrees as shown.

NOTE.—There is a difference of opinion as to the best angle a of the cutting edge. As this angle is decreased the pressure required to force the drill through the metal becomes less, but the length of each cutting edge is increased with the result that more power is required to turn the drill. An included angle of 118 degrees is thought by some to equalize the thrust and torsion to the best advantage, while others advocate much more acute angles.

2. Grind away the metal back of each cutting edge, indicated by the shaded portion (Fig. 2), by moving the outer end of the drill, which is fulcrumed on the tool-rest, up and down with the right hand. Continue grinding until a surface, which should be approximately conical in form, is blended into the flat part previously ground. The backing or clearance of the cutting edges should be of such a form and angle as to allow the drill to cut freely and without binding as it is fed into the metal.

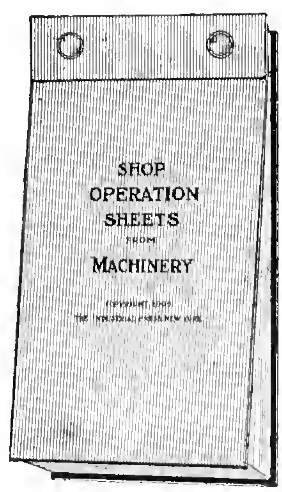
3. The clearance for each cutting edge may be tested by placing the drill point against a flat surface, and then slowly revolving it close to a scale held in the position shown in Fig. 3. If the clearances are not approximately alike, this will be shown by their relative positions to the graduation marks upon the scale, as the drill is turned.

The Shop Operations are laid out in note-book form, three operations on a sheet which measures about 9 x 13 inches. They are printed on tough manila paper and may be cut apart for filing in a binder, which is furnished at cost. Most of the Shop Operation Sheets have been issued monthly with MACHINERY, as supplements, and have been reprinted for general sale; but some have been and are published independently from time to time.

The Shop Operation Sheets contain the essentials for the apprentice as well as for the skilled worker who lacks the knowledge and experience of the all-around mechanic. Draftsmen can acquire a knowledge of a wide range of shop operations by studying these sheets, in which the instructions are so direct, simple and straightforward, that it is possible for any intelligent man to acquire a fundamental knowledge of all-around shop practice, and which only a comparatively few have an opportunity to secure except by actual experience in the works. Teachers of machine shop practice show their appreciation of the practical value of these Shop Operation Sheets by using them as instruction sheets in their classes, and supplying the students with them.

The Binder for MACHINERY'S Shop Operation Sheets will conveniently hold all the sheets that have been published, and all that will be published during the next two or three years.

The complete set of Shop Operation Sheets now comprises 141 distinct operations laid down so you can go right ahead. The complete set, in binder $2.00.



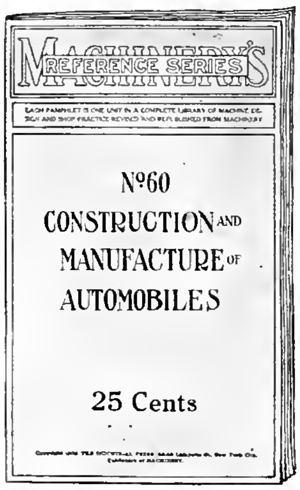
In this number of MACHINERY, on the fourth page of this announcement we make a special offer worth considering.

MACHINERY, The Industrial Press, 49-55 Lafayette St., New York City

The Automobile as the Machinist Sees it

No. 59—Machines and Methods of Automobile Manufacture

These two books on Automobile practice give you exactly the kind of information MACHINERY endeavors always to give to its readers. It is such information as practical men want and can instantly grasp. There is no discussion or introduction to waste time and effort. There is in No. 59, a simple, direct, straightforward description of Automobile Shop organization, equipment, machines, tools, etc.; an exceedingly interesting and informing chapter on the rapid assembly of Motor Cars and a concluding chapter on the treatment of gears for automobiles. A book packed with well-digested, definite information, and sold at 25 cents, which wouldn't pay for one of the photographs in it.



No. 60—Construction and Manufacture of Automobiles

No. 60 contains exactly what its title says it does. The engraving shown on page 5 is alone worth the price of the book. The purpose behind these books is carried effectively through them from cover to cover. It is educational in the practical sense. It is to bring to the reader the information he would work hard to secure if he were right there himself. The mechanical details are described and illustrated with great care by men thoroughly trained for such work and perfectly familiar with mechanical problems from actual experience in shop and drafting-room. The chapter on equalizing gears would serve very well as an advertisement for the whole Reference Series comprising 60 books. Price 25 cents and up to the minute.

A FEW GROUP HEADINGS

The 412 Receipts are Carefully Classified

- Blue-print Writing Fluids.
- Solutions for Preparing Blue-printing Paper.
- Methods of Treating Blue- and Brown-prints.
- Miscellaneous Drafting-room Receipts.
- Cements for Metals.
- Cements and Filling for Cast Iron.
- Cements for Pipe Joints.
- Cements for Attaching Cloth, Emery, etc., to Iron.
- Cements for Leather.
- Cements for Leather and Metals.
- Cements for Attaching Glass and Marble to Metals.
- Cements for Gluing Emery, Metals, etc., to Wood.
- Cements for Miscellaneous Purposes.
- Glues and their Preparation.
- Etching Fluids, etc., etc.

412 Shop Receipts and Formulas

NEW AND ENLARGED EDITION

A Receipt may cost the man who works it out to a success anywhere from five to five hundred dollars. There are men working in manufacturing plants in whom the spirit of invention and enterprise is persistent and irrepressible, and takes no note of costs. It just works for results and they are willing instruments of its activity. Actually these men are one with the alchemists of old, ever boiling and testing and seeking—and all for the race. And having studied and labored, and endured a thousand disappointments, they make their discovery at last, or at least they make a good one they weren't looking for, and, like eager children, run with it all full of happiness to give all gladly to their kind. We don't know what sum might measure the cost of these 412 Receipts. Doubtless, there are items in the cost that money couldn't measure at all, any more than money can measure the depth of joy or disappointment. We have put the 412 together in a splendid book, sold at one dollar, and on the basis of ordinary book prices, worth at least two.

The Shop Operation Sheets, Some Reference Books and a Subscription

AN AUGUST OFFER, GOOD UNTIL SEPTEMBER 10, 1910

OFFER A 4

412 Shop Receipts	$1.00
141 Shop Operation Sheets and Binder	2.00
24 Reference Books (Your selection, See titles.)	6.00
MACHINERY Subscription Your choice of Editions: Engineering Edition, 1 year or Shop Edition, 2 years OR Railway Edition, 1 year	2.00
	$11.00
Allowance until Sept. 10, 1910 on Shop Operation Sheets and Books	2.50
Net	$8.50

50 cents with order, $1.00 monthly for 8 months.

OFFER A 5

141 Shop Operation Sheets and Binder	$2.00
412 Shop Receipts	1.00
4 Reference Books (Your selection, See titles.)	1.00
MACHINERY Subscription Your choice of Editions: Engineering Edition, 1 year or Shop Edition, 2 years OR Railway Edition, 1 year	2.00
	$6.00
Allowance until Sept. 10, 1910	$1.50
Net	$4.50

50 cents with order, $1.00 monthly for 4 months.

Please don't ask us in October to fill one of these offers. They expire September 10, and MACHINERY'S Offers, as hundreds have learned, are never repeated. Material and conditions change constantly and an offer out today cancels all former offers and ends on the day specified.

But the right to return anything you buy from us if not satisfied always holds good whether specified or not. You can surely tell in 30 days. Just send in your order at once, with or without the first payment, and the order will be put right through. The first payment may be held back for 10 days if you like. We know the men in the mechanical field. Remember that these offers expire September 10, 1910. Messrs. Wm. Dawson & Sons, Ltd., London, E. C. will take care of friends in Great Britain, and no delay. They carry a stock. Figure the pound sterling at $4.86.

There's No Prettier Example of Mechanical Evolution

in a small way, than the supersession of the old fashioned solid mandrels by

Nicholson Expanding Mandrels

One set of **nine** of the latter will take the place of a **ton** of the former and give you a mandrel instantly at hand to fit any hole from one to seven inches.

The surprisingly big saving of time thus effected ought to impel you to investigate this great expense-shaver and profit-maker **at once.**

And There's the Nicholson Driving Block

This companion device at a trifling cost (only $13.50) affords the easiest and quickest way of driving the Nicholson Expanding Mandrel in or out—and for all sorts of machine shop driving.

Its distinguishing feature is the leather-covered adjustable shelf, which slips into any slot desired, according to the length of the arbor, and prevents it from falling on the floor or being otherwise injured when driven out.

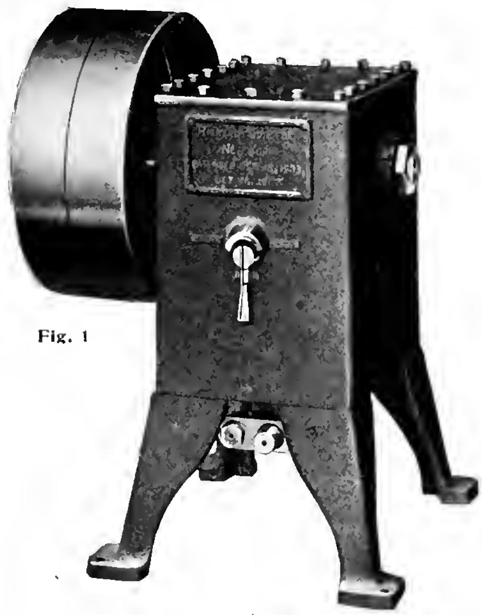

Fig. 1

The Best Ability is Reliability

Dudgeon Hydraulic Jacks and Pressure Pumps have this in good measure. Their reliability remains an unchanging quantity under all conditions of service.

The duplex double pump Cistern Power Pump shown, is self-contained and portable, and, although very small, is capable of giving a high pressure.

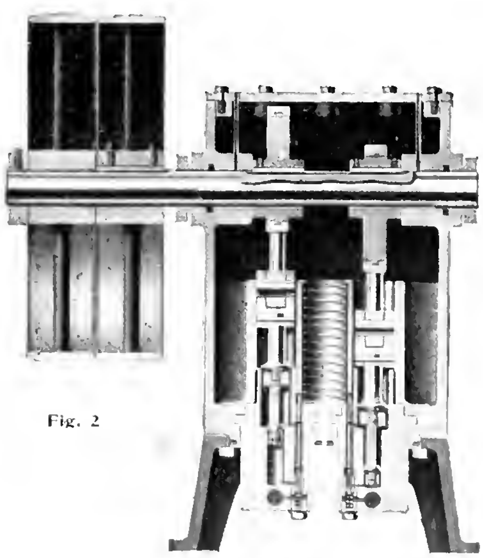

Fig. 2

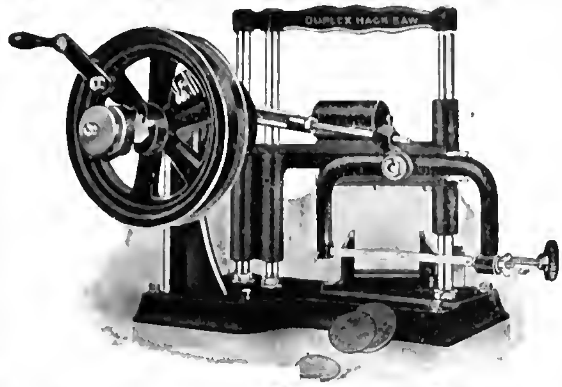
Boilers and other vessels can be filled through the pump and the desired pressure easily and quickly obtained.

Dudgeon Jacks and Pressure Pumps are made in sizes, styles and capacities for every purpose, and where a power driven pump is required for high pressure this one is recommended. *Send for the complete price list and catalog.*

MADE ONLY BY

RICHARD DUDGEON, Broome and Columbia Sts., New York

Twice the Work at Half the Cost



THE DUPLEX HACK SAW cuts as clean, straight and square as a die. It cuts with astonishing rapidity because the saw blade cuts its entire length and because the slide bearing in which the saw arm operates is so proportioned as to insure perfect alignment with positively no vibration, "binding," or friction. Breaking of saw blades is practically an impossibility. The "Duplex" can be operated by **Hand or Power.**

While primarily a hand machine it can be instantly converted into a powerful, high class power hack saw, by simply attaching a belt to the machine, the momentum wheel being also a pulley. It cuts any size bar up to 4" by 4".

We will send you the machine on **15 DAYS' FREE TRIAL** without cost or obligation. Price, if entirely satisfactory, to be $16.

Write to-day for further particulars.

Little Giant Auxiliary Screw Drill Chuck.

A Few Advantages of the Coit 20th Century Ball Bearing Drill Chuck

The Coit Drill Chuck

has few parts, is simple in construction and equally simple in operation. No wrench or key is required to adjust it, a turn of the threaded mandrel sleeve serves to open or close the jaws. It is the only self-tightening, ball bearing drill chuck with round removable jaws, and the jaws can be removed without taking the chuck apart. The mandrel is part of the tool, bearings are dust proof, one oiling will serve for months.

The special business of a drill chuck is to *hold the drill* and the Coit does this to perfection—no slip, no twist, no broken drill shanks; the greater the resistance on the drill, the tighter the grip of the chuck—moreover, this chuck holds short tang drills as firmly and easily as those of full length.

Made in five sizes; may we send our book?

THE STANDARD MACHINERY CO.

T. R. ALMOND MANUFACTURING COMPANY

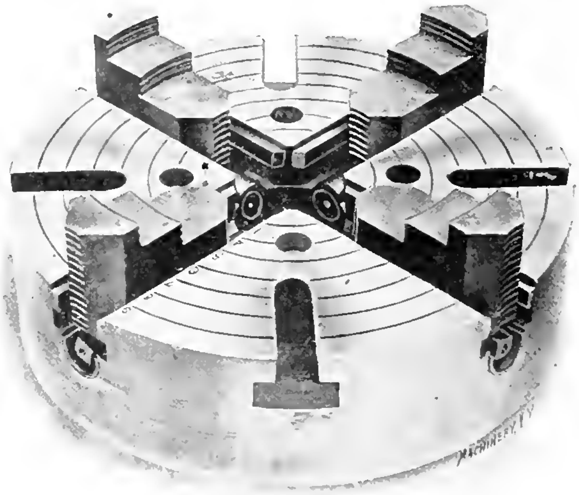
2 MAPLE AVE., ASHBURNHAM, MASS.

Cincinnati—the Independent Chuck

A CHUCK WITH NINE LIVES

Screws are mounted in hardened steel bushings which receive all end thrust and provide full bearings for the screw trunnions.

Wear and end play are also minimized by the highest grade spindle steel screws.



When worn, these bearings are quickly replaced and the Chuck is as good as new. Screws always held in line with the jaws to prevent tilting and cutting of threads. All bearings are perfectly ground and fitted by expert machinists.

Those who use them agree that the Cincinnati is the best Independent Four Jaw Chuck on the market. Write to the makers while you think of the best.

Chicago Office: 11-13-15 N. Canal St. **New York Office; 136 Liberty St.**

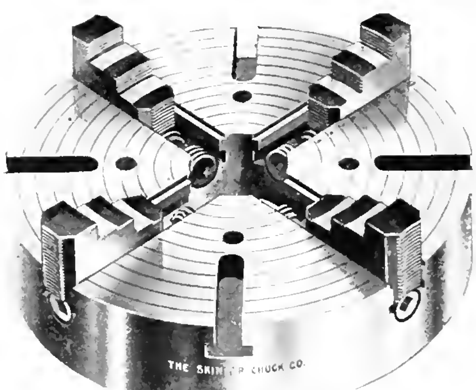

Figure 900

Buy The Skinner Independent Chucks They are Reliable

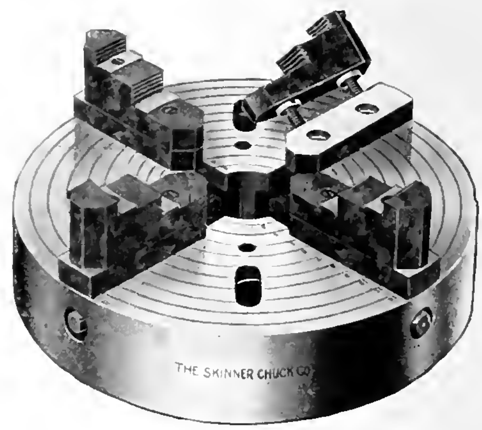

Figure 100

Our Fig. 900 Independent Chuck is made exceptionally heavy, strong and durable, and embraces all the very latest improved methods of Chuck making. It is practically impossible to improve upon the construction of this Chuck.

Hardened steel thrust bearings for taking the thrust of the jaw adjusting screws insure the Chuck long life, these bearings being practically indestructible. Because of the jaw screws being threaded their full length, the Chuck will hold much larger pieces than the rated size. The jaws are carefully hardened and, after being assembled in the Chuck body, are ground on the steps to insure accuracy. The Face of the Chuck is accurately graduated in inches.

You will not find all these features contained in any other one Chuck. Give us your next order. We guarantee you satisfaction.

Our Fig. 100 Independent Chuck is not intended for quite as heavy work as the Fig. 900, but is a very serviceable and convenient tool, being equipped with our Patent Reversible "J" Jaws. They can be reversed very quickly and without difficulty.

We manufacture all kinds and sizes of high grade Lathe, Drill, and Planer Chucks, Drill Press Vises, Heavy Face Plate Jaws, etc.

Write for our **free catalog.**

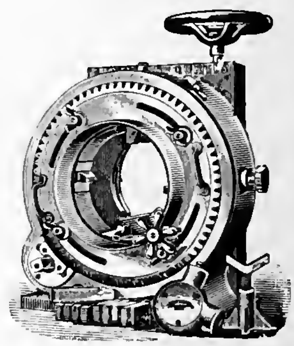
Cold Hard Facts about a Pipe Cutting Machine

Looking at the Forbes from a purely business standpoint—your business possibilities and profits are limited without one. Pretty strong statement but here's how we back it up—



It saves the wages of two to five men.

With a Forbes, one man can cut off and thread all sizes of pipe up to fifteen inches—a boy is capable for the smaller sizes.

It's the only Portable Pipe Machine on the market

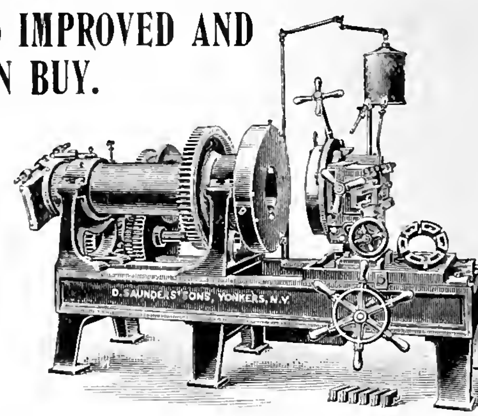
Its strength and lightness make it portable for outside work—eliminating carting expense and delay. Its great compactness adapts it for use in confined places—threading pipes in the trench, etc.

Forbes Dies are adjustable and can be ground on an ordinary grindstone without first drawing the temper. Lost or broken dies we can replace without buying a new set. All parts are interchangeable. Simply name it and send shop number.

If you are interested in Profitable Equipment, you should know the How and Why details of the Forbes. A postal will bring them.

The Curtis & Curtis Co.
8 Garden Street, BRIDGEPORT, CONN.

THERE'S A DIFFERENCE BETWEEN SAUNDERS' No. 6 IMPROVED AND THE BEST MACHINE OF ANY OTHER MAKE YOU CAN BUY.



But the additional cost is so slight, when greatly increased output and quality of work is considered, that you'd never hesitate to choose a Saunders' for your work.

This machine provides ample power and speed for every size of work between 2½" and 8". Instantaneous control, adjustable expanding die heads, interchangeable chasers, etc., peculiar to this line are not attributes to machines other than as made by Saunders.

Pipe Threaders and Cutters

With efficiency as well as beauty.

Heavy—none more so; bed cast in one piece, no stands or legs to work loose. No oil soaked floors; fire risk reduced.

Single speed pulley; all gear speed changes through semi-steel cut gears.

Deep chasers cutting long taper perfect threads in one cut as easily on steel as on iron pipes.

Let us prove to you that the higher cost of a modern tool is justified by the character and quantity of its product. *Circulars for the asking.*

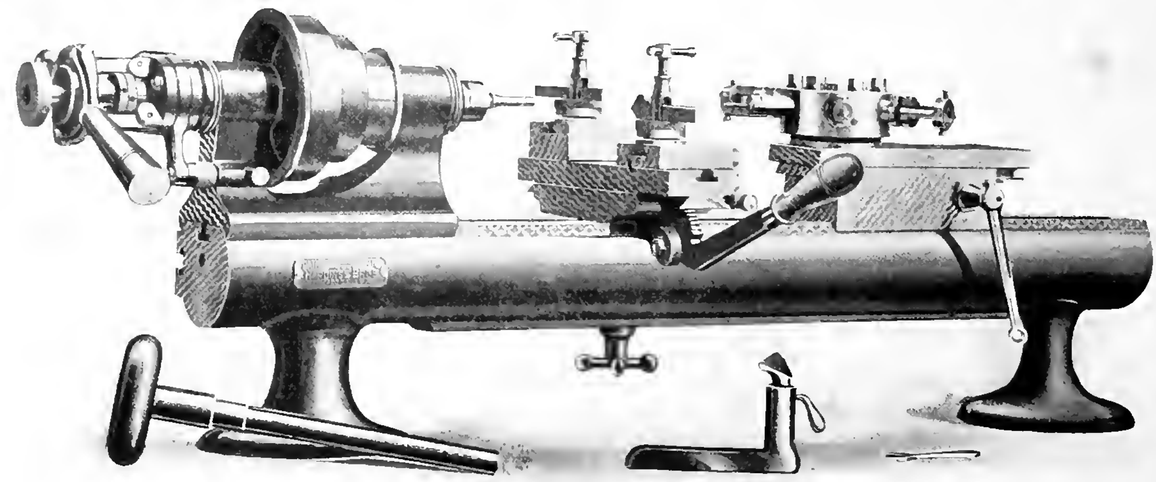
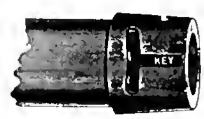
The "Little-Friction" Lathe for Precision Work



HARDINGE CATARACT No. 3 LATHE

Maintains spindle alignment regardless of end shake and runs free from heat at the highest speeds. Drills up to ½" may be used with the Hardinge—although it carries only a 1" belt. With end thrust and friction on the bearings practically eliminated, roughing and drilling that was formerly impossible on a small lathe is readily accomplished, and a big percentage of time and trouble saved. The patent taper nose spindle, another Hardinge advantage, permits interchangeable chuck fixtures to be run dead true and driven right or left as desired. Other features advantageous both to work and operator are described in the Catalogue 07.



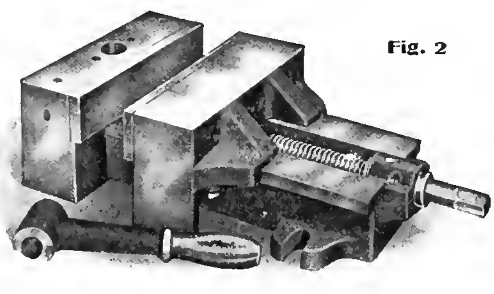
Three Sizes. Full List of Attachments. Special Standard Bench Equipment.

HARDINGE BROTHERS, Inc., 3133-3141 Lincoln Ave., Chicago, Ill.

DRILL VISE WITH JIG ATTACHMENTS

PATENTED

Fig. 2



As an ordinary Vise

Always a good Vise for **general shop use** and at the same time holds work for duplicate drilling **without the cost of a jig.**

They will pay. More time is consumed in catching work than in drilling it.

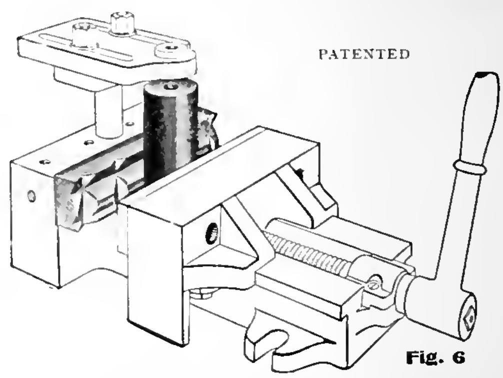


Fig. 6

V-Jaw and Part of Jig Fixture

Made with Jaws, 6", 9" or 12" long.

In circulars we show special features.

PATENTED

DRILL SPEEDER

For use in all presses from 20" up

NOTE

1—It increases the speed **three times.**

2—It has **safety frictions** to save the drills.

3—It has **sensitive feed** lever.

KNURL HOLDER

For Turret Machines

SOME THINGS ABOUT IT

1—It fits into any turret head.

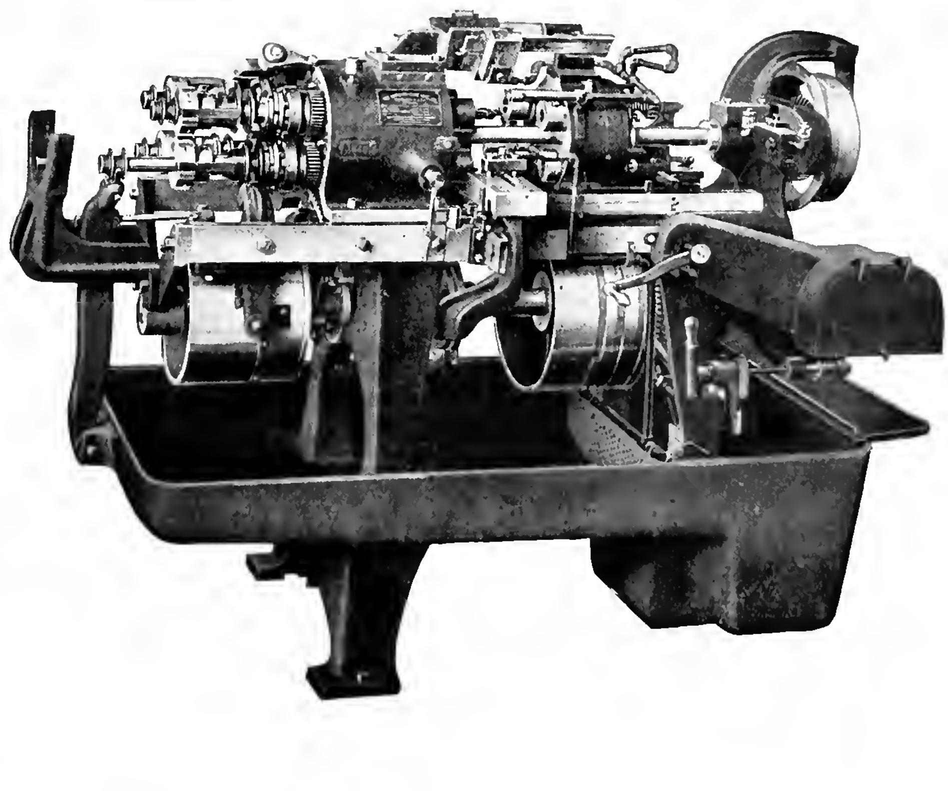
2—It will knurl any size within its capacity, viz: 2½ diam. by 2½ long.

3—It is run onto the work like a screw plate.

Patented Aug. 10, 1909

THE GRAHAM MFG. COMPANY, PROVIDENCE, R. I.

Germany, Schuchardt & Schutte



Divided Responsibility means Added Efficiency

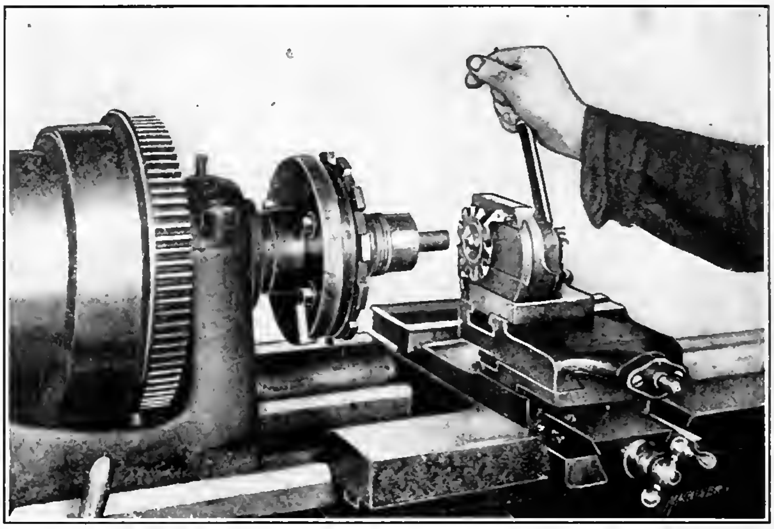
Each of the ten points on the

Rivett-Dock Threading Tool

cuts its share of the finished thread.

Designed for high speed on hard, tough work where the one-point tool falls down.

It not only saves all strain on the machine by having a support directly under the point, but chatter is entirely eliminated and inaccurate results from an overworked tool become practically impossible.



Showing the tool in position on lathe.

The Rivett-Dock tool has the capacity of a hundred single point tools, and is so nearly automatic in action that even the unskilled operator cannot make a mistake and spoil either work or tool.

If **accurate** duplicate threading is a factor in your product, write for the Rivett Catalogs.

Also builders of the Rivett Precision Lathe and Rivett Internal Grinders.
